MODERN SURGERY

GENERAL AND OPERATIVE

BY

JOHN CHALMERS DACOSTA, M.D., LL. D.

SAMUEL D. GROSS PROFESSOR OF SURGERY, JEFFERSON MEDICAL COLLEGE, PHILADELPHIA; SURGEON TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL; SURGEON TO ST. JOSEPH'S HOSPITAL, PHILADELPHIA; FELLOW OF THE AMERICAN SURGICAL ASSOCIATION; MEMBER OF THE AMERICAN PHILOSOPHICAL SOCIETY; MEMBRE DE LA SOCIÉTÉ INTERNATIONAL DE CHIRURGIE; MEMBER OF THE MEDICAL RESERVE CORPS, U. S. NAVY, ETC.

Seventh Edition, Revised, Enlarged, and Reset
With 1085 Illustrations, Some of Them in Colors

PHILADELPHIA AND LONDON

W. B. SAUNDERS COMPANY

1914

PRINTED IN AMERICA

PRESS OF
W. B. SAUNDERS COMPANY
PHILADELPHIA

"Yet each man, following his sympathies,
Unto himself assimilating all,
Using men's thoughts and forms as steps to rise,
Who speaks at last his individual word,
The free result of all things seen and heard,
Is in the noblest sense original.
Each to himself must be his final rule,
Supreme dictator, to reject or use,
Employing what he takes but as his tool.
But he who, self-sufficient, dares refuse
All aid of men, must be a god or fool."

W. W. Story ("A Contemporary Criticism").

THIS BOOK IS DEDICATED TO THE CHIEF SURGEON AND INSPIRATION OF ONE OF THE GREATEST, MOST PROGRESSIVE, AND MOST INFLUENTIAL SURGICAL CLINICS IN THE WORLD. A CLINIC FROM WHICH COME IMPORTANT FACTS, REAL IDEAS, AND BRILLIANT MEN.

TO THE OPERATOR, THE TEACHER, THE INVESTIGATOR, AND THE SURGICAL PHILOSOPHER. TO

DR. WILLIAM STEWART HALSTED,

THE DISTINGUISHED PROFESSOR OF SURGERY IN

JOHNS HOPKINS UNIVERSITY.

PREFACE TO SEVENTH EDITION

It is the custom to have a preface in a medical book. So this book, too, shall have its preface. The natural tendency is to do the customary thing in the conventional way. Were I to do this I would tell how many volumes of previous editions have been sold, would claim appreciation as the due of the seventh edition, give a list of the attractive novelties it contains, and express the conviction that the latest edition (like the newest baby) is superior to all of its predecessors. I have done this sort of thing in the past, but I shall do it no more, because such a preliminary proclamation has in it an unpleasant suggestion of the shopkeeper advertising his stock or the peddler vending his wares.

A man who has worked long and earnestly in the completion of a book has upon him a sense of disenchantment and has within him a host of misgivings. Hope is seldom a constant companion of the solitary worker. No one can be more conscious than the author that there are defects in this book. I have done my best to correct them and have corrected many of them, but others are uncorrectable without writing an entirely new book.

In the making of this, as of previous editions, I have again and again been in profound perplexity as to whether an alleged discovery is a fragment of eternal truth or a nebulous emanation of chaos. To make many mistakes of judgment in regard to such matters would mean a book rich in misinformation. If all of the alleged improvements of recent years were gathered together, the company would be decidedly mixed, and one would have to be cautious in receiving and in making introductions. In that company we would find the productions of the mistaken enthusiast, of the brilliant confidence man, of the deluded observer, of the conscientious worker, of the dull pretender, of the man with occasional flashes of genius, of the profound scholar, and of the grandee of science.

In a book like this the author is held by a short tether. He must strive to attain a happy medium between undue length and undue brevity. The former tends to become prolixity, the latter a Gradgrind catalogue of undigested and unexplained facts. Almost every very long book, like almost every very long congressional speech, contains many words which tell little. Too brief a book is like Mrs. General's mind, free from opinions. She had "a little circular set of mental grooves or rails on which she started little trains of other people's opinions, which never overtook one another and never got anywhere." Many times I have set forth opinions, but as want of space

has forbidden argument and discussion, the imperative mood has dominated the text, and many of the views must appear dogmatic and oracular.

I have tried to keep out of these pages the ornaments of plagiarism. I have sought to do so by giving the authority for every important statement. When possible I have used the author's words, believing that his description of his own work must be better than any description that could be written for him. In consequence, the book contains numerous quotations. As I must use other men's work, it is only fair that I should acknowledge it. The vital necessity for using the work of others is emphasized in Mr. Story's lines, which are printed on page 7.

The author wishes to thank warmly several gentlemen who have given able, unselfish, and highly valuable aid. To the sections on Orthopedic Surgery, The Surgery of the Bones, of the Joints, of the Muscles, and of the Tendons, Dr. J. Torrance Rugh, Associate in Orthopedic Surgery in the Jefferson Medical College, contributed some of the results of his extensive experience.

The section on Röntgenology was revised by that most skilful operator, Dr. Willis F. Manges, the Röntgenologist of the Jefferson College Hospital. Dr. Thomas C. Stellwagen, Jr., assistant Genito-urinary Surgeon of the Jefferson College Hospital, was of great help to me in the revision of the sections on Genito-urinary Diseases.

Dr. Hubley R. Owen, Surgeon to the Philadelphia Hospital, has efficiently and in many ways lessened the burdens of the author.

To Dr. Chevalier Jackson, of Pittsburgh, the distinguished laryngologist, I extend sincere acknowledgments. He did me the honor to contribute to this book. He wrote a section upon Tracheobronchoscopy and Esophagoscopy, describing the very valuable methods he devised.

A contemplation of the achievements of modern surgery must fill the surgical student with hope and confidence, must inspire him with the conviction that we are on the threshold of great events, and that the first few hesitating words of truth have as yet but scarce been lisped by the baby lips of Science.

John Chalmers DaCosta.

MODERN SURGERY

MODERN SURGERY

I. BACTERIOLOGY

Bacteriology is the science of micro-organisms. Though a science in the youth of its years, bacteriology has not only profoundly altered, but it has also revolutionized, pathology, and our views of surgery would be incomplete, misleading, and erroneous without its aid.

Micro-organisms, or **microbes,** are minute non-nucleated vegetable cells closely connected with fungi and algæ, many of them being visible only by means of a highly powerful microscope and after they have been brightly stained. The contents of these cells are protoplasm and nuclear chromatin enclosed by an albuminous structure which in some cases contains cellulose. There is considerable evidence that certain diseases are caused by micro-organisms so minute as to escape detection even by the most powerful microscope. The French Yellow Fever Commission asserted that the yellow fever micro-organism (which is perhaps protozoal) passes through a porcelain filter ("Annals of the Pasteur Institute," Nov., 1903). The micro-organism of rabies probably does the same thing.

Simon Flexner believes that many diseases are due to submicroscopical parasites (Ether Day Address, 1911).

Even in the most remote times some have believed that "the mysterious cause of contagious and epidemic diseases must be sought in living entities" (Monti on "Modern Pathology"), but all such beliefs were ingenious guesses or unproved theories, unsustained by a scrap of experimental demonstration. Bacteria were discovered in 1683 by the Dutch optician Leeuwenhoek, of Delft. In his researches he used the simple microscope, that is, single lenses of short focal length. By means of this primitive instrument he saw spermatozoids, capillaries, blood-corpuscles, the structure of the crystalline lens, yeast-cells, and certain large bacteria. The Dutch observer regarded bacteria as animalculæ.

In 1762 Plenciz, of Vienna, impressed by the publications of Leeuwenhoek, asserted that each disease is caused by a special organism, that decomposition is caused by micro-organisms, and that bacteria can grow in living tissue.

In 1832 Bassi claimed that a certain disease of silkworms was due to a fungus. In 1839 Schönlein discovered the vegetable parasite causative of favus.

In 1840 Henle came to the conclusion that fungi cause all infectious diseases. In 1843 Oliver Wendell Holmes published his famous essay on the Contagiousness of Puerperal Fever, and in 1847 Semmelweiss, of Vienna, strongly maintained the same thesis.

In 1847 Professor John K. Mitchell put forth the theory that malarial and epidemic fevers have a "cryptogamic origin." In 1849 Malmsten pointed to a fungus as the cause of ringworm.

Cohn, who for over twenty years subsequent to 1850 contributed actively to science, described round bacteria (cocci), rod-shaped bacteria (bacilli), and in 1872 admitted disease-producing bacteria to his classification.

In 1863 Davaine found bacilli in the blood of victims of splenic fever and made a strong argument to prove that the bacilli caused the disease. Absolute proof was furnished by Koch in 1876. He inoculated animals with pure cultures of the bacilli and produced the disease ("Bacteria and Their Products," by Sims Woodhead).

The first definite knowledge of bacteria and their products came from a chemist and not a physician, and dates from the study of fermentation by the illustrious Frenchman Pasteur.

Before his day "bacteria were known, theories of infection had been elaborated, and vaccination practised," but he "definitely established the importance of bacteria in putrefaction, fermentation, and disease, and gave to vaccination a scientific basis" ("Research in Medicine," by Prof. Richard M. Pearce, in "Popular Science Monthly," July, 1912).

In 1858 Pasteur asserted that every fermentation has invariably its specific ferment; that this ferment consists of living cells; that these cells produce fermentation by absorbing the oxygen of the substance acted upon; that putrefaction is caused by an organized ferment; that all organized ferments are carried about in the air; and that the entire exclusion of air prevents putrefaction or fermentation.

In 1860 Pasteur published the observation that sterile liquids will not be contaminated by air if the air gains entry only through a long curved tube, the reason being that dust and growths fall from the entering air by gravity ("Comptes rendus," 1860).

In 1863 Pasteur published experiments which proved that beer cannot ferment without yeast and that wine received in sterile vessels and defended from external contamination will not undergo ammoniacal change.

Most of the subsequent life of Pasteur was passed in seeking the causes, the prevention, and the cure of infectious diseases in man and animals.

The views of Pasteur, which were radical departures from accepted belief, inaugurated a bitter controversy, and in that controversy were born the microbic theory of disease, the doctrine of preventive inoculation, antiseptic surgery, and serum-therapy.

The word *microbe*, which signifies a small living being, was introduced in 1878 by the late Professor Sédillot, of Paris. At that time the nature of these bodies was in doubt; some thought them animal, and called them *microzoaria;* others thought them vegetable, and called them *microphyta;* the designation "microbe" does not commit us to either view. We now know them to be vegetable, but the term "microbe" has remained in use.

The micro-organisms connected with disease in man are divided into:

1. Yeasts, Saccharomyces, or Blastomycetes;
2. Molds, or Hyphomycetes;
3. Bacteria, or Schizomycetes.

Yeasts, or **budding fungi,** include most of those fungi which can cause alcoholic fermentation in saccharine matter. They consist of small round or oval cells, which are devoid of chlorophyl, which can live without free oxygen, and which multiply by *gemmation* or *budding*. Definite nuclei are not demonstrable in the cells. When a cell multiplies a small bud of protoplasm projects from or near the end, or buds project from or near both ends of the cell. Buds increase progressively in size and a constriction appears between each bud and the parent-cell. Each constriction deepens as the corresponding projection enlarges, until the bud attains a considerable size and is cast off as a daughter-cell. In some cases buds are not cast off, but remain attached, a chain or series of rounded yeast-cells being formed. Yeast-cells contain spores when nourishment is insufficient. Under certain conditions yeast fungi can form interwoven threads called *mycelial threads*.

Molds, or filamentous fungi, consist of filaments, each filament being composed of a single row of cells arranged end to end, and all filaments springing from a germinal tube which grows from a germinating spore. A thread grows by increase at the apex, and this area eventually gives origin to new spores. The yeast fungi are the common, but not the only cause of fermentation. Mold fungi are connected with processes of decomposition. Putrefaction is due to bacteria and retards the growth of yeasts and molds.

Most yeasts and molds grow best upon dead organic matter, some attack plants, a few the lower animals, and a very few grow upon or in the tissues of the human body. The term *mycosis* means an infection with budding fungi or with filamentous fungi.

The *oïdium albicans* is a fungus which by growing in the mucous membrane produces the disease known as *thrush.* Some observers believe that the thrush fungus is a mold. Others maintain that it is a budding fungus which may develop filaments. Thrush attacks especially the mucous membrane of the tongue, lips, cheeks, gums, and pharynx, but occasionally the growth takes place upon the esophagus, the vocal cords, the stomach, the vagina of a pregnant woman, the respiratory tract, and the areola of the breast of a nursing woman. The fungus has been found in areas of bronchopneumonia. The proliferating fungus presents the appearance of milky white spots which by thickening and coalescence form curd-like masses, the superficial layer of epithelium being raised and cast off. Thrush is particularly common in infants during the second week of life, and in infants suffering from marasmus, but it may occur in older children and even in adults who have been weakened by some exhausting disease like typhoid fever or tuberculosis.

Fig. 1.—Actinomyces (Ziegler).

Blastomycetes dermatitis is an inflammation of the skin due to yeast fungi and bearing a resemblance to tuberculosis or syphilis. Pharyngomycoses, keratomycoses, otomycoses, pneumomycoses, and mycoses of the liver, kidney, etc., have been reported. Sanfelice and others maintain that pathogenic yeasts are responsible for the growth of *malignant tumors.* It is certain that yeasts may exist in a carcinoma and can be cultivated, but proof is entirely lacking that they are anything but a contamination. Many skin diseases are due to fungi; among them should be mentioned favus, pityriasis versicolor, herpes tonsurans, parasitic sycosis, and eczema marginatum.

Actinomycosis (**streptotrichosis**) is a disease due to infection with some variety of streptothrix. Usually the streptothrices are regarded as molds, but they possibly constitute a sort of transition stage between filamentous fungi and bacteria.

It was long believed that the ray fungus (Fig. 1) was the only cause of actinomycosis. We now know that other members of the streptothrix group may be responsible (see page 309).

Madura-foot, or mycetoma, is due to the *Streptothrix maduræ.*

Schizomycetes, or bacteria, chiefly claim our attention. It is important to remember that the term "bacteria," though applied to the class *schizomycetes*, has also a more restricted application—that is, to a division of the class; it may mean either *schizomycetes* in general, or rod-shaped *schizomycetes*, whose length is not more than twice their breadth. In this work it is employed to designate *schizomycetes* as a class.

Bacteria are minute, unbranched, non-nucleated, vegetable cells, free from chlorophyl, varying in shape and occasionally presenting locomotive flagella. Though devoid of chlorophyl (leaf coloring-matter), many of them

produce pigment. The cell consists of a *cell membrane*, a *layer of protoplasm*, and some *central fluid*. No true nucleus has yet been demonstrated, but granules are found within the cells which some call *metachromatic bodies* (Babés) and others *nuclei* (Ernst). The cell membrane varies greatly in thickness, and when it is very thick the cell is said to have a *capsule*. The round cells have a smooth outer surface, but some of the rod-shaped cells show many *flagella* or at the end a single flagellum (Fig. 2). Flagella enable some bacteria to move (*motile bacteria*), but all organisms which possess them are not motile, and under certain conditions bacteria without flagella may develop them, or organisms which possess flagella may lose the power to develop them.

Some bacteria, known as *non-pathogenic*, cannot grow and produce poison either in the tissues, in wound-fluid, or in the fluid moistening a mucous surface. Others grow upon dead organic matter, but are not able to invade living tissues. They can live and multiply in dead material, as the discharge from a wound or in the fluid covering a mucous surface, and are called *saprophytes*, *saprophytic microbes*, or *putrefactive bacteria*. *Obligate* saprophytes only live in dead matter and never become parasites. *Facultative* saprophytes can become parasites under certain circumstances, but normally grow in dead organic matter. Bacteria, known as the *pathogenic*, under certain conditions invade living tissue and cause various diseases. Harmless bacteria are *non-pathogenic*. *Parasitic* bacteria can grow on or in the tissues of the body.

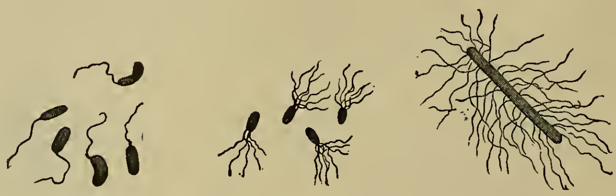

Fig. 2.—Types of flagella: *a*, Vibrio choleræ, one flagellum at the end—monotrichia type; *b*, Bact. syncyaneum tuft of flagella at the end, rarely at the side—Lopotrichia type; *c*, Bact. vulgare, flagella arranged all about—Peritrichia type (Lehmann and Neumann).

Obligate parasites are those which have not been cultivated outside of the body (as the spirilla of relapsing fever). *Facultative* parasites usually live outside the body, but may enter into the body and produce disease. The schizomycetes vary much in shape, size, color, arrangement, mode of growth, and action upon the body. One form cannot be transformed into another, but each maintains its specific identity. Every organism comes from a pre-existing organism, this being true of all forms. Pasteur proved that spontaneous generation is impossible. Although numerous attempts have been made to overthrow this view it still stands unshaken. The protoplasm of these cells can be stained with anilin colors, and the cell-wall is more readily detected after treating it with water, which causes it to swell.

Many bacteria are colored; others are colorless. Some move (*motile bacteria*); others do not move (*amotile bacteria*). The bacilli of anthrax and tuberculosis and all cocci are amotile. Most bacteria can change from motile to amotile, or from amotile to motile, when subjected to certain changes of soil and environment. The oscillations of cocci are physical in nature, not vital; they are Brunonian or Brownian movements, movements due to alterations in equilibrium because of currents or changes of level in the fluid in which the micro-organisms are contained. Bacteria seem to possess the power of attracting elements necessary for their nutrition (*positive chemiotaxis* or *chemotaxis*) and of repelling harmful elements (*negative chemiotaxis* or *chemotaxis*).

Bacterial Products.—Bacteria when active produce many different products. Among them are gases (H, H_2S, CO_2, NH_3), water, alcohols, fatty acids, carbohydrates, phenol, coloring-matter, toxins, enzymes, etc. Some of these materials are given off from the living cell, some are found only when the cell is dead. Some of them are excretions, some of them secretions. Some are formed within the cell (intracellular), others are excreted by the bacteria into the material in which the cell lies (extracellular).

Forms of Bacteria.—The three chief forms of bacteria are—

1. The *Coccus* or *Micrococcus*—the berry-shaped, oval, or round bacterium (Fig. 3);
2. The *Bacillus*—the rod-shaped bacterium (Fig. 4);
3. The *Spirillum* or *Vibrio*—the corkscrew-shaped or spiral bacterium (Fig. 5). A short spiral organism is called a *comma bacillus*. Spirochetes are sharply bent curved rods twisted like the thread of a screw.

Fig. 3.—Micrococci.

Fig. 4.—Bacilli.

Fig. 5.—Spirilla.

De Bary compares these forms, respectively, to the billiard-ball, the lead-pencil, and the corkscrew.

Cocci and Bacilli.—As surgeons we have to do chiefly with *cocci* and *bacilli.* Cocci may be designated according to their arrangement with one another; namely, when existing singly they are called *monococci* (Fig. 3); in pairs they are called *diplococci* (Fig. 8, A); arranged end to end in a chain they are called *streptococci* (Fig. 8, C); in group side by side clustered like a bunch of grapes they are called *staphylococci* (Fig. 8, B); in groups of four they are called plate *cocci* or *tetracocci;* in cubic groups they are called *sarcinæ* or *wool-sack* cocci (Fig. 6). Irregular masses, resembling frog-spawn, constitute *zoöglea masses* (Fig. 9). The gelatinous matter in such a mass is formed by a trans-

Fig. 6.—Sarcinæ forming bales of packets. Single packets regularly grouped together (Lehmann and Neumann).

Fig. 7.—Ascococcus Billrothii Cohn (after F. Cohn).

formation in the walls of the bacteria. The term *ascococci* is applied to a group of cocci enclosed in a capsule (G. S. Woodhead) (Fig. 7).

The cocci are often named according to their function, as, for example, "*pyogenic,*" or pus-forming. Cocci may be named according to the color of the culture. The name may embody the form, arrangement, color of culture, and function; for instance, *Staphylococcus pyogenes aureus* signifies a round micro-organism, which arranges itself with its fellows in the form of a bunch of grapes, which produces pus, and which gives golden-yellow cultures.

The *bacilli* are long, staff-shaped organisms. Long, delicate, jointed bacilli having wavy outlines are known as *leptothrix* forms. Chain-like bacilli are called *streptobacilli.* Bacilli give origin to many surgical diseases.

Dichotomy or Branching.—It is very seldom that a side bud appears upon bacteria except in the bacteria of tuberculosis and diphtheria.

Pseudodichotomy is by no means unusual. It occurs when one end of a bacillus grows by the end of the adjacent bacillus or when a bacillus in a chain divides in a line parallel to the chain and thus begins another chain (Fig. 10).

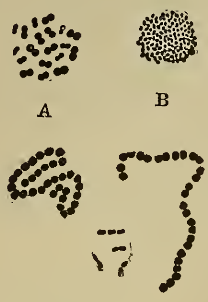

Fig. 8.—Forms of cocci: A, Diplococci; B, staphylococci; C, streptococci.

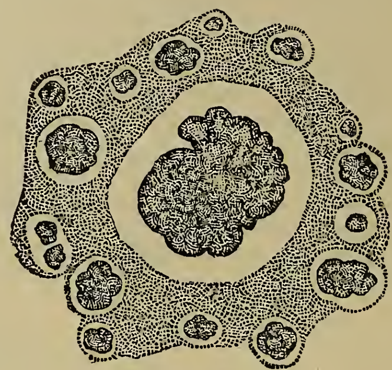

Fig. 9.—Zoöglea (Ball).

Multiplication of Bacteria.—Bacteria multiply with great rapidity when placed under suitable conditions. They can multiply by transverse fission or by spore-formation. Some bacteria multiply by both methods. In

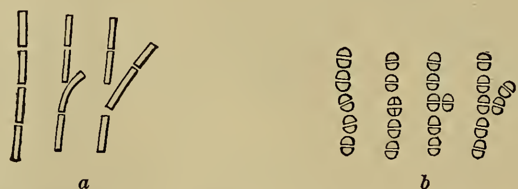

Fig. 10.—Pseudodichotomy: *a*, In bacilli; *b*, in streptococci (Lehmann and Neumann).

fission, or *segmentation*, a bacillus undergoes an increase in size and length; a coccus does not increase in size, but slightly elongates. In either case about the middle of the cell a transverse constriction begins, which deepens until the cell has divided into two parts, each of which soon grows as large as its parent (Figs. 11, 12). As a rule, the micro-organisms separate after division of the cell; but they may not do so; and if they do not separate, the special grouping receives a particular name (diplococci, streptococci, etc.). If the division is invariably in the same direction, and if the new cells remain in contact, streptococci or streptobacilli are formed. Tetracocci and sarcinæ are formed when a number of cocci "divide in two or three successively vertical directions" ("Clinical Bacteriology," by Levy and Klemperer), forming four quadrants (*tetracocci*) or eight octants (*sarcinæ*). All cocci and most bacilli multiply by fission.

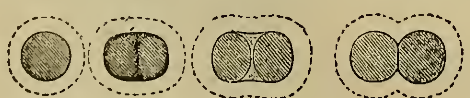

Fig. 11.—Divisions of a micrococcus (after Macé).

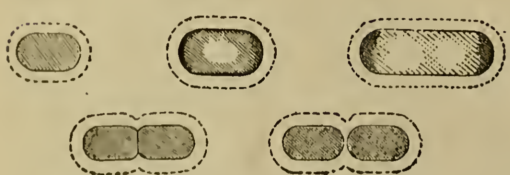

Fig. 12.—Divisions of a bacillus (after Macé).

Hence the common term of *fission fungi.* The time required for the multiplication of a bacterium varies. Some varieties, when placed under favorable conditions, undergo fission in two hours. The cholera bacillus requires only twenty minutes to divide. The tubercle bacillus requires several days. If segmentation of a single cell and the growth to maturity of its products require one hour, a single cell in a single day, if the conditions for increase were ideally favorable, would have 16,000,000 descendants, and in three days the mass of new cells would weigh 7500 tons (Cohn). In order, however, for such enormous multiplication to occur conditions would have to be absolutely favorable for the cells, and conditions are never absolutely favorable. Were it otherwise, all other forms of life would be destroyed. During growth in a culture-medium inhibitory substances are formed, and these substances are detrimental to the bacteria themselves and to all bacteria of the same type. Such substances are known as *autotoxins* (Conradi and Kurpjuweweit, in "Muenchen. med. Woch.," No. 32, September 12, 1905). In a culture of cholera bacilli the number of living microbes begins to lessen after twenty-four hours, and after forty-eight hours the diminution is distinct.

Spores.—A *spore* is a germ, and corresponds with the seed of a plant. Some bacilli, a few spirilla, and it may be sarcinæ, multiply by spore-formation. Cocci do not undergo spore-formation after the manner of bacilli, though some observers maintain that cocci occasionally undergo an alteration that makes them very resistant to any destructive influences. When spore-formation is about to occur in a bacillus, a point of cloudiness or an area of bright refraction appears in the protoplasm and the cell generally elongates. When a row of cells sporulate, the segments, each of which contains a lustrous area or a region of cloudiness, look like parts of a necklace of beads (Fig. 13). The spore enlarges, the cell membrane bursts, and the young bacillus emerges through the opening. A cell usually contains but one spore, which may be situated at the end of the cell (*endspore*) or in the middle of the cell (*endospore*). Sometimes a single cell contains several spores. If an endspore exists, the end of the cell containing the spore is swollen or club shaped (*drumstick bacterium*). If an endospore exists, the cell becomes spindle shaped (*clostridium*). When multiplication is by a single endospore, the bacillus does not elongate. When multiplication takes place by a process of combined spore-formation and fission, the mother-cell divides into a number of daughter-cells, which are called *arthrospores*. Organisms which when active multiply by fission take on spore-formation when subjected to certain conditions.

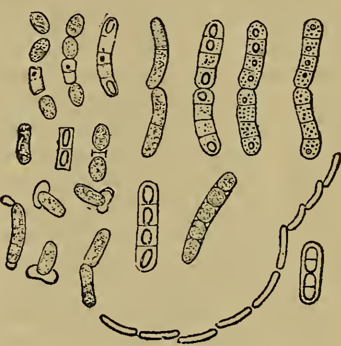

Fig. 13.—Sporulation (after De Bary).

Spore-formation tends to occur when bacilli are about to die for want of nourishment or when there is an excess of oxygen present. The spore has a dense envelope or covering which is very resistant to destructive agents. So resistant is the covering that twice the amount of heat is necessary to kill a spore as to kill an active adult cell. Spores when placed under conditions unfavorable for development may remain inactive for an indefinite period, just as seeds remain inactive when unplanted. Drying, even drying for years, may not destroy them. A dry temperature of nearly 300° F. destroys the spores of anthrax, but only after acting for three hours. Steam or boiling water kills most spores in a few minutes. Some spores are able to withstand the action of live steam for several or perhaps for many hours. Direct sunlight quickly

destroys spores ("Clinical Bacteriology," by Levy and Klemperer). When spores encounter favorable conditions, they develop very rapidly into adult cells, just as seeds develop when planted. It seems probable that spores occasionally remain dormant in the human body for long periods, and finally awaken into activity because of injury or disease of the tissue in which they lie.

Chemical Composition of Bacteria.—The protoplasm of bacteria consists of water, salts, albuminous material, extractives soluble in alcohol, and extractives soluble in ether.

Life-conditions of Bacteria.—In order to grow and to multiply, bacteria require a suitable soil and the favoring influences of heat and moisture. The soil demanded consists of highly organized compounds rather than crude substances, and slight modifications in it may prove fatal to some forms of bacterial life, but highly advantageous to others. Some organisms require albuminous matter, others need carbohydrates; they all require water, carbon, nitrogen, oxygen, hydrogen, and certain inorganic materials, especially lime and potassium (Woodhead). All organisms require water. If dried, no micro-organisms will multiply, and many forms will die. The fluids and tissues of the individual may or may not afford a favorable soil for the germs of a disease, or, in the same person, may afford it at one time and not at another. Some individuals seem to possess indestructible immunity from, and others are especially prone to, certain bacterial diseases, and these immunities and predispositions may be hereditary. The Japanese show high immunity to scarlet fever and negroes to yellow fever. Drunkards are predisposed to pneumonia. Some families exhibit high susceptibility to scarlet fever. Negroes are very susceptible to tuberculosis and small-pox. Impairment of health, by altering some subtle condition of the soil, may make a person liable who previously was exempt. The insane are predisposed to infections. Injury or disease of a tissue may increase local liability.

Again, some bacteria which under normal conditions are harmless may become virulent under certain conditions. Colon bacilli, which under normal conditions seem to be putrefactive organisms inhabiting the intestine, may attack a point of least resistance in the intestine itself: this point being established by congestion, strangulation, inflammation, or injury, and descendants of the bacteria which attacked the point of least resistance may become so virulent that they can live and develop in tissues distant and apparently normal and cause disease in them.

The presence of oxygen influences microbic growth. Most organisms thrive best when exposed to the oxygen of the air, and they are known as *aërobic*. The term *anaërobic* is employed to designate organisms that can grow and multiply and produce particular products only when air is absent, free oxygen being fatal to them. They may need oxygen; but if they do, they are able to obtain it from the tissues when air is excluded. Tetanus bacilli and the bacilli of malignant edema are anaërobic. An organism which grows as well in the presence as in the absence of oxygen is called a *facultative-anaërobic bacterium*. Most microbic diseases in man are due to facultative-anaërobic bacteria.

Effect of Motion, Sunlight, the X-rays, Radium, Cold, and Heat.—The majority of fungi grow best when at rest; violent agitation retards the growth of some. Sunlight antagonizes the growth of certain bacteria, especially tubercle bacilli and the bacilli of typhoid fever. Direct sunlight even destroys spores. Ordinary daylight is very slowly germicidal to bacteria. Direct sunlight is quickly fatal to them. Sunlight is bactericidal even when heat rays are intercepted. The active agent is the light. The blue and violet are the most active, while the rays of the red end of the spectrum are devoid of power to kill bacteria. The electric arc-light acts on bacteria like sunlight. It is claimed by some that the x-rays retard bacterial growth. Radium rays are bactericidal.

Sunlight, the arc-light, radium emanations, and x-rays stimulate tissue activities, and so aid the tissues to rid themselves of bacteria. Temperature influences bacterial growth. Some organisms will grow only within narrow temperature limits, while others can sustain sweeping alterations, but most grow best between the limits of from 86° to 104° F. Freezing renders bacteria motionless and incapable of multiplication, but it does not kill them; they again become active when the temperature is raised. Prudden showed that typhoid bacilli can live in ice one hundred and three days. The absurdity of employing cold as a germicide is evident when the fact is known that a temperature of 200° F. below zero is not fatal to germ-life, cell-activities by such a temperature only being rendered dormant. Bacteria have been placed in hermetically sealed tubes and the tubes immersed in liquid air for seven days. The germs were thus subjected to a temperature of —190° C., but there was no change produced in their virulence (A. MacFayden and S. Roland, in "Lancet," March 24, 1900). High temperatures are fatal to bacteria; moist heat is more destructive than dry heat, and adult cells are more easily killed than spores. A temperature less than 212° F. will kill many organisms, and boiling will kill every pathogenic organism that does not form spores. Some spores are not destroyed after prolonged boiling, and some will withstand a temperature of 120° C. As a practical fact, however, boiling water kills in a few minutes all cocci, most bacilli, and all pathogenic spores; though the spores of anthrax, tetanus, and malignant edema are killed with more difficulty than are the spores of other bacteria.

Effect of Bacteria Upon Bacteria.—Some bacteria are antagonistic to others, some are synergistic to others. When certain bacteria favor the growth of other bacteria the process is called *symbiosis*. When certain bacteria retard the growth of other bacteria the process is known as *antibiosis*. The streptococcus of erysipelas is antagonistic to the bacillus of anthrax and also to syphilis and tuberculosis. The Bacillus prodigiosus makes the streptococcus of erysipelas more active, and the bacillus of anthrax less active. The growth of some microbes in culture-media makes a soil favorable or unfavorable for other microbes, and the same process may occur in the human body. Influenza renders the lungs prone to infection with pneumococci. Aërobic organisms prepare a wound for tetanus bacilli. Saprophytes on mucous surfaces are antagonistic to certain pathogenic bacteria. The organisms productive of lactic acid fermentation are destructive to many injurious intestinal bacteria. We are not yet able to cure a microbic disease by inoculating the sufferer with antagonistic microbes, on the principle of sending a thief to catch a thief, although Hankin ("British Medical Journal," August 14, 1897) suggests purifying water infected with colon bacilli or typhoid bacilli by means of the Micrococcus Ghadiallii, which is fatal to them.

Latent Bacteria.—Sometimes pathogenic organisms remain latent in the body for a considerable time. They are not destroyed, but produce no symptoms, or only local symptoms, possibly because the individual is immune for the time being. Pneumococci, staphylococci, and typhoid bacilli may become latent. Tubercle bacilli may remain long latent in a lymph-gland or in any old area of caseation. Syphilis may remain latent for a long time.

Latent bacteria may take on active growth when the tissue containing them is damaged by injury or disease. I have seen active disease arise in an apparently cured and stiff tuberculous joint as a result of forcibly breaking up adhesions. An attack of bronchitis may light up an old and latent area of pulmonary tuberculosis. The administration of ether or chloroform by inhalation may render active a previously inactive tuberculous focus in the lung. A partial or incomplete operation on a quiescent tuberculous lesion is apt to be followed by active spread and may result in wide dissemination of disease.

Mixed Infection.—A fact of practical importance to the surgeon is that an area infected by one form of micro-organism may be invaded by another form. This is known as a *mixed* infection, and consists in a *primary* infection with one variety of organism, and a *secondary* infection with another, or in an infection at the same time with different micro-organisms. Mixed infection is especially common on surfaces exposed to air and wound infection is usually mixed. Koch found both bacilli and micrococci in the same lesion of tuberculosis. A soil filled with pneumococci favors the growth of pus cocci and tubercle bacilli. Tuberculous or syphilitic lesions may be attacked by erysipelas. Chancre and chancroid can exist together. A syphilitic ulcer is a good culture-soil for tubercle bacilli (Schnitzler). Suppuration in lesions of tuberculosis is due to secondary infection with pus organisms. Occasionally in empyema and other conditions due to pus organisms the diseased process ceases to be active, the pyogenic bacteria having lost much of their virulence, but a mixed infection with some germ usually harmless may break down surrounding barriers, intensify the virulence of bacteria, and aggravate the disease into an acute outburst. When secondary infection occurs the primary infection may remain as before, may be aggravated, may be mitigated in intensity, may be destroyed, or may be disseminated.

Intra-uterine or Placental Infection.—The infection of the embryo from the diseased ovum or the diseased sperm-cell occurs only in syphilis. Such an embryo is diseased at the first moment of life. The direct transmission of bacteria from parent to fetus is a problem still in course of solution. Certain it is that some diseases may follow the transmission of the micro-organism through the septum of separation between the circulations of the mother and child. Placental transmission may occur in syphilis, scarlatina, pneumonia, anthrax, measles, pyogenic conditions, and tuberculosis (Hektoen). A child born of a woman recently the subject of pneumonia may be born with that disease, and a child may be born with pneumonia when the mother has never had it. Mothers free from infectious disease may give birth to infected children. It is stated that Mauriceau (a noted French obstetrician of the 17th century) was born with small-pox, though his mother had never had a sign of the disease. Few cases of congenital tuberculosis have been reported, but Rosenberger claims to have found the bacilli in the umbilical vein from the placenta of a tuberculous mother. A child of a tuberculous parent may not be born tuberculous, but may have weakened tissue-cells that easily fall a prey to the tubercle bacillus when it reaches them by any avenue. Placental transmission of bacteria is favored by disease or injury of the placenta.

Chemical Antiseptics and Germicides and Aseptic Agents.—It is necessary to make a distinction between deodorizers, antiseptics, and germicides, although the two latter terms are usually regarded as being interchangable. In the methods of antiseptic surgery we use germicides.

A *deodorizer* is an agent which destroys an offensive odor. It is true that an offensive odor may be due to microbic growth. It is also true that nasty odors may prove injurious to those who inhale them. But, nevertheless, the odor is the result of microbic action, and destroying an odor does not render harmless the bacteria which caused it. Charcoal is a well-known deodorizer.

An *antiseptic* is an agent which retards or prevents putrefaction. It acts by weakening or killing saprophytic organisms, but is not fatal to spores.

A *germicide* or *disinfectant* is an agent which is fatal to adult bacteria and spores. The destruction of the germs of disease on the skin, in clothing, in excreta, in a wound, etc., is known as *disinfection*. Disinfection of the skin, of a wound, of dressings, or of instruments is called also *sterilization*.

Antiseptics and germicides should not be used in surgically clean wounds. Repair will occur more quickly if they are not used. Tillmanns has pointed

out that when antiseptics are used cell-division begins late and progresses slowly. Germicides are not efficient in fatty tissue, as bacteria surrounded with oil cannot be reached by the drug, and the chemical is irritant and apt to induce fat necrosis (Haenel, in "Deutsch. med. Woch.," 1895, No. 8).

Corrosive Sublimate.—Many chemical agents will kill bacteria, one of the most popular of them all being corrosive sublimate. Koch showed that corrosive sublimate is an efficient test-tube germicide when present in the proportion of only 1 part to 50,000. It is used in surgery in strengths of 1 part of the salt to 1000, 2000, 3000, or more parts of water. Badly infected wounds are occasionally irrigated with solutions of a strength of 1 : 500. Contact with albumin precipitates from a solution of corrosive sublimate an insoluble albuminate of mercury which forms a white layer upon the surface of the wound, is not a germicide, and prevents deep diffusion of the mercurial fluid. In surgical operations by the antiseptic method the mercurial salt should be combined with tartaric acid in the proportion of 1 to 5, which combination prevents the formation of the insoluble albuminate of mercury.

But though corrosive sublimate under certain conditions is extremely powerful, it is not always absolutely reliable. Many spores are very resistant to its action. Even a 1 per cent. solution of bichlorid of mercury is not certainly destructive to the spores of anthrax. Geppert tells us that anthrax spores may be active after a twenty-five-hour immersion in a 1 : 100 solution of sublimate (Schimmelbusch). In the presence of hydrogen sulphid corrosive sublimate is useless, inert and insoluble sulphid of mercury being precipitated; hence corrosive sublimate is without value as a rectal antiseptic; in fact, Gerloczy has proved that a concentrated aqueous solution of sublimate will not disinfect an equal quantity of feces. Corrosive sublimate contained in dressings after a time undergoes decomposition and ceases to be a germicide. It is not germicidal in fatty tissues because it is unable to attack bacteria which are coated with oil. Corrosive sublimate is very irritating to the tissues and causes copious exudation. Hence, if an extensive wound has been irrigated with this agent, drainage must be employed to obtain exit for the wound fluid. In some wounds which have been irritated by corrosive sublimate the tissues seem to loose to a great extent their power of resistance to bacteria and infection may be actually facilitated by irrigation with bichlorid of mercury. In rare instances corrosive sublimate is absorbed and produces poisoning. In spite of these shortcomings and drawbacks it is a valuable aid to the surgeon and is very frequently used, especially upon the skin of the patient and the hands of the operator and his assistants. It should be dissolved in distilled water. Ordinary water causes a precipitate to form (common salt prevents the formation of this precipitate).

Because of the fact that corrosive sublimate is poisonous and very irritant, it should not be used upon serous membranes. It is absorbed quickly from serous membranes and destroys the endothelial cells and should not be introduced into the pleural sac, into joints, or into the peritoneal cavity. It should never be put within the dura, and should not be applied, in strong solution at least, to mucous membranes. It should not be introduced into the rectum for three reasons: First, it is intensely irritant and causes pain and inflammation. Second, it is useless, being largely and promptly converted into insoluble and inert sulphid of mercury. Third, a poisonous dose may be absorbed. Instruments cannot be placed in corrosive sublimate without being dulled, stained, and corroded. It is better to make the solution at the time it is needed, so as to have it fresh, for in old solutions much of the soluble corrosive sulbimate has been converted into insoluble oxychlorid of mercury, and the fluid has ceased to be germicidal. In order to make up fresh solutions use tablets, each of which contains about 7½ grains of the drug—one of these tablets added

to a pint of water makes a solution of a strength of 1 : 1000. Tablets which also contain ammonium chlorid are more soluble than those which contain corrosive sublimate only. Hot solutions of the drug are more powerfully germicidal than cold solutions. As corrosive sublimate is irritant, leads to profuse exudation, and may produce tissue necrosis, it should never be introduced into an aseptic wound. In such a wound it can do no good and may do much harm.

Griffin, in Foster's "Practical Therapeutics," sets forth the strengths of solutions applicable to different regions:

For disinfection of the surgeon's hands and the patient's skin, 1 : 1000; for irrigating trivial wounds, 1 : 2000; for irrigating larger wounds and cavities, 1 : 10,000 to 1 : 5000; for irrigating vagina, 1 : 10,000 to 1 : 5000; for irrigating urethra, 1 : 40,000 to 1 : 20,000; for irrigating conjunctiva, 1 : 5000; for gargling, 1 : 10,000 to 1 : 5000.

Corrosive Sublimate Poisoning.—Corrosive sublimate may be absorbed from a wound, a serous surface, or a mucous membrane, ptyalism and diarrhea resulting. The absorption of bichlorid of mercury may be followed by cramp in the limbs and belly, feeble pulse, cold skin, extreme restlessness, and even collapse and death. At the first sign of trouble withdraw the drug and treat the ptyalism (see page 338).

Lithiomercuric Iodid.—This material was prepared and tested by Dr. Rosenberger and Mr. England ("American Medicine," 1904, p. 1021). It is asserted that the iodid of mercury and lithium is more powerfully germicidal than corrosive sublimate, does not form inert albuminate when placed in a wound, and is not precipitated by alkalis. It is not nearly so irritant nor is it so poisonous as corrosive sublimate. I have given it an extensive trial in my clinic and am satisfied that it is superior to corrosive sublimate as a germicide, is less irritant, and is less poisonous. Its only objection is that it is more expensive.

Carbolic acid is a valuable germicide in the strength of from 1:40 to 1: 20. It is certainly fatal to pus-organisms, but weak solutions fail to kill most bacteria and do not destroy spores. Unfortunately, this acid attacks the hands of the surgeon; consequently in the United States dilute carbolic acid is chiefly employed as a solution in which to place the sterilized operating instruments, or as a germicide to prepare the skin of the patient before the operation is performed.

Carbolic acid is very irritant to tissues, and carbolized dressings may be responsible for sloughing of the wound or dry gangrene (see p. 182). Because of its irritant properties wounds which have been irrigated with it should be well drained. Carbolic acid, like corrosive sublimate, is inert in fatty tissues.

Pure carbolic acid is a reliable disinfectant for certain conditions. It is used to destroy chancroids, to purify infected wounds and abscess cavities, to disinfect the medullary cavity in osteomyelitis, to stimulate granulation after the open operation for hydrocele, or to purify sloughing burns and ulcerated areas. The pure acid rarely produces constitutional symptoms, but it occasionally causes sloughing. Its application causes pain for a moment only, and then analgesia ensues. Even dilute solutions of carbolic acid greatly relieve pain when applied to raw surfaces. The local action of carbolic acid can be at once antidoted by the application of alcohol (Seneca D. Powell). When carbolic acid is applied to a wound, the area about the wound should first be moistened with alcohol. After the application of pure carbolic acid to the interior of a joint, a wound, the medullary canal, or an infected area the surgeon should wait about one minute and then apply alcohol.

Dilute carbolic acid acts more slowly and less certainly than corrosive sublimate. It requires twenty-four hours for a 5 per cent. solution to kill anthrax

spores. Pus or blood (albuminous matter) greatly weakens the germicidal power of carbolic acid, and fatty tissue cannot be disinfected by it. It is not even the best of agents in which to place instruments, as it dulls them. After operation upon the mouth it may be used as a wash or gargle, 1 to 2 per cent. being a suitable strength. It is used sometimes to irrigate the bladder and often to cleanse sinuses, but is not employed in the peritoneal cavity, the pleural sac, the rectum, or the brain. It is occasionally injected into tuberculous joints. Carbolic solution should never be used in clean wounds.

Carbolic Acid Poisoning.—Carbolic acid is readily absorbed, and may thus produce toxic symptoms. Absorption is not uncommon when the weaker solutions are used, but seldom occurs when a wound has been brushed over with pure acid, because the pure acid at once forms an extensive zone of coagulated albumin, which acts as a barrier to absoprtion. One of the early indications of the absorption of carbolic acid is the assumption by the urine of a smoky, greenish, or blackish hue. This hue appears a little time after the urine has been voided, whereas the smoky hue of hematuria is noted in urine at once after it has been passed. The condition produced by carbolic acid is known as *carboluria*, and examination of such urine shows a great diminution or entire absence of sulphates when the acidulated urine is heated with chlorid of barium. The diminution of precipitable sulphates is explained by the fact that these salts are combined with carbolic acid, forming soluble sulphocarbolates. Such urine is apt to contain albumin. If during the use of carbolized dresssing or the employment of carbolic solutions the urine becomes smoky, the use of the drug in any form must be at once discontinued, otherwise dangerous symptoms will soon appear. These symptoms are subnormal temperature, feeble pulse and respiration, muscular weakness, and vertigo. If death occurs, it is due, as a rule, to respiratory failure. The treatment of slow poisoning by carbolic acid consists in at once withdrawing the drug, giving stimulants and nourishing food, administering sulphate of sodium several times a day, and atropin in the morning and evening. (For Carbolic Acid Gangrene, see page 182.)

Boric Acid.—This drug is a very mild antiseptic. It is used to dust wounds. A solution of it is used to irrigate wounds and as the fluid for hot antiseptic fomentations. The solution should be concentrated.

Acetate of Aluminum.—This is a mild antiseptic, useful as a constituent of irrigating fluids and of hot fomentations. Its prolonged use hardens the tissues. A strength of 1 or 2 per cent. is employed.

Saline Solution.—Sodium chlorid solution of normal strength (0.9 of 1 per cent.) does not damage the cells of serous surfaces or of a wound, hence it is used as an irrigating fluid, and it is the best fluid for such a purpose. In intravenous infusion, in shock, or hemorrhage it is very valuable. It does not damage the blood-corpuscles as plain water does. It is, however, irritant to the kidneys when used by hypodermoclysis or intravenous infusion; hence if the kidneys are diseased saline fluid of one-half normal strength should be used for either of the latter purposes. Normal salt solution is prepared as follows: A quart of water is filtered and sterilized and in this $1\frac{1}{2}$ drams of table salt are dissolved, and the fluid is again boiled (see pages 466 and 467).

Thiersch's Fluid.—This fluid is used upon mucous and serous surfaces and is employed to irrigate wounds. It is non-toxic and non-irritant. It consists of 1 gr. of salicylic acid and 6 gr. of boric acid to 1 oz. of sterile water.

Alcohol is a germicidal agent, which is most powerful when of the strength of 70 per cent. It may be used on the hands of the surgeon or the skin of the patient in a strength of 70 per cent. and may be used plain or mixed with corrosive sublimate, of the strength of 1 part of corrosive to 1000 parts of alcohol. Pure alcohol is used to arrest the local action of pure carbolic acid.

Boiled water is used to dissolve antiseptic materials; to inject by hypodermoclysis; to irrigate wounds, mucous cavities or serous surfaces, and as a fluid in which to keep instruments during the operation. It damages somewhat the tissue-cells of the surface of a wound and injures the cells of serous surfaces, hence for irrigation and hypodermoclysis salt solution is to be preferred.

Creolin, which is a preparation made by the dry distillation of English coal, is a germicide without irritant or powerful toxic effects. It is less powerful than carbolic acid, but acts similarly. It is not soluble in water, but is used in emulsion of a strength of from 1 to 5 per cent. It does not irritate the skin like carbolic acid.

Peroxid or **dioxid of hydrogen** is an excellent agent for cleansing a purulent or putrid area, but it is never applied to a sterile wound. It is prepared in a 10-volume solution, which should be diluted one-half to two-thirds before using. A 30 per cent. solution is known as *perhydrol.* It probably destroys the albuminous element upon which bacteria live, and thus starves the fungi. When peroxid of hydrogen is applied to a purulent area ebullition occurs, liberated oxygen bubbling up through the fluid and the pus being oxidized. The peroxid reaches every cranny and diverticulum containing pus. The peroxid of hydrogen is not fatal to tetanus bacilli; in fact, tetanus bacilli can be cultivated in a strong solution of it. It is very valuable as a mouth-wash to cleanse the mouth before and after operations in the oral cavity. Some surgeons use it to wash out appendicular abscesses (R. T. Morris). It must not be injected into a deep abscess in any region unless a large opening exists, as otherwise the evolved gas may tear apart structures, dissect up the cellular tissue, and spread infection. The use of peroxid should not be too long continued, for if used for a considerable period it makes the granulations edematous and retards healing. In fact, its continued use may actually prevent a sinus closing.

Iodoform is largely used by surgeons in spite of the fact that laboratory workers have assured us it is not truly a germicide, as bacteria will grow upon it. Clinical evidence, however, is in its favor and surgeons long ago concluded that it at least hinders the development of bacteria, directly antagonizes the action of the toxic products of germ-life, and stimulates the production of connective tissue. It is of the greatest value when applied to putrid foci, suppurating areas, and tuberculous processes. In putrid foci it probably combines with toxins and renders them less poisonous or even inert.

It attenuates the virulence of pus cocci and organisms of putrefaction. It renders its greatest service in tuberculous processes and is infinitely more powerful when oxygen is excluded than when it is present. The laboratory workers who condemn it have in many cases used nutrient material in which it does not dissolve (P. F. Lomry, "Archiv für klin. Chir.," 1896). D. B. Heile ("Proceedings of the German Surgical Congress of 1903") insists that iodoform is a valuable germicide if oxygen is excluded. He says, if iodoform is mixed with tissue juice, oxygen being excluded, the mixture becomes powerfully germicidal, even to streptococci, in from three to five days, although, as he maintains, neither constituent of the mixture when alone is germicidal. Tissue juice decomposes iodoform, liver juice decomposing it most rapidly, brain and fat decomposing it slowly. Granulation tissue decomposes it and tuberculous granulation tissue acts upon it most rapidly.

The conclusion of Heile is that this study confirms the clinical observation that iodoform is valuable in cavities, but not in free surfaces. My own belief is that it is more valuable in cavities than upon free surfaces, but when we are dealing with putrefactive areas, even on free surfaces, it is of great value. When iodoform decomposes on a free surface it sets free I, which we now know is a powerful germicide. When it decomposes in tissue juice Heile says it forms a powerful germicide which is rendered inert by oxygen. Clinically,

no real substitute for iodoform has yet been found. It can be rendered sterile by several washings with a solution of corrosive sublimate. It need not be applied to clean wounds, but the powder is very useful when dusted into infected wounds. It prevents wound discharges from decomposing and distinctly allays pain. Gauze impregnated with iodoform is used to keep abscesses open after evacuation, to drain the belly after certain operations, to pack aside the intestines and prevent their infection during some abdominal operations, and as packing to arrest intracranial hemorrhage. Iodoform gauze will drain serum well, but will not drain pus. In fact, it blocks up a pus-cavity, and if long retained leads to the collection of purulent matter behind and about the supposed drain. If used in an abscess, it must be replaced in twenty-four or thirty-six hours. Tuberculous joints and cold abscesses are injected with iodoform emulsion, which is made by adding the drug to sterile glycerin or olive oil. The emulsion contains from 4 to 10 per cent. of iodoform. Dunham's iodoform emulsion is valuable in suppurating cavities ("Annals of Surgery," May, 1909). In order to prepare it he adds to 100 c.c. of glycerin, 1 gm. of iodin, and 1 gm. of iodid of potassium, sets the mixture in an Arnold sterilizer, and boils the fluid in the sterilizer. By shaking the mixture the iodin goes into solution in the glycerin. When the mixture cools, 10 gm. of iodoform are added and ground into the mixture by use of a sterile mortar. A solution in ether of a strength of 10 per cent. may be used to inject the cavity of a cold abscess, but it is dangerous, may rupture the wall, and is more apt to produce poisoning than is the emulsion. Iodoform wax is used to fill cavities in bone (see p. 502).

Iodoform-poisoning.—The drug must be used with some caution. Absorption from a wound sometimes happens, producing toxic symptoms. These symptoms are frequently misinterpreted, being usually attributed to infection. R. T. Morris has pointed out that in iodoform-poisoning the wound seems to be in excellent condition, whereas in sepsis the wound appears unhealthy. The symptoms in some cases are acute and arise suddenly, and consist of hallucinatory delirium, nausea, fever, watery eyes, contracted pupils, metallic taste in the mouth, yellowness of the skin and eyes, an odor of iodoform upon the breath, the presence of the drug in the urine, the outbreak of a skin eruption resembling measles or one which is erythematous, vesicular, bullous, or petechial. There is often nephritis and always excessive loss of flesh and strength. Patients with such acute symptoms usually pass into coma and die within a week. Such attacks are most apt to arise in those beyond middle life (see Gerster and Lilienthal, in Foster's "Practical Therapeutics"). Iodin can be recognized in urine by adding a few drops of commercial nitric acid and a little chloroform. When the mixture is shaken the chloroform will take up the free iodin and become purple, and on standing the purple layer will settle to the bottom of the tube. Another method is as follows: Put a little urine in a saucer, add a little calomel, and stir. If the urine contains iodoform a brown color will be noted (R. T. Morris). The finding of iodin in the urine, however, is not proof that the patient is poisoned. We may find it when no sign of poisoning exists. In chronic cases of iodoform-poisoning the first symptoms usually observed are moroseness, bewilderment, and irritability, followed by depression, with unsystematized persecutory delusions, delirium, coma, and even death.

In systemic poisoning by iodoform, discontinue the use of the drug, sustain the strength of the patient, and favor the elimination of the poison.

Iodoform sometimes produces great local irritation of the cutaneous surface, the dermatitis being eczematous or else being manifested by crops of vesicles filled with turbid yellow serum or even bloody serum. These vesicles rupture and expose a raw, oozing surface, looking not unlike a burn. The dermatitis usually exists only in the region with which iodoform was in contact, but in some cases it spreads widely. The use of the drug must be at

once abandoned, for to continue it will not only increase the dermatitis, but may produce constitutional symptoms. Wash the vesiculated area with a stream of normal salt solution to remove iodoform, open each vesicle, and dress the part for several days with gauze wet with normal salt solution. After acute inflammation ceases apply zinc ointment or cosmolin.

Aristol is an odorless iodin compound used by some as an antiseptic dusting-powder.

Loretin is an antiseptic powder which is odorless, germicidal, non-irritant, and which is said to be non-toxic.

Euphoren is a powder containing iodin, and the iodin separates from it slowly when the powder is applied to wounds or burns. It does not produce toxic symptoms readily, if at all, and is a valuable substitute for iodoform. It is used especially in the treatment of ulcers and burns.

Nosophen is a pale-yellow powder containing 60 per cent. of iodin. Its bismuth salt is known as **antinosin.** Nosophen is not toxic, is free from odor, and is the best of the substitutes for iodoform.

Acetanilid is frequently used as a substitute for iodoform. It is of value when applied to suppurating, ulcerating, or sloughing areas, but it does not benefit tuberculous conditions. Sometimes absorption takes place to a sufficient extent to cause cyanosis, sweating, and weakness of the pulse and respiration. If cyanosis arises, suspend the administration of the drug and administer stimulants by the stomach.

Airol is a substitute for pure iodoform, and is composed of gallic acid, bismuth, and iodoform. It is non-irritant and non-toxic.

Among other powders we may mention iodol, amyloform, subiodid of bismuth, and dermatol or subgallate of bismuth.

Silver is a valuable antiseptic. Halsted and Bolton have shown that metallic silver exerts an inhibitive action upon the growth of micro-organisms and does not irritate the tissues. Credé has also demonstrated the same facts. These statements indicate one great reason why silver wire is such a useful suture material (see page 74). Halsted is accustomed to place silver foil over wounds after they have been sutured, and Credé employes as a dressing a fabric in which metallic silver is intimately incorporated.

Credé considers silver lactate (**actol**) an admirable antiseptic. It does not form an insoluble albuminate when introduced into the tissues and is not an irritant. Silver citrate (**itrol**) is said to be even a better preparation than silver lactate, and it is a useful dusting-powder. A preparation of metallic silver, known as *colloidal silver* or *collargolum*, is made. This preparation is soluble in water and in albuminous fluids. It is said to remain as metallic silver when in solution and to be powerfully germicidal. It certainly seems to cause temporary leukocytosis, but so do some other drugs which are not antagonistic to infections. It comes put up in 1- and 2-gr. tablets. A solution of the strength of from 1 to 5 per cent. is used. In severe cases of sepsis some advocate injecting this solution into a vein which has been rendered prominent by applying a bandage above the elbow. The dose is from 1 to 2 gr. of the drug. One injection or more may be given. I have never seen it do the slightest good and I believe that intravenous injections are dangerous. Some have given it subcutaneously, some by the mouth, others by enema. Subcutaneous injections are often very irritant and it is doubtful if the drug is absorbed from either the stomach or rectum. The most extraordinary claims have been put forth regarding the therapeutic value of collargolum. Its use has been advocated in the most diverse general infections. I believe it is of no real value. Its claims, in my opinion, have been shattered by the majority report of the committee of the American Medical Association ("Jour. Am. Med. Assoc.," March 13, 1909). **Credé's ointment of silver,** I believe, is of use in

infections of the skin and lymphatic vessels. I have used it repeatedly in such cases. In a child, 15 gr., in an adult, 45 gr. of the ointment are rubbed into the skin at one time, and the rubbing should be kept up from ten to thirty minutes. There is said to be no risk of argyria. **Protargol** is a silver salt much used in gonorrhea. A solution in water is made. It is not precipitated by albumin, alkalis, nor acids. In gonorrhea a 1 to 5 per cent. solution is used. **Argyrol** is a new and valuable preparation of silver which I have used frequently with much satisfaction. It is known as silver vitelline, is not irritant, and contains 30 per cent. of metallic silver. It is not precipitated by albumin. In a strength of 5 per cent. it is a very useful injection for gonorrhea, as it has powerful gonococcidal properties. In some types of chronic cystitis several drams of a 3 per cent. solution may be injected into the bladder from time to time, and much stronger solutions can be used with safety. Inflamed mucous membranes may be painted with a solution of a strength of from 20 to 50 per cent. A sinus or a sluggish area of granulation may be stimulated by touching with a solution of a strength of from 25 to 50 per cent. I have found it of much service in sinuses.

Formaldehyd, or **formic aldehyd,** has valuable antiseptic properties. **Formalin** (liquor formaldehydi) is a 37 per cent. solution of the gas in water. Solutions of this strength cauterize the tissues, but 1 per cent. solutions can be used to disinfect wounds. A solution of a strength of 0.5 per cent. is used to irrigate sinuses, tuberculous areas, abscess cavities, and suppurating joints. A strong solution is used to asepticize chancroids and other ulcers. A 2 per cent. solution disinfects instruments. The vapor of formalin can be so applied as to disinfect wounds, and Wood suggested its employment in septic peritonitis as a means of disinfection after the abdomen has been opened. Formic aldehyd gas thoroughly disinfects catheters.

Formalin-gelatin was introduced by Schleich as an antiseptic powder. The commercial preparation is known as **glutol.** When applied to a clean wound it gives off formalin and keeps the wound aseptic. When it is applied to a sloughing surface it will not give off formalin unless it is mixed with pepsin and hydrochloric acid. Formalin-gelatin has been used to fill bone cavities.

Lysol is a clear, brownish, oily fluid with an odor like creasote. It is a valuable germicidal agent. It is saponified phenol and is used in a solution of a strength of from 1 to 3 per cent. It does not attack the hands like carbolic acid and is much less poisonous.

Mustard is an excellent emergency germicide. Its value has been demonstrated by Roswell Park, who uses a mixture of soap, cornmeal, and mustard flour to scrub the surgeon's hands or the patient's skin. I have used it repeatedly with entire satisfaction. Mustard removes the odor of decay at once.

Commercial gasolene is used by Riordan and others to clean wounds and ulcers, and to prepare the field of operation. Its vapor is so inflammable that the material must not be used when gas or lamp light is necessary. It is used only in the daytime or in a room lighted by electricity, and on free surfaces where evaporation is rapid. It is sterile, non-irritant, and on evaporation leaves a dry, clean surface.

Iodin.—This drug was strongly endorsed by the late Prof. Nicholas Senn ("Surgery, Gynecology, and Obstetrics," July, 1905). He regarded it as the most powerful and the safest of antiseptics, and claimed that in solutions of a strength of 1 per cent. it is non-irritant and causes a protective phagocytosis. It may be used in great dilution or the tincture may be applied to an infected wound in the same manner as is pure carbolic acid; a method advocated by Carl Beck. In dilute solution it is used to irrigate sinuses. The proper dilu-

tion for irrigation of a sinus is obtained when the tincture is diluted to the color of sherry wine. Its employment for sterilizing the skin is described on page 68.

Nucleins, especially protonuclein, possess germicidal powers. Nuclein is composed of nucleinic acid and protein material. When injected hypodermatically and to a less degree when taken by the mouth it increases the germicidal power of the blood-serum, causes leukocytosis and increased phagocytosis, and thus prevents or opposes infection. Mikulicz has used nucleinic acid to increase vital resistance as a preliminary to operation (see page 42). A 1 per cent. solution of nucleinic acid is on the market. This acid is made from yeast. The dose of the preparation is from 10 to 60 minims hypodermatically, once or several times a day. *Protonuclein* probably contains nucleinic acid and is of some value when applied locally to areas of infection, particularly when sloughing exists.

Heat.—The best germicide is heat, and the best form in which to apply heat is by means of boiling water (which is even better than steam). One can use boiling water upon instruments and dressings, but seldom upon a patient. Jeannel, of Toulouse, uses boiling salt solution in abscess cavities, and some other surgeons employ steam or boiling water to disinfect the medullary canal in osteomyelitis. Nevertheless, boiling water is seldom applied to a patient, and in many cases a chemical germicide must be used.

Among other antiseptics and germicides of more or less value we may mention trichlorid of iodin, chlorid of zinc (10 per cent. solution), chlorid of iron, salol, oxycyanid of mercury, fluorid of sodium, argonin, sugar, lannaiol, bichlorid of palladium (in very dilute solution), thymol, potash soap, salicylic acid, sulphate of copper, arsenite of copper, camphor, eucalyptol, cinnamon, bromin, chlorin (as gas or as chlorin-water), cinnamic acid, permanganate of potassium or of calcium, chlorate of potassium, and oxalic acid. The surgeon before operating should always scrub his hands in a germicidal solution.

Distribution of Bacteria.—Microbes are very wide y distributed in nature. They are found in all water except that which comes from very deep springs; in all soil to the depth of 3 ft.; and in air, except that over the desert, over the open sea, and that about lofty mountains. Dust-free air does not contain them; the more dust, the more microbes, hence they are present in greatest number in the air of towns. There are more in narrow courts than in broad highways, more in crowded attics than in roomy apartments. Bacteria are present on and in the skin, in the alimentary canal, in the nose, mouth, and pharynx, and in the blood and lymph. As Adami points out, under normal conditions the bacteria which enter the blood are very quickly killed.

Microbes may be useful. Some of them are scavengers, and clean the surface of the earth of its dead by the process known as "*putrefaction*," in which complex organic matter is reduced to harmless gases and to a mineral condition. The gases are taken up from the air by vegetables, and the mineral matter is dissolved in rain-water and passes into the soil from which it came, there again to be food for plants, which plants will become food for animals. Other organisms purify rivers; others cause bread to rise; still others give rise to fermentation in liquors. Microbes may be harmful. They may poison rivers and soils; they may be parasites on vegetable life; they cause diseases of the growing vine, and also of wine; they produce the mold on stale, damp bread; they occasionally form poisonous matter in sausages, in ice-cream, and in canned goods; and they produce many diseases among men and the lower animals.

With so universal a distribution of these *fungi*, man must constantly take them into his organism. They are upon the surface of his body, he inhales them with every breath, and he swallows them with his food and drink. Most

of them, fortunately, are entirely harmless; others cannot act on the living tissues; but some are virulent, and these are generally, but not always, destroyed by the cells of the human body. The alimentary canal always contains bacteria of putrefaction, which act only upon the dead food, and not upon the living body; but when a man dies these organisms at once attack the tissues, and postmortem putrefaction begins in the abdomen. Even pathogenic bacteria may exist for long periods in the tissues without causing illness in the host, but when such bacteria do persist, they may at any time and from a variety of causes become active in producing disease in the carrier, or when they pass from the host they may perhaps infect other people (see Typhoid Carriers, page 38). Sternberg found pneumococci in healthy sputum. In fact, pneumococci can be found in the mouths of 25 per cent. of people free from pneumonia. Pneumococci obtained from the mouth of an individual free from pneumonia "are just as pathogenic as the diplococci obtained from a culture from the sputum of a pneumonic patient" (Sir Thomas Oliver, in "British Medical Journal," April 30, 1910). If the lungs become irritated, insufflation of diplococci from the mouth may be followed by pneumonia. Every infection is at first local. Some infections remain local, but others become general. In a general infection the micro-organisms are in the blood, though often we cannot find them because of imperfect methods (Ball, in "Lancet," June 8, 1912).

Welch long ago pointed out that the human skin normally contains the Staphylococcus epidermidis albus, even after the most careful surgical cleansing. Dudgeon, in the Horace Dobell Lecture for 1908 ("Lancet," Dec. 5, 1908, "Latent Persistence and the Reactivation of Pathogenic Bacteria in the Body"), says that healthy organs may contain various bacteria, that the tissues of the fetus are sterile, but in childhood and adult life "bacteria are found in various parts of the human body; that Staphylococcus albus can be cultivated from the human omentum in cases in which the peritoneal cavity is apparently healthy"; that pus cocci may persist for long periods in a scar; that virulent diphtheria bacilli may be "found in the throats of persons who have come in contact with diphtheria patients, but show no signs of the disease"; that the Bacillus proteus is frequently found in the urine; that colon bacilli normally inhabit the intestinal tract and appendix and frequently exist in the urinary tract without giving rise to inflammation or symptoms of disease, and that typhoid bacilli tend notably to persist (see page 38). As previously stated, the organisms of tuberculosis and of syphilis may long rest latent.

Koch's Circuit.—To prove that a microbe is the cause of a disease it must fulfil Koch's circuit. It must always be found associated with the disease; it must be capable of forming pure cultures outside the body; these cultures must be capable of reproducing the disease; and the microbe must again be found associated with the artificially produced morbid process.

Infection or Disease Production by Micro-organisms.—Most infections are caused by bacteria, some result from molds, a few from protozoa. Pathogenic organisms cannot enter through the sound skin and the unbroken skin without causing the formation of lesions at the point of entrance. The sound skin is the very best antiseptic covering for tissue, as ordinary bacteria cannot pass it at all. Some bacteria by entering the ducts of cutaneous glands may cause disease. Disease-producing organisms which enter the body may reach the focus in which they act from outside of the body, entering by inoculation, inhalation, or ingestion. In most instances organisms which enter the body from without are rapidly destroyed. When they enter in large numbers, or when they are very virulent, or when the vital resistance of the individual is at a low ebb they cause disease. Bacteria may reach the region in which they become active from some other part of the body. Bacteria seldom dwell in the body long without inducing disease, but spores can lie dormant in the

system for years. When bacteria or spores from some other part of the body reach a region of injury or disease they may become active; this area is a damaged and weakened part, in it the circulation is abnormal, it is a so-called *point of least resistance* (a *locus minoris resistentiæ*) which affords a nest for them to develop and to multiply, the cellular activities of the weakened part being unable to cope with the activities of the germs. Even large numbers of pathogenic organisms may induce no trouble in a healthy man; but let them reach a damaged spot, and mischief is apt to arise. Kocher established subcutaneous bone injuries in dogs, and these injuries pursued a healthy course until the animal was fed upon putrid meat, whereupon suppuration took place. This experiment proves that micro-organisms can reach a damaged area by means of the blood, and it enables us to understand how a knee-joint can suppurate when we merely break up adhesions, and how osteomyelitis can follow trauma when the skin is intact. A given number of organisms might produce no effect on a healthy man, whereas the same number might produce disease in an individual who was weak or ill-nourished, suffering from depression or fear, or debilitated by the habitual use of alcohol. The personal equation plays a great part in disease production. Some individuals seem to be immune to certain diseases; and these immunities and liabilites may be hereditary or acquired, temporary or permanent.

The local infection may be violent and yet never be generalized. Sometimes the local reaction at the point of bacterial entry is so trivial as to be overlooked, or by the time general infection occurs the initial point of local infection may have healed.

It is not at all unusual to observe lymphangitis or lymphadenitis "above a healed focus" (J. C. Bloodgood, in "Progressive Medicine," Dec., 1911). A few infections generalize primarily by way of the blood—most do so by the lymphatics. From the moment there is lymphangitis or lymphadenitis the infection is to be regarded as general, and the blood contains toxins or bacteria, the lymph-glands filtering out and holding comparatively few micro-organisms. (See J. C. Bloodgood, in "Progressive Medicine," Dec., 1911, and Noetzel, in "Beitr. z. klin. Chir.," 1909, lxv).

A general infection in which the blood contains toxins but not bacteria is called a *toxemia*. A general infection in which the blood contains bacteria is called a *bacteremia*.

The intensity of an infection may often be estimated by the degree of leukocytosis and anemia (see page 42).

Enzymes.—Bacteria contain and excrete ferments, and these ferments are known as enzymes. Bacterial ferments resemble pepsin and trypsin, the digestive ferments. The digestive ferments convert albumin into peptone, starch into sugar, and break up fat. Some enzymes are proteolytic (dissolve albumin); some are diastatic (change starch into sugar); some convert cane-sugar into grape-sugar; some coagulate milk. When microbic infection of the tissues occurs the enzymes of the bacteria act upon the tissues just as the digestive ferments act upon the food, and form microbic albumoses. The enzymes are the weapons of micro-organisms. By means of these ferments bacteria not only prepare substances for assimilation, but seek to destroy antagonists and cell enemies. It is probable that enzymes when absorbed are frequently productive of toxemia.

Toxins are poisons produced by microbic action. The action of pathogenic bacteria upon the tissues is of great importance. In the first place, they invade the tissue, the capacity for invasion varying greatly and depending on their power to sweep aside the defenses of the body. When they invade the tissues they abstract from the blood, the lymph, and the cells certain elements necessary to the body—as water, oxygen, albumins, carbohydrates, etc.—

and thus cause body wasting and exhaustion from want of food. In the second place, bacteria produce a vast number of compounds, some harmless and others highly poisonous. The symptoms of a microbic disease are largely due to the absorption of poisonous materials from the area of infection. These poisons may be formed from the tissues by the action upon them of the bacterial ferments (see page 36), may be excreted by the bacteria (*extracellular toxins*), or may be liberated from the bodies of degenerating microbes (*bacterial protein*, *intracellular toxins*, or *endotoxins*). Intracellular toxins are very insoluble. Bacteria contain and secrete ferments; and as albumoses are formed in the alimentary canal by the action of digestive ferments upon proteins, sugars, and starches, so microbic albumoses are formed by the action of microbic ferments upon tissues. Just as the albumoses formed in digestion are poisonous when injected, so the albumoses of microbic action are poisonous when absorbed. The albumoses of microbic action are called *toxalbumins*, and these albumoses often operate as virulent poisons to the body-cells.

A number of compounds formed during the microbic destruction of tissue are *alkaloidal* in nature. These poisonous alkaloids are readily diffusible and, many of them, very virulent. It is probable that every pathogenic organism has its own special toxin which produces its characteristic effects, although the effects are modified by the nature of the soil—that is to say, by the condition of the tissues. Again, one micro-organism may produce several toxins. The absorption of toxins may be very rapid; for instance, the toxins of cholera may kill a man before the bacilli have migrated from the intestine. Brieger uses the term *toxin* to designate all of the poisonous products of bacterial action. He divides toxins into alkaloidal or crystallizable and amorphous, the latter being called toxalbumins.

Ptomains.—By many writers the term "ptomain" is used to designate these toxins, but, in reality, a ptomain is a form of toxin produced by the action of saprophytic bacteria. A ptomain is a putrefactive alkaloid and a toxin is any poison of microbic origin. Among these putrefactive alkaloids may be mentioned tetanin, typhotoxin, sepsin, putrescin, tyrotoxicon, muscarin, and spasmotoxin. The poison which occasionally forms in cheese, ice-cream, sausage, and canned goods is composed of ptomains. Poisoning by any putrid food is called ptomain-poisoning.

Leukomains must not be confounded with the above-mentioned bodies. Leukomains are alkaloidal substances existing normally in the tissues and not produced by bacteria, but arising from physiologic fermentations or retrograde chemical changes. They are natural body constituents, in contrast to toxins, which are morbid constituents. Leukomains are found in expired air, saliva, urine, feces, tissues, and the venom of serpents. If not excreted, these bodies may induce illness, and when injected may act as poisons. Ordinary colds and some fevers result from leukomains; they play a great part in uremia, and when excretion is deficient the retained leukomains make the system a hospitable host for pathogenic bacteria. Sickness due to the retention and absorption of leukomains is known as *auto-intoxication*. Among leukomains may be mentioned adenin, hypoxanthin, and xanthin, allied to uric acid, and other substances allied to creatin and creatinin. The surgeon should never forget the possibility of harm being done by retained leukomains, and should endeavor to prevent auto-intoxication in all cases by keeping the skin, the bowels, and the kidneys active.

Immunity.—*Resistance* is the fight of the body against bacteria. Even a person with high resistance may be infected, but even though infected the body still fights the bacteria. If a person cannot be infected with a certain disease, he is said to be immune to it. Some persons seem naturally immune to certain diseases (*natural immunity*). Immunity to some diseases may be produced

artificially. When the body itself produces the materials which render it immune the immunity is called *active*. When immunity is produced by the introduction of substances artificially produced the immunity is called *passive* or *artificial*. It has long been known that when a person recovers from certain diseases he has become immune to the disease from which he suffered (*acquired immunity*). Immunity may be transitory, prolonged, or permanent. Acquired immunity may be compared to fermentation. When fermentation ceases, the addition of more ferment is without result. When a person recovers from certain diseases, the addition to his blood of more of the causative bacteria is also void of result.

Immunity was long believed to arise from the exhaustion of some unknown constituent of tissue necessary to the life of the bacteria. This theory was advanced by Pasteur. It has been abandoned because of the demonstration that though an animal may become immune to a disease caused by certain bacteria, these bacteria may continue to live in the host. It is true that when recovery ensues upon infections, as a rule, the causative bacteria disappear, but there are enough exceptions to this rule to invalidate the theory of Pasteur. It is well known that even for years after an attack of typhoid fever the bacilli may exist in the gall-bladder or the bone-marrow, or be passed in the urine or feces. A person apparently well, yet holding, for instance, in his gall-bladder infectious bacteria, is called a "*bacteria carrier*." From 1 to 2 per cent. of persons who have had typhoid fever years ago pass bacilli in the stools, and such carriers are often responsible for the spread of the disease. Hutchinson ("British Medical Journal," March 26, 1910) reports a "carrier" whose attack had been fifteen years before. Gregg ("Boston Med. and Surg. Jour.," July 16, 1908) reported the case of a typhoid carrier fifty-two years after recovery from typhoid. Some carriers never knew they had had typhoid, the attack having been very mild. Some have never had it, but have been in contact with it. Such people were immune. A carrier may give the disease to others, but is practically immune. "Certain protective immune bodies, such as opsonins and stimulins, are augmented by the attack; others, such as the bactericidins and bacteriolysins, are not augmented to the point of destruction of the bacilli" (Willard J. Stone, in "American Journal of Medical Sciences," April, 1912). Fromme operated upon 4 typhoid carriers. In each case he removed the gall-bladder. In the bile of each he found bacilli. After operation the bacilli disappeared from the feces of each woman ("Deutsch. Zeitsch. f. Chir.," Nov., 1910). A theory proposed by Chauveau is known as the "retention theory," and is the opposite of Pasteur's "exhaustion theory." According to Chauveau, bacteria growing within the body leave as a legacy excrementitious material, and the accumulation and retention of excrementitious products produce immunity.

Until very recently one set of investigators maintained that immunity depends upon the activity of certain body cells which attack, consume, and destroy bacteria, this is the theory of *phagocytosis* (see page 41). Another set asserted the claims of Nuttal and Buchner, that normal fresh blood-serum is germicidal, the power varying for different bacteria and being limited. A fixed amount of serum is capable of destroying a fixed number of bacteria of a certain variety. Vaughan and others states that the germicidal agent is probably a nuclein furnished chiefly by the white cells and held in solution by the alkaline serum. This germicidal agent of normal serum Buchner called "*alexin*" or *defensive protein*, and explained immunity by its presence. This theory is known as the "*humoral theory*." According to this theory as originally maintained, when an animal is naturally immune to a bacterial disease it is assumed that the blood-serum and body fluids contain enough of this alexin to dissolve or destroy the bacteria. Neither method of defense is the only one.

In all probability both phagocytosis and bacterial solution are occurring in the same patient at the same time, phagocytosis being impossible but for the serum and bacteriolysis being impossible without leukocytes.

Since the above theories were set forth it has been found that when an animal recovers from some bacterial diseases the blood-serum and body fluids contain new protective materials called, in general, *antibodies*. The toxins of bacteria stimulate body cells to the production of antibodies, and antibodies bring the disease to an end and secure immunity. It is thus seen that the very poisons produced by bacteria cause the body cells to produce poison antidotes. The bacteria may be so virulent or the patient so susceptible that poison overwhelms the cells, antibodies are not formed in sufficient quantity, and death ensues. The cells may be badly poisoned and the patient may become very ill, and yet after a time the cells may regain enough vitality to furnish antibodies in sufficient quantity to bring about cure and to secure immunity. The bacteria may be so few in number or so attenuated in virulence or the cells of the patient may be so active that quantities of antibodies are quickly formed under mild stimulation, and the individual does not take the disease at all or takes it very mildly.

The **lytic** or **bacteriolytic antibodies** or **lysins** destroy and dissolve bacteria. All bacteria are not susceptible to lysis, for instance, streptococci, tubercle bacilli, and pneumococci. When recovery ensues the causative bacteria usually but not always disappear (see page 38). These lytic bodies are formed by the leukocytes, bone-marrow, spleen, and lymph-glands (Wassermann, in "Berlin. klin. Woch.," No. 4, 1898, and Levaditi, in "Annales de l'Inst. Pasteur," 1904).

Agglutinins and **precipitins** gather in the blood-serum of an animal when the animal has been injected with bacteria or certain cells. When these antibodies appear in blood after an animal has been injected with bacteria they agglutinate and precipitate the bacteria injected. It is probable that agglutinins and precipitins are formed by the endothelium of vessels walls (Kraus and Schiffman, in "Annales de l'Inst. Pasteur.," 1906). These materials only appear after certain infections.

Opsonins are materials which by attaching themselves to certain bacteria so alter the bacteria that they easily become the victims of phagocytosis (see Phagocytosis, page 41).

Antitoxins are specific bodies secreted, as Roux says, by the body cells. They pass into the serum and body fluids. They fix and neutralize the bacterial toxin by combining with it, but do not dissolve, kill, precipitate, or agglutinate the bacteria. The first antitoxin to be discovered was that of diphtheria. The discovery was made by Behring in 1890.[1] He found that if an animal is injected with gradually increasing amounts of diphtheria toxin the serum comes to contain an antitoxic material. Very soon after this discovery was announced Behring and Kitasato made a like discovery in regard to tetanus toxin. It was pointed out by Kitasato and Behring that animals can be rendered immune to tetanus by artificial means and that the blood-serum of immune animals will, if injected into other animals, render them immune, or perhaps cure the disease if injected into animals suffering from tetanus. The same statements were also proved to be true of diphtheria. Now many experimenters are endeavoring to find the antitoxin of each microbic disease for the purpose of using it therapeutically and also as a preventive agent.

In some infections soluble toxins are not formed and the body resistance depends largely on the formation by the bacteria of substances which finally, when present in sufficient amounts, destroy bacteria.

Surely one of the most important of modern discoveries is that certain

[1] "Deutsche Med. Wochenschrift," 1890, Nos. 49 and 50.

substances introduced into the body cause a reaction which results in the formation of antibodies. Any material which causes antibodies to form is called an antigen. In the preceding section we have spoken of bacterial products as the antigens. But other antigens exist, for instance, blood-corpuscles and other cells, blood-serum, some vegetable poisons, and some animal poisons. Thought is now directed to treating bacterial diseases by the introduction of the proper antigen to produce lysins, opsonins, antitoxins, as the case may be. Streptococci produce no antigen which leads to lysin formation, but do produce antigens which lead to antitoxin and opsonin formation.

The subject is of enormous importance and is vastly complicated.

Ehrlich's Theory of the Mechanism of Immunity by Antitoxins.—Ehrlich's theory was advanced in 1898 and is generally accepted at the present time. "Ehrlich's theory of the mechanism of immunity is based upon Weigert's teaching of the process of tissue repair. It is a matter of universal observation that nature is prodigal in her attempts to repair an injury. This is shown in the healing process in an ordinary wound. A much larger amount of material is thrown out to bridge the chasm than is really utilized in the formation of new tissue. The presence of an excessive amount of new material is shown by the fact that the part is raised above the level of the surrounding sound tissue, and this excess is removed gradually as the new-formed tissue becomes stronger and stronger, until finally the wound is marked by a line of white scar-tissue, the excess gradually passing into the blood-current.

"Ehrlich believed that the mechanism of immunity was explainable on a similar basis. It had become evident from the experiments of Wassermann with the tetanus bacillus that its toxin had an especial affinity for the cells of the central nervous system. Experiments with other bacteria pointed to the fact that the toxins of different species of bacteria had an especial affinity for the cells of different organs of the body. When the amount of poison entering the body is not sufficient to destroy the cells which have an especial affinity for it, these cells may be injured only to such an extent as to permit subsequent repair. In order to comprehend Ehrlich's hypothesis it is necessary to conceive the cells of the body as having a complex structure which may be stated diagrammatically as consisting of a central mass or nucleus from which radiate a number of 'lateral chains,' or bonds, each of which serves to bind the cell to other substances. In the case of the cells of the central nervous system one of these lateral bonds has an especial affinity for tetanus toxin and suffers destruction. The cell now finds itself in unstable equilibrium, and at once proceeds to repair the damage wrought. As in the case of tissue repair, the new material produced is far in excess of the required amount. The excess finds its way into the blood-current. This material now circulating in the blood-current has the same affinity for tetanus toxin as when united with the central mass of a cell as its lateral bond, and can, therefore, combine with tetanus toxin floating in the blood-current, thus preserving other cells from injury. The union formed between the lateral bond of the cell (which is really the antitoxin) and the tetanus toxin results in the formation of a compound which is physiologically inert. According to Ehrlich's idea, therefore, the antitoxin is simply the excess of lateral bonds floating in the blood-current. This substance can neutralize the effect of the tetanus toxin in a test-tube just as readily as it does within the body" (D. H. Bergey, "American Medicine," October 11, 1902).

Phagocytes.—It was generally believed after Metschnikoff's important discoveries that leukocytes were the agents which protected the body from infection. When other observers found that in blood-serum is material that damages or destroys bacteria, opinion swung to the veiw that the blood-serum contains the protective element, and that the leukocytes are simply scavengers

and remove dead bacteria, but do not destroy living ones. It has recently been shown that under some circumstances leukocytes destroy living bacteria and under other circumstances they do not, and that the presence or absence of this property depends in most instances upon the presence or absence in the blood-serum of substances which act upon bacteria and render them susceptible to the phagocytic action of leukocytes. We say in most instances, not in all instances, because certain bacteria, for instance, influenza bacilli, are phagocytable without the presence of opsonic serum (Ludvig Hektoen, address in "Section of Physiology and Experimental Medicine, American Assoc. for Advancement of Science," 1908; "Science," Feb. 12, 1909). The existence of substances in the serum provocative of phagocytosis was demonstrated by Wright and Douglas in 1903, and they named them *opsonins*. If opsonins are present, they act upon bacteria, and render the bacteria susceptible to phagocytosis. (See Ludvig Hektoen, in "Jour. Am. Med. Assoc.," May 12, 1906.) Opsonins act upon bacteria and alter them, and the altered bacteria are easily eaten up by leukocytes. Very virulent bacteria resist phagocytosis because they have little affinity for opsonin, and such virulent bacteria may grow in opsonic serum. The source of opsonins is not known, but serum normally contains "opsonins for many different bacteria" (Hektoen, in "Jour. Am. Med. Assoc.," May 12, 1906). When experiment determines the fact that an individual's leukocytes are highly phagocytic toward particular bacteria, we believe that a quantity of opsonin for that variety of bacteria is present, and we may say the individual has a high *opsonic index* as regards them. Under opposite conditions we say he has a low opsonic index. "The opsonic index of Wright with respect to a given bacterium is obtained by comparing the number of the bacteria taken up under the influence of the serum of the person or animal in question with the number taken up under the influence of the corresponding standard of normal serum under conditions that are as comparable as they possibly can be made" (Ludvig Hektoen, address in "Section of Advancement and Physiology and Experimental Medicine in Am. Assoc. for Science," 1909; "Science," Feb. 12, 1909).

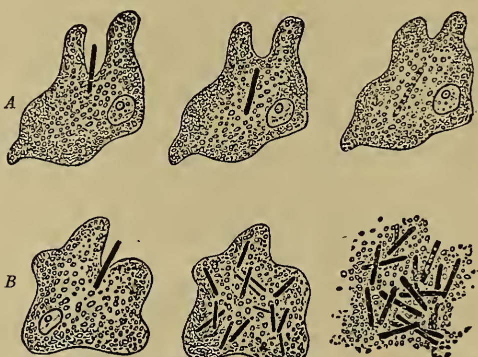

Fig. 14.—Phagocytosis: *A*, Successful; *B*, unsuccessful (Senn).

The Process of Phagocytosis.—We have just seen how opsonins stimulate phagocytosis. The process of destruction of bacteria by cells is known as *phagocytosis*, and the destroying cells are called *phagocytes*. The cells active in phagocytosis are the endothelial cells of the blood-vessels, lymph-channels and lymph-spaces, and particularly the leukocytes. When infection occurs, the white blood-cells gather in enormous numbers at the seat of disease, encompass and surround the bacteria, and build a barrier to prevent dissemination of the microbes and general infection of the victim. The force which draws leukocytes to a region of infection also tends to draw them to an area where there is cellular degeneration or death. This force is called *positive chemiotaxis* and is greatly stimulated by opsonins. In very virulent infections the leukocytes may fail to collect and may actually be repelled and scattered under the influence of what has been called *negative chemiotaxis*. Phagocytes at the seat of infection try to eat up, carry away to a gland, and there digest

and destroy bacteria. A battle royal occurs, the microbes fighting the body cells with most active ferments and destroying the opsonic power of the blood-liquor; the body cells endeavoring to devour and destroy the bacteria (Fig. 14), in which effort opsonins give them aid. In some cases the bacteria win absolutely and the patient dies. In other cases they win for a time and overwhelm the system; but presently the body cells, whose movements were inhibited by the poison, regain their activity and are then immune to the bacterial poison. It is probable that the materials thrown out by the white cells during the combat with the microbes tend to destroy bacterial products and to neutralize toxic products of tissue destruction. These materials, which neutralize toxic products, are known as *antitoxins* (see page 39). After the attack of disease has passed away the body cells have been educated to withstand this poison, and new cells in the future retain this capacity; the weak cells were killed, the fittest survived, and the body fluids contain antitoxin. The new cells formed in the body are insusceptible to the poison and the individual is said to be *insusceptible* or *immune.* The theory of phagocytosis immunity assumes an educated white corpuscle and body cell. This view originated with Sternberg, but it is usually accredited to Metschnikoff. Lankester gave us the term "educated corpuscle."

Leukocytosis.—In a number of infectious and inflammatory diseases leukocytosis occurs. By this term we mean a notable increase of leukocytes in the blood, the polynuclear neutrophiles being increased relatively and absolutely. Leukocytosis in an infection indicates that the body is trying to protect itself against poisons by furnishing more phagocytes to attack bacteria. The degree of the leukocytosis is a sort of gauge of the virulence of the infection and of the reacting or resisting powers of the individual. In a very trivial infection there may be a slight leukocytosis or no leukocytosis at all. A violent infection, if resistance is high, is accompanied by a high degree of leukocytosis; if resistance is low, there is a low degree or no leukocytosis at all.

In a virulent infection absence of leukocytosis is of unfavorable import. It means that tissue resistance is at an end and that the body cells have ceased to fight the bacteria.

Normally, the blood should contain about 7500 leukocytes per c.mm. From 60 to 75 per cent. of the cells are polynuclear neutrophiles. If the cells number well above 10,000, and if the percentage of polynuclear neutrophiles is increased, the condition is regarded as leukocytosis.

In most cases the leukocyte count is below 20,000. Over 20,000 is high leukocytosis. It is very seldom that a count of over 30,000 is obtained (see page 93).

Artificial Stimulation of Phagocytosis.—When active hyperemia is induced by heat, when irritants are applied to an inflamed surface, or when an inflamed joint is treated by Bier's method of passive hyperemia, local leukocytosis is stimulated and phagocytosis becomes more active. A few years ago Issaëff affirmed that the introduction of certain materials, as salt solution, into the peritoneal cavity, lead, for a time, to great increase in the resistance to abdominal infection. This period of increased resistance he called the *resistance period.* It begins a few hours after the injection and terminates by the end of the fifth day. During this period the great increase in intraperitoneal leukocytes saves the animal from infection with bacteria, which would otherwise cause a dangerous or fatal inflammation. Mikulicz believed it possible to establish this resistance period before abdominal operations and was working on the problem just before his lamented death. Mikulicz used diluted nucleinic acid injected twenty-four to forty-eight hours previous to operation (Mikulicz, "Verhandl. d. 33. Congress d. Deutsch. Ges. f. Chir.," 1904). Graf's studies of nucleinic acid used to secure immunity from puerperal sepsis were inconclusive

("Zentralblatt für Gynäkologie," 1910, No. 27). Some surgeons have injected fresh warm horse-serum for the same purpose (Petie, Jayle, and Federmann; see "Le Presse Medicale," 1905). The agents used must not be of a nature to damage opsonins, for leukocytosis without plenty of opsonins would do no good. A true infectious or inflammatory leukocytosis is much more protective than an artificial leukocytosis, however induced. In fact leukocytosis induced, for instance, by injecting such a material as nuclein is of very little use against an established infection. It is probably of more value as a protective against infection. How slight or how great this value may be is not yet certainly determined.

Vital Resistance.—Local resistance is lowered by injury or disease of the skin or mucous membrane. Sound skin and mucous membrane are most important elements in resistance. For instance, disease of the intestinal mucosa may permit colon bacilli or other micro-organisms to be taken through the damaged mucous membrane and be carried to distant regions, in which regions of arrest disease may arise.

In the same manner pulmonary tuberculosis may develop subsequent to disease of the bronchial mucous membrane. The general vital resistance to infection depends in part upon germicidal and opsonic blood-liquor and in part upon active leukocytes.

Vital resistance is increased by agents which cause active phagocytosis without destruction of opsonins.

Anything that lessens the germicidal and opsonic power of blood-serum or the phagocytic activity of corpuscles lessens general vital resistance. Among these causes are ill health, worry, unhygienic life, chronic drug intoxications, alcoholism, chronic visceral diseases, diabetes, Bright's disease, gout, rheumatism, violent and sudden fluctuations of temperature, bodily or mental overwork, improper food, insufficient food, too little sleep, fear, antecedent illness, exposure to cold, and the creation of points of least resistance (see page 36). The general vital resistance to infection is also lowered by inordinate prolongation of a surgical operation, by shock, by hemorrhage, by protraction of the anesthetic state with ether or chloroform. Exham ("Brit. Med. Jour.," Jan. 27, 1912) points out that inflammation is a factor in resistance (this is seen by pus limitation in appendiceal abscess), and so is fever. Elevated temperature means that the body is fighting the infection (see page 129).

Different tissues in the same individual show great differences in resistance. We know that certain bacteria have a predisposition to attack certain tissues. This is notably true of tubercle bacilli. The resistance of an individual varies at different times. Heredity often plays a part in predisposition and resistance and sex has some influence upon it. Race is influential regarding some diseases (see page 24). Resistance varies at different ages. Exham ("Brit. Med. Jour.," Jan. 27, 1912) points out that children are particularly prone to acute infections, but are less apt to die of them than are adults.

Protective and Preventive Inoculations.—Our knowledge of protective inoculations for contagious diseases dates from Jenner's discovery of vaccination against small-pox in 1798. Preventive inoculations with attenuated virus are due to the experiments of Pasteur. This observer discovered the cause of chicken-cholera, and cultivated the micro-organism of the disease outside the body. He found that by keeping his cultures for some time they became attenuated in virulence, and that these attenuated cultures, inoculated in fowls, caused a mild attack of the disease, which attack was protective, and rendered the fowl immune to the most virulent cultures. Cultures can be attenuated by keeping them for some time, by exposing them for a short period to a temperature just below that necessary to kill the organisms, or by treating them with certain antiseptics. It has further been shown that injection of the

blood-serum of an animal rendered immune by inoculation is capable of making a susceptible animal also immune.

A most important fact is that animals may be rendered immune to certain diseases by inoculating them with filtered cultures of the microbes of the disease, the filtrate containing microbic products, but not living microbes. By this method animals can be rendered immune to tetanus and diphtheria. Pasteur's protective inoculations against hydrophobia owe their power to microbic products, and Koch's lymph contains them as its active ingredients. Injections of dead bacteria is the basis of inoculation against typhoid fever. Inoculation with dead bacteria is called *vaccination* and the dead bacteria constitute the *vaccine* (see page 47).

Vaccination against typhoid has been notably successful in the army and navy of the United States. Surgeon-General Stokes of the U. S. Navy reports the entire disappearance of typhoid from the navy as the result of vaccination. During the summer of 1911 an army division of nearly 13,000 men was stationed in Texas for four months. It was in a region where typhoid existed. Every man was vaccinated and only one developed typhoid. The chief feature in acquired immunity is the presence in the blood and tissues of elements which can neutralize the toxic products of bacteria. These elements are "antitoxins" (see page 39). Microbic products are dead and cannot multiply as can living bacteria, hence the human organism is not overwhelmed unless the dose is too large, but the microbic products cause the development of antitoxin as certainly as do the living microbes. The above facts are of immense importance, for on these lines may be solved the problems of the prevention and treatment of microbic maladies.

Orrhotherapy, or **serum-therapy,** is an attempt to utilize therapeutically the germicidal properties of blood-serum. It is believed that when a person recovers from an infectious disease the alkaline blood-serum is saturated with protective material, particularly with antitoxin. If this belief is true, a proper deduction is, that blood-serum containing protective material should cure the disease if injected into a patient suffering from an attack. Some sera used therapeutically are antitoxic (antitoxin), that is, they do not kill bacteria, but merely neutralize the toxin. Others are bacteriolytic, destroying and dissolving bacteria. An antitoxic serum is made by injecting a horse with toxin. The horse-serum comes to contain antitoxin. Antibacterial serum is obtained by injecting an animal first with the dead and then with the living bacteria. The serum contains the bacteriolytic material. Instead of using the blood-serum itself, some observers have precipitated the supposed curative material from the serum, have dissolved this material, and have administered the solution in fixed amounts. Instead of using the serum of persons rendered immune by an attack of the disease, many physicians have employed the serum of animals rendered artificially immune by injections of attenuated cultures of the bacteria or injections of bacterial products. Some experimenters have even employed the serum of animals naturally immune to the disease. In some cases the serum is given hypodermatically, in some intravenously, in some by lumbar puncture, in some by intracerebral, and in others by intraneural, injection. Claims have been made that serums are efficient when given by the mouth or by the rectum. Paten, of Melbourne, claimed in 1906 that the oral administration of immune serum raises the opsonic index ("Med. Press and Circular," Jan. 31 and Feb. 7, 1906).

Latham ("Lancet," Feb. 15, 1908) and others claim that clinical and bacteriologic evidences are in favor of the view that serums are efficient when given by the mouth. If these views are proved to be true serum-therapy will receive an enormous impetus. Calmette has perfected an antivenomous serum (antivenene) for use after cobra bites. Pasteur has devised a method which will usu-

ally prevent hydrophobia (see page 306). That Murri, of Bologna, has apparently cured a case of hydrophobia seems proved (see page 307). Hosts of observers believe in the utility of diphtheria antitoxin and many are convinced of the value of tetanus antitoxin. The earlier in the disease the injection of an antitoxic serum is practised and the larger the dose, the more apt it is to prove curative. When the toxin has not yet combined with cells, antitoxin may keep it from doing so, and when it has recently combined and the combination is still unstable, antitoxin may cause dissociation of the combination. When the disease is well established and the cell combination of toxin is firm, antitoxin will, in all probability, fail to cure. If we decide to give serum in an acute infection, give it early and as advised by Ball ("Lancet," June 8, 1912).

A rapid effect will be obtained by mixing the serum with normal salt solution and throwing 100 c.c. of the mixture into a vein. Each day after this 50 to 100 c.c. are given subcutaneously.

Ball advises that we obtain the serum which is most nearly autogenous. The best is obtained from the blood of one who has recently recovered from the identical infection. The next best is obtained from a person who has been artificially immunized. Make a vaccine at once, and as soon as it is made, substitute it for the serum injections.

It is very important to remember that the water of the salt solution must have been recently distilled. Otherwise an intravenous injection of serum and salt solution will be followed by a chill in from one-half to two hours after the injection (Ball, in "Lancet," June 8, 1912). In order to make diphtheria antitoxin a horse is immunized to diphtheria toxin by injecting subcutaneously increasing doses of diphtheria toxin. It requires two or three months for the blood of the animal to acquire sufficient potency. The blood containing antitoxin is withdrawn by bleeding, the serum is separated from the clot, and its antitoxic potency is determined by complicated methods. We signify the degree of potency of a serum by saying that it is of so many "immunizing units," a unit being an arbitrary standard. The average dose for a child is 1000 units and for an adult 2000 units. (Tetanus Antitoxin is considered on page 208; Antivenene is considered on page 300.)

Anthrax in animals and human beings has been treated with success by Sclavo's serum (the serum of an actively immunized animal). The antimeningococcus serum of Flexner and Jobling seems to possess distinct power in the treatment of epidemic cerebrospinal meningitis. It is given by lumbar puncture. Cholera serum seems of no avail therapeutically. Shiga's antidysenteric serum is of value. Claims are made for plague serum. Inconclusive experiments have been made in the treatment of syphilis by the serum of dog's blood and by the blood-serum of men laboring under tertiary syphilis; in the treatment of pneumonia by the blood-serum of persons convalescent from pneumonia; and in the treatment of sufferers from septic diseases by antistreptococcic serum—blood-serum of horses rendered immune to virulent streptococci. The serum treatment of pneumonia is a failure. The real value of antistreptococcic serum is yet uncertain. Occasionally it seems to do great good; at other times it appears to produce no benefit whatever. Some observers claim remarkable results in erysipelas. In several cases of phlegmonous erysipelas and in 2 cases of malignant endocarditis I thought it was of benefit. Tavel, in an elaborate research ("Klinische-therapeutische Wochenschrift," Vienna, August, 1902), states that he obtained brilliant results in some cases, but no results in others. He does not undertake to explain this variability of action. He thinks the serum benefits staphylococcus as well as streptococcus infections. Antistreptococcic serum often fails completely. This is supposed to be due to the fact that there are many different families of streptococci. It was hoped that a polyvalent serum would prove efficient, but the hope is still

only a hope. It has been proved that some antistreptococcic sera have not as high an opsonic index for streptococci as has normal horse-serum, and "the opsonin content of an antistreptococcic serum seems to be the factor that gives the serum whatever" value it possesses (Jordan's "General Bacteriology"). Tavel and Moser, believing that scarlatina is a streptococcic malady, prepare serum by using cultures of streptococci obtained from a number of cases of scarlet fever. Van de Velde uses cultures of streptococci obtained from various streptococcic infections. According to Burkard antistreptococcic serum destroys neutrophiles in the blood. This destruction is not harmful if leukocytosis follows the injections, and it does follow them in all cases when the body is able to react to the serum ("Archiv. f. Gynäk.," lxxx, No. 3). Before removing a tongue or an upper jaw it is my custom to give antistreptococcic serum, and I believe that it lessens the tendency to toxemia and to septic bronchopneumonia. Malignant tumors (both sarcomata and carcinomata) have been treated with the blood-serum of dogs, which animals had been injected with fluid expressed from malignant growths (Richet and Hericourt). Von Leyden and Blumenthal obtain a serum by compression of a recent cancerous growth and treat human victims of cancer with it. They claim that the results are encouraging ("Deutsche medicinische Wochenschrift," Sept. 4, 1902). Many claims made for serum-therapy in surgical diseases are exaggerated, sensational, and unscientific. It does not seem possible to obtain an antitoxin for each bacterial malady, and the bacteria of most specific diseases are potent for harm for more reasons than because they form crystalloidal toxic matter. That there is truth in the method seems highly probable, but how much truth there is, is not yet definitely ascertained. It is our duty to study, experiment, and observe, and to reach a conclusion only after honest, careful, and thorough investigation. A little skepticism is as yet a safe rule.

Anaphylaxis, or Untoward Effects of Serum Injections.—Anaphylaxis is a term introduced by Richet in 1904 to designate a state of hypersusceptibility (congenital or acquired) "to a strange protein or antigen with a reaction body formed in the body of the organism undergoing immunity" (St. George T. Grinnan, in "Jour. Amer. Med. Assoc.," Jan. 20, 1912). It has been known for a considerable time that guinea-pigs which had been injected with antitoxin frequently died when injected with the serum again some time later; the curious fact is that the first dose does no harm, but the second dose, given after several days, produces the trouble. In man unpleasant or even dangerous effects may follow the injection of any serum. They occur in certain hypersensitive individuals. They may occur from a first dose, but are far more apt to arise from the second, the third, or some later injection. They are most apt to occur when there has been an interval of two or three weeks between injections. In some cases where death followed a first injection an enlarged thymus existed. In a recent case in Philadelphia this was proved by autopsy.

The symptoms may be trivial and not arise for several hours. The most common ones are joint pains, weakness, depression, dyspnea, urticaria or erythema, cough, itching, sneezing, edema of the face, and swelling of the tongue ("Progressive Medicine," Dec. 1, 1908).

The symptoms may be serious and arise in a few minutes. In such a condition any of the previously mentioned symptoms may exist, but the dyspnea is urgent, the face is often cyanosed, and collapse occurs. In some cases death occurs in a few minutes after an injection. When untoward results follow a first injection the condition is regarded as *hypersusceptibility to serum.* When it follows a later injection it is called *serum disease.* We fear fatality from an initial dose when there is hypersusceptibility. Serum disease is usually made manifest by minor symptoms developing from eight to thirteen

days after a first injection or almost at once after an injection given from fourteen days to four months after the first one. There is no way of knowing beforehand that a person is hypersensitive or that he is liable to serum disease except that asthma is ominous and makes us fear some untoward effect. The dyspnea in some cases may have been due to enlarged thymus. In using diphtheria antitoxin or tetanus antitoxin the serum should be given at close intervals and not at intervals of several days.

Vaccine Therapy, or Treatment of Infections by Bacterial Vaccines (*Bacterines*, as S. Solis Cohen calls them).[1]—The studies of Wright and Douglas upon opsonins led to the adoption of this plan of treating certain infections.

By the injection of an antitoxic serum we seek to directly neutralize toxic products. By the injection of the bacterial vaccines we seek to stimulate the body cells to produce antibodies and particularly opsonin. An injection of antitoxic serum has only a temporary effect. Injections of bacterial vaccine cause a much more enduring effect. After such an injection the opsonic index usually begins to rise in from twelve to twenty-four hours. Additional doses gain more pronounced response. The injections appear to be free from all danger. Bacterial vaccine consists of dead bacteria and their endotoxins made into emulsion in normal salt solution. Each individual has his own response to such an injection, but this response varies at different times. An antitoxic serum contains other antibodies besides antitoxin. Bacterial vaccine is made up with salt solution and is truly specific. A vaccine made up from a certain variety of organisms is valuable only in infections from that variety of organism. In some cases stock cultures are used, but it is better whenever possible to obtain the bacteria from the infected person and obtain our cultures from them (**autogenous vaccine**). In some cases, however, we cannot wait for the development of a culture and must then use stock vaccines. In erysipelas we cannot use autogenous vaccine. In a mixed infection it is sometimes uncertain which organism is the main factor in causing the trouble and danger, and yet that is the main factor against which the vaccine must be leveled. Until recently it was believed that the dose must be determined by the opsonic index. This plan is now seldom followed. Each cubic centimeter of Wright's stock vaccine contains 600,000,000 dead bacteria. The first dose is $\frac{1}{2}$ c.c. and the second dose is 1 c.c. Hartwell and Lee repeat the full dose every fourth or fifth day until the lesions are cleared up ("Publications of Mass. General Hosp.," Oct., 1908). Each injection is made in the subcutaneous tissue, the skin having been previously scrubbed with soap and water and washed with alcohol. In many cases there is a trivial reaction after injection. This reaction is not febrile, is of brief duration, and is manifested by headache, backache, and languor. It might well be asked, Why inject dead bacteria to stimulate resistance when live bacteria in the individual have failed to do it? The theory is that the bacteria causing the disease have died too quickly in the blood or, for some other reason, have failed to produce enough stimulation to result in the copious production of antibodies.

There is much testimony as to the value of this plan of treatment. The temperature of some cases of streptococcic infection may be rapidly lowered by vaccine treatment, pus formation may be lessened, and delirium be abolished. It is particularly serviceable in superficial infections from the Staphylococcus aureus (boils and carbuncles). In many cases pain and tenderness begin to abate a few hours after the first injection, a profuse discharge flows from the lesion if it is open, and gathers in the tissues if there is no opening. If the focus

[1] In this connection see particularly article by Roger J. Lee and article by H. F. Hartwell and Roger J. Lee in "Publications of Mass. General Hosp.," October, 1908; also article by Ball, in "Lancet," June 8, 1912. I have used these articles freely.

of infection is closed it should be incised, but Wright insists that antiseptics must not be used, as they destroy the activity of opsonins. The treatment is of little or no value in abscess, pyemia, septicemia, and mixed infections. It seems certain that in an overwhelming infection a vaccine can do no possible good. In such a condition it cannot possibly cause the patient's tissues to produce antibodies. We may lay it down as a rule that vaccines are particularly indicated for chronic and for local infections, and serums for general infections. In an acute infection give serum at once and autogenous vaccine as soon as it can be made (Ball's rule).

Tuberculin.—(See page 220.)

Special Surgical Microbes.—Suppuration (see page 132) is caused by microbes. Does it ever exist without them? The answer is, "Practically no." Injection of a sterile fluid containing dead organisms, or the injection of the sterile products of the growth of pyogenic cocci, will form a limited amount of pus. Injection of an irritant causes the formation of a thin fluid which may resemble pus, but is not pus. In surgery pus very seldom forms without the actual presence of living micro-organisms (see page 133), and the presence of pus is regarded as proving the presence of living micro-organisms.

Pyogenic Bacteria.—*Pus microbes*, or *pyogenic microbes*, are strongly proteolytic, that is, they possess the property of peptonizing albumin, and thus forming pus. The peptonizing action is brought about by bacterial products. Some believe that pus is not formed by a peptonizing action of the bacteria, but that the bacteria furnish a poison (leukolysin) which breaks up the leukocytes, and that the breaking up of leukocytes liberates an enzyme which dissolves albumin. The inflammation which surrounds an area of pyogenic infection is caused by the irritant products of bacterial action (tox-albumins, ammonia, etc.). In the presence of the pyogenic peptones the coagulation of inflammatory exudate is retarded or prevented. Bacteria which ordinarily cause suppuration may fail to cause it, producing instead a non-suppurative inflammation. Non-suppurating inflammation may arise if bacteria are present in small numbers or if the tissue resistance is at a high level, or if the virulence of the bacteria has been modified by adverse antecedent conditions. Bacteria which ordinarily do not cause suppuration may do so under certain conditions of increased bacterial virulence or lessened tissue resistance. The typhoid bacillus is at times pyogenic, but, as a rule, it is not pyogenic. The usual causes of suppuration are the following micro-organisms.

The term *Micrococcus pyogenes* (Fig. 15) includes the Staphylococcus aureus, the Staphylococcus albus, and the Staphylococcus citreus. These forms are deviations from one form and are not specifically different. The albus and citreus may be grown from the aureus, and they may remain white and yellow or may revert in part to the aureus form ("Atlas of Bacteriology," by Lehmann and Neumann). Some observers maintain that these forms vary greatly in virulence and hence are specifically different, but the varying virulence has been disputed, and it seems to have been proved that virulence may be lessened greatly even when the color does not change. Eighty per cent. of acute abscesses are due to staphylococci. Staphylococci are found also in osteomyelitis, in carbuncle, in boil, in acne, in pemphigus, in periostitis, in septicemia, and in pyemia, and in some cases of empyema and peritonitis. Some toxic products of staphylococci destroy leukocytes. All of the staphylococci are non-motile.

Staphylococcus pyogenes aureus (Plate 1, Figs. 1 and 15), is the golden-yellow coccus. When grown in the air it produces orange-yellow pigment. This is the most usual cause of abscesses (circumscribed suppurations). The Staphylococcus pyogenes aureus grows best in air, but can grow when air is ex-

3. Bacillus tuberculosis on glycerin-agar.

(Warren's *Surgical Pathology.*)

cluded. As it can thus grow it is a facultative anaërobic parasite. It is widely distributed in nature, and is found in the soil, the dust of air, water, the alimentary canal, under the nails, on and in the superficial layers of skin, especially in the axillæ and perineum, in the mouth, the nasal cavities, the vagina, and human milk. It forms the characteristic color only when it grows in air (Plate 1, Fig. 1). It is killed in ten minutes by a moist temperature of 58° C. and is instantly killed by boiling water. Carbolic acid (1 : 40) and corrosive sublimate (1 : 2000) are quickly fatal to this coccus.

Staphylococcus pyogenes albus (Plate 1, Fig. 2), the white staphylococcus, acts like the aureus, but is usually more feeble in power. When this organism is found upon and in the skin it is called the *Staphylococcus epidermidis albus*, an organism which Welch proved to be the usual cause of stitch-abscesses.

Staphylococcus pyogenes citreus, the lemon-yellow coccus, is found occasionally in acute circumscribed suppurations, but less often than are the other two forms. Its pyogenic power is even weaker than that of the albus.

The *Staphylococcus cereus albus* and the *Staphylococcus cereus flavus* are found occasionally in acute abscesses, but these forms cannot be sharply differentiated from the Micrococcus pyogenes and the names should be abandoned.

Staphylococcus flavescens is occasionally found in abscesses. It is intermediate between the aureus and albus.

Micrococcus pyogenes tenuis rarely takes the form of a bunch of grapes. It is occasionally found in the pus of acute abscesses.

Fig. 15.—Micrococcus pyogenes aureus (× 1000) (Lehmann and Neumann).

Fig. 16.—Streptococcus pyogenes (× 700) (Lehmann and Neumann).

The *Micrococcus tetragenus* is thought to be the bacterium chiefly responsible for the suppuration of tuberculous pulmonary lesions.

Streptococcus pyogenes (Fig. 16).—This coccus, known as the chain coccus, grows best in air and can also grow when air is excluded. It is non-motile and does not bear spores. It is found in the healthy human body in the nasal cavities, urethra, mouth, vagina, and on the skin. It has been found in spreading inflammation and suppuration, erysipelas, pneumonia, otitis, puerperal fever, pyemia, septicemia, lymphangitis, some very acute abscesses, and some cases of meningitis, empyema, peritonitis, ulcerative endocarditis, pericarditis, osteomyelitis, diarrhea, and in certain sore throats. It varies very greatly in virulence and the intensity of its action is strongly influenced by the nature of the soil in which it is implanted. Streptococci are apt to cause serious local lesions, violent constitutional involvement, and frequently death. Not only do streptococci produce virulent toxins, but they also produce a non-toxic material called hemolysin, which dissolves red corpuscles. Some bacteria always get in the blood during the existence of a streptococcic infection. In a mild case those which enter the blood are soon killed. Even in a very severe case we may be unable to demonstrate them, but they are surely there. Woodhead tells us (Treves's "System of Surgery") that six organisms, each of which bears a separate name, are discussed under this designation. Three of these organ-

isms he places in one group, two in another, and says the sixth may be a separate species.

1st Group.—*Streptococcus pyogenes* (Fig. 16), found especially in spreading suppuration. Such suppurations spread because streptococci only feebly attract leukocytes and prevent the coagulation of exudate. Streptococci are also found in very acute abscesses. About 15 per cent. of acute abscesses contain streptococci. The Streptococcus pyogenes is easily killed by boiling, and can be destroyed by carbolic acid and corrosive sublimate. These organisms are normally present in the nasal passages, vagina, mouth, and urethra.

Streptococcus pyogenes malignus, an uncommon organism found in splenic abscess.

Streptococcus septicus has a strong tendency to break up into diplococci.

2d Group.—*Streptococcus of erysipelas* is found in the capillary lymph-spaces in erysipelas. Many bacteriologists believe it to be identical with the Streptococcus pyogenes. These bacteria tend particularly to gather in the lymph-spaces. They rarely produce pus and when they do it is usually watery. When ordinary thick pus forms there is a mixed infection with staphylococci.

Streptococcus of Septicemia and Pyemia.—Most observers maintain that it is identical with the Streptococcus pyogenes and the streptococcus of erysipelas.

3d Group.—*Streptococcus articulorum*, found in the false membrane of diphtheria (see the article by Woodhead in the "System of Surgery," by Sir Frederick Treves).

Other Pyogenic Organisms.—The various forms of colon bacillus, the typhoid bacillus, the Streptococcus intracellularis, the Micrococcus tetragenus, and the pneumococcus, are at times pyogenic. Pneumococci may produce arthritis (see page 638), peritonitis (see page 1030), cholecystitis, empyema, necrosis of bone, or wound infection. A case of wound infection due to pneumococci was reported by J. H. Beaty ("Northwestern Lancet," July 1, 1907). In many persons pneumococci exist in the mouth. A common form of colon bacillus is the Bacillus pyogenes fetidus: it is found in stinking peritoneal pus and in the pus of ischiorectal abscesses. The gonococcus is also pyogenic.

The Bacillus pyocyaneus may be the sole cause of a suppuration, but usually when it appears it constitutes a secondary infection in a suppurating area. It causes a blue or blue-green hue in pus and wound discharges.

It is normally found in water and exists in the mouth, intestine, and skin.

Other Surgical Microbes.—*Streptococcus of erysipelas* (Fehleisen's coccus), as stated before, is thought by many to be identical with the Streptococcus pyogenes. Their difference in action is believed by Sternberg to be due to difference in virulence induced by external conditions and by the state of the tissues of the host. The coccus of erysipelas is somewhat larger than the ordinary form of Streptococcus pyogenes. Infection takes place by a wound, often a very trivial wound of the skin or mucous membrane. The cocci multiply in the small lymph-channels. This coccus will cause puerperal fever in a woman in childbed when it gains access to any area in the genital tract from which absorption can occur. The streptococcus seldom causes suppuration in erysipelas; when it does so the pus is usually watery. Thick pus means mixed infection.

Fig. 17.—Micrococci gonorrhœæ, highly magnified, schematic (Lehmann and Neumann).

The *gonococcus*, or the *Micrococcus gonorrhœæ* (the bacillus of Neisser) (Fig. 18), is the diplococcus which causes gonorrhea. Neisser, in 1879, observed this bacillus in pus from gonorrheal ophthalmia and urethral gonorrhea. Bumm, in 1887, proved the causative influence of the gonococcus. He reproduced the disease in a healthy female urethra by inoculation with the twentieth genera-

tion in descent from a pure culture. These micrococci are in pairs, and each member of a pair is kidney shaped (Fig. 17). Gonococci grow best in air, but can grow when air is excluded. Diplococci are found often in the secretions of apparently healthy mucous membranes, and simulate very closely gonococci, but genuine gonococci are not so found. The gonococcus is a pure parasite and is not found outside of the organism except upon articles contaminated with gonorrheal discharge. In male gonorrhea the gonococci are in the urethra and prostate; in female gonorrhea they are in the urethra, glands of Bartholin, and cervix uteri. These cocci may cause gonorrheal conjunctivitis, lymphangitis, lymphadenitis, rhinitis, otitis, proctitis, endometritis, salpingitis, oöphoritis, cystitis, peritonitis, bursitis, thecitis, pleuritis, malignant endocarditis, arthritis, periostitis, abscess, and parotitis. In chronic urethral gonorrhea the gonococci may at times be absent from the discharge, returning when there has been sexual or alcoholic excess, traumatism, or contact with an irritant secretion. In such a case there could have been but a very few gonococci in the urethra before the irritation was applied, and the discharge was kept up, in part at least, by irritant toxins. If a part in such a condition is irritated, active multiplication begins and the cocci reappear in the discharge. Gonococci cannot be cultivated upon ordinary media, but grow best upon human blood or human blood-serum. In gonorrhea the organisms are found both within and outside of pus-cells and on mucous cells (Fig. 18). The gonococci infect a surface covered with cylindrical epithelium much more readily than a surface covered with pavement-epithelium. They pass into the submucous tissue, cause inflammation, and spread by way of the lymph-paths. It seems certain that the gonococcus is pyogenic, although mixed infection with other pyogenic organisms may exist in this disease. Their presence inside of pus-cells means phagocytosis. Gonococci stain easily by methylene-blue and are readily decolorized by Gram's method.

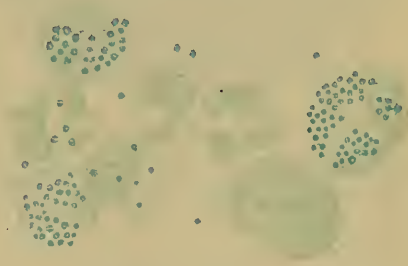

Fig. 18.—Gonococci from gonorrheal pus.

In noma *streptococci* are found. No specific organism has been isolated for traumatic spreading gangrene or hospital gangrene.

The *bacillus of tetanus* or the *Bacillus tetani* (Nicolaier's bacillus) (Fig. 19) was discovered by Nicolaier in 1884. In 1889 Kitasato obtained a pure culture. It is an obligate anaërobic organism. In recent cultures at least it ceases to grow in the presence of free oxygen. It grows *within* the tissues of the animal body. In a wound to which air has access the bacilli may lie so surrounded by fluid that air cannot reach the bacteria. Pyogenic or saprophytic bacteria may consume the air or the bacilli may lie in a laceration of the tissue the outlet of which is sealed by exudate or blood. The bacillus of tetanus is a facultative saprophyte, that is, under certain conditions it can grow in dead organic material. It is possible to develop by cultivation bacilli which will live in air, but such bacilli have lost their virulence.

The bacilli of tetanus are widely distributed. They are found particularly in hay, in the soil of gardens, in the dust of old buildings, in street dust and dirt, and in the sweepings of stables. The feces of healthy horses, cattle, and men may contain the bacilli. Tetanus develops after a wound and the bacilli remain in the wound and do not enter the blood. They furnish deadly toxins which are absorbed. The symptoms are due to intoxication, not to infection. The toxin of tetanus is alkaloidal, not albuminoidal. These bacilli stain by

Gram's method. Cultures are made in agar-agar punctures, the air being excluded, or on gelatin-containing glucose and in an atmosphere of hydrogen. These bacilli when placed under somewhat unfavorable conditions sporulate with great rapidity, and the spores are seen at the ends (Fig. 19). The spores are far more resistant than the adult bacilli, and it is difficult to kill them in a wound. A drug which is very fatal to tetanus bacilli is bromin.

Fig. 19.—Bacillus of tetanus, with spores.

The *Bacillus tuberculosis* (Koch's bacillus) (Fig. 20). This bacillus is the cause of all tuberculous processes. It was discovered and cultivated by Koch in 1882.

It is non-motile and requires oxygen in order to grow, but may obtain this from the body cells or fluids. It stains by Gram's method and by fuchsin. These bacilli are cultivated upon glycerin-agar or solid blood-serum (Plate 1, Fig. 3).

They are found in dust containing the dried sputum of victims of phthisis and dried discharges and secretions of tuberculous patients. This infected dusty air is influential in conveying infection (inhalation tuberculosis). Infection can also be conveyed by inoculation of bacilli (inoculation tuberculosis) and by eating the meat and drinking the milk of tuberculous animals (ingestion tuberculosis). Tuberculin is discussed on page 220.

Koch maintains that the human type of bacilli is almost altogether responsible for tuberculosis in human beings. Behring and many other observers dispute this statement, and assert that bovine bacilli are frequently responsible for tuberculosis in human beings. It seems certain that in children many cases of glandular tuberculosis and abdominal tuberculosis are due to bovine bacilli. The bacilli of cattle are not so long or thick and are straighter than human bacilli. It is not yet quite certain that the bovine bacilli are identical with human bacilli. They are at least very close blood relations.

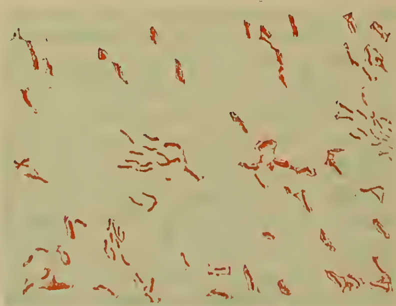

Fig. 20.—Tubercle bacilli in sputum (Ziegler).

Bacillus anthracis, or the *bacillus of anthrax* (Fig. 21), is the cause of malignant pustule, anthrax, or splenic fever. This bacillus was first observed by Pollender in 1849, and its causal influence was first strongly asserted by Davaine in 1863. Davaine's contention was proved by Koch in 1876. It is non-motile. Tissue containing it is stained by Gram's method. Cover-glass preparations are stained by a watery solution of an analine dye. It will grow without oxygen, but grows best in air. In the presence of air sporulation occurs, but it does not occur in the infected animal. It grows upon or in gelatin or agar. Only outside of the diseased body are spores found, and they exist in the hides and hair of infected animals and in stalls and pastures in which diseased animals were kept.

Bacillus mallei, or the *bacillus of glanders*, is the cause of glanders. It was

discovered by Löffler and Schütz in 1882. It is non-motile and grows best in air, growing with great difficulty when air is excluded. It grows well upon glycerin-agar and does not stain by Gram's method. It is never found except in the body of a diseased man or other animal. It is best cultivated in solid blood-serum. Under certain circumstances some few of the bacilli contain spores.

The *pneumococcus*, called also the *Diplococcus pneumoniæ*, *Fränkel's bacillus*, and the *Streptococcus lanceolatus*, was discovered by Sternberg in 1880. It is often found in the saliva of healthy individuals. It is not found outside of the

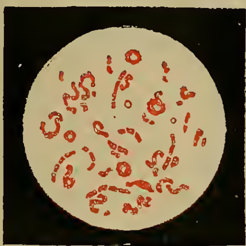

Fig. 21.—Bacillus anthracis (× 1000) (Lehmann and Neumann).

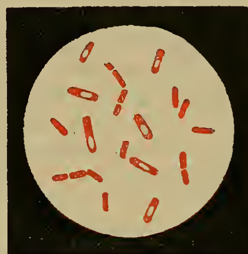

Fig. 22.—Bacillus of malignant edema (Lehmann and Neumann).

body. It varies greatly in virulence, but when virulent can establish inflammation and even suppuration, particularly of mucous and serous surfaces. It is especially apt to lodge and multiply in the lung, but it may lodge in a joint, in the brain membranes, in the peritoneum, or in other parts. It may cause croupous pneumonia, catarrhal pneumonia, pleuritis, meningitis, conjunctivitis, arthritis, peritonitis, periostitis, osteomyelitis, parotitis, salpingitis, empyema, cholecystitis, perinephric and other abscesses, nephritis, tonsillitis, mastoiditis, and septicemia. In any of these conditions it may appear in the blood. Pneumococci in the blood constitute pneumococcemia. In fact, it may appear in the blood when the lungs have not been diseased. Pneumococcic arthritis, peritonitis, cholecystitis, or empyema may arise without coexisting or antecedent pneumonia. The pneumococcus grows best in bouillon cultures, in blood-serum and in glycerin-agar. Sir Thomas Oliver ("Brit. Med. Jour.," April 30, 1910) points out the interesting fact that in pneumococcic meningitis, although symptoms are largely cerebral, the patient looks like one suffering from pneumonia.

Fig. 23.—Bacillus coli communis.

The *Bacillus coli communis*, called also the *Bacterium coli commune*, the *colon bacillus*, or the *bacillus of Escherich* (Fig. 23), was discovered in feces by Emmerich in 1885. Under ordinary conditions this is a putrefactive bacillus inhabiting the intestinal canal and feces invariably contain it. It is found in the mouth, nose, and vagina, on the skin, and under the nails. The bacillus is normally found in water, even in water regarded by the users as pure. It has already been stated that this ordinarily harmless micro-organism may, under certain conditions, acquire pathogenic power and enter the circulation. This bacterium grows best in air, but it can also grow when air is excluded. It is not

stained by Gram's method and has pyogenic power. It stains with anilin dyes and is decolorized by iodin solution. There are numerous forms of colon bacilli, and some of them are motile, some are amotile. This bacillus may be responsible for appendicitis, peritonitis, inflammation of the genito-urinary tract, pneumonia, inflammation of the intestine, leptomeningitis, perineal abscess, cholangitis, cholecystitis, myelitis, puerperal fever, wound infection, and septicemia. It is the cause of many abscesses about the intestine, and is responsible for many ischiorectal abscesses. From the pus of an appendiceal abscess we may perhaps obtain a pure culture of Escherich's bacillus, but usually find also streptococci or staphylococci, and sometimes pneumococci. Colon bacilli introduced into the system by tainted food may be responsible for epidemic pneumonia. A few years ago there was such an epidemic in Middlesbrough, England (Oliver, in "Brit. Med. Jour.," April 30, 1910).

Lehmann and Neumann point out that there are occasionally encountered "gaseous phlegmons and similar diseases of internal organs, in which are found the bacterium coli alone or usually in combination with other varieties, but without any anaërobes being present" ("Atlas and Principles of Bacteriology," vol. ii, edited by Geo. H. Weaver).

The *Bacillus œdematis maligni*, the *bacillus of malignant edema*, or the *vibrione septique* of Pasteur (Fig. 22), was discovered by Pasteur in 1875. This bacillus is found especially in stagnant water and certain varieties of soil and exists in putrefying material. It is sometimes motile, but is often amotile, and multiplies by spore formation. It is anaërobic and in its growth produces bubbles of gas. In the disease known as malignant edema there is usually a mixed infection with the bacilli of malignant edema and saprophytic organisms, and the latter also form considerable quantities of gas in the tissues. The bacilli of malignant edema may cause either spreading bloody edema containing gas-bubbles or spreading emphysematous gangrene. The bacilli enter the blood and produce septicemia. The bacillus is grown in the interior of a stab in gelatin agar-agar or solid blood-serum when the mouth of the stab has been sealed up.

The *Bacillus aërogenes capsulatus* of Welch was described by Welch and Nuttal in 1892. This bacillus is found sometimes in abscesses containing gas. It is causative of some cases of gangrenous cellulitis, which is a spreading gangrene with gas formation.

It has a capsule and very seldom forms spores. It stains by Gram's method and grows well upon blood-serum.

The *Bacterium typhi*, the *typhoid bacillus*, or *Eberth's bacillus*, was discovered by Eberth in 1880. It is sometimes found in water or soil contaminated by typhoid fecal matter. It never exists in the healthy human body (except in typhoid carriers). It causes typhoid fever and in this disease can be obtained and cultivated, particularly from the spleen and lymphatic glands and frequently from the blood. It has been found in the urine, kidney, bone-marrow, and bile. It is difficult to cultivate typhoid bacilli from feces because of the presence of multitudes of other bacteria. The bacillus of typhoid is motile, does not stain by Gram's method, and grows best in air, but can grow when air is excluded. It grows upon all the ordinary nutrient media. This bacillus is particularly apt to be confounded with the colon bacillus, and it is even possible that the former develops from the latter. Besides typhoid fever the typhoid bacillus may cause peritonitis, chronic osteomyelitis, epididymitis, orchitis, gangrene, cholecystitis, thrombosis, embolism, synovitis, arthritis, and pulmonary inflammation. If pneumonia is caused by the typhoid bacillus, there are the ordinary physical signs of pneumonia and there are no abdominal symptoms, but the appearance of the patient and the duration of the disease are suggestive of typhoid fever. It is interesting to note that relapse may occur (Oliver, in

"Brit. Med. Jour.," April 30, 1910). This bacillus, under certain conditions, is pyogenic. Typhoid bacilli are agglutinated and lose motion by contact with a 1 to 50 dilution of the blood-serum of a patient with tyhpoid fever or convalescent from typhoid fever (the *Widal reaction*).

Putrefactive Bacteria.—By putrefaction we mean the decomposition of albuminous matter with the production of materials possessed of a foul odor. The bacilli of putrefaction act upon dead tissue exposed to air and are most active when the supply of air is somewhat limited. The surgeon encounters these bacteria in areas of necrosis or in tissues previously destroyed by other microbes. In the latter case they cause a mixed infection. An instance of such a mixed infection is putrid pus. Some of the products of putrefactive bacteria are highly poisonous (ptomains). Absorption of a small amount of putrid toxin causes surgical fever and absorption of a large amount causes putrid intoxication.

The chief putrefactive bacteria are: The colon bacillus (when under normal conditions); the bacillus of malignant edema; the Proteus vulgaris; the Proteus mirabilis; the three forms of the Bacillus saprogenes; and the Proteus zenkeri.

We may mention, in conclusion, as of occasional surgical importance the bacillus of influenza, bacillus of diphtheria, bacillus of bubonic plague, bacillus of leprosy, bacillus of rhinoscleroma, bacillus of fetid ozena, bacillus of hemorrhagic septicemia, and the Bacillus lactis aërogenes, which is an unusual cause of peritonitis.

The *ray-fungus* is considered on page 309.

Infections by Protozoa.—Protozoa is the name given to the lowest forms of animal life. This group of organisms shows transitions from forms certainly animal toward forms certainly vegetable. The protozoa are minute unicellular organisms. The cell has a definite nucleus and is composed of protoplasm and a more or less dense cell wall. Many species have organs of locomotion (cilia or flagella). Most parasitic protozoa are sporozoa. The sporozoa multiply by spore formation, feed by osmosis, and, when freely formed, possess neither cilia nor flagella. Pébrine or silkworm disease is due to protozoa, so is trypanosomiasis. Protozoa are known to cause malaria (the plasmodium malariæ), tropical dysentery (the Entameba histolytica), and syphilis. Some observers maintain that they cause cancer, others assert that they are responsible for hydrophobia; and it is thought probable that they may produce measles, small-pox, yellow fever, scarlatina, and spotted fever.

The Spirochæta Pallida (the *Treponema Pallidum*).—A bacterial cause of syphilis has long been sought. Lustgarten thought he had found it in a bacillus resembling the tubercle bacillus, but this view has been disproved. Schaudinn and Hoffmann have described an organism constantly present in the initial lesion of syphilis and in secondary lesions and which they call the Spirochæta pallida ("Arbeiten aus dem Kaiserlichen gesundheitsamte," Berlin, April 10, Heft 2). The studies of Schaudinn and Hoffmann were confirmed by Metchnikoff ("Bull. Acad. de med. de Paris," May 16, 1905). These organisms are found in great numbers in the juice of syphilitic glands, in condylomata, and in chancres. They are motile, are without flagella, curve from three to twelve times, are stained with difficulty, and are transported by the lymph and blood (Blaschko, in "Berlin klin. Woch.," No. 11, 1907). The organism is thought by many to be a protozoön. The fact that the cell divides longitudinally and not transversely suggests that it is not a bacterium (Noguchi). Many observers place the organism with bacteria. The matter is still in doubt. The spirochetes were originally discovered by Bordet and Gengou in 1903. These observers found them in chancres, but thought their presence was inconstant. Schaudinn and Hoffmann show that it is constant. Very positive claims are now made as to the causal influence of the pale spirochete, and it seems prac-

tically certain that syphilis is a chronic spirillosis. The micro-organism is present in primary syphilis and all early secondary lesions and in congenital syphilis. It is not found in gummata. Noguchi obtained pure cultures of the spirochete, and inoculation of monkeys with these cultures caused the development of sores resembling chancres.

II. ASEPSIS AND ANTISEPSIS

The effort in all operations is to secure and maintain scrupulous surgical cleanliness. What is known as the antiseptic method we owe to the splendid labors of Lord Lister, and the aseptic method is but a natural evolution of the antiseptic method. It is true that Agostino Bassi, over half a century ago, convinced that various maladies were due to parasites, treated wounds with a solution of corrosive sublimate. It is true that Oliver Wendell Holmes in 1843 insisted on the contagiousness of puerperal fever. It is also true that Semmelweiss in 1847 demonstrated the infectiousness of puerperal fever and the method of preventing it; that Jules Lemaire in 1863 published a treatise on carbolic acid and advocated the use of this drug in the treatment of wounds in order to destroy living germs; and that Bottini in 1866 employed carbolic acid in the treatment of putrid and suppurating wounds because he believed germs to be responsible for such conditions (Monti, on "Modern Pathology"). In spite of the above facts, Lister is the real father of asepsis and taught all nations how to prevent infection. Monti says: "But Lister, with that practical spirit which forms one of the best characteristics of English genius, from the scientific studies of Pasteur deduced the general laws of antisepsis and the rules for their methodical application to practical surgery." Lister called the attention of the profession to a new method of treating wounds, compound fractures, and abscesses in 1867.[1] The processes first employed were extremely complicated, but have been made in the last few years simple and easy of performance. Lister believed the chief danger to be from air. It is now believed that the chief danger is from actual contact of hands, instruments, dressings, or foreign bodies with a wound. Air carries but few micro-organisms unless it is filled with dust. Infection through air is most apt to occur if the air is dusty, and is more common after an aseptic than an antiseptic operation.

Of course, some bacteria from the air must settle in every wound, but the majority of the air fungi are harmless. Comparatively few reach the wound unless the air is dusty, and these few the tissues are usually able to destroy. Schimmelbusch made experiments in v. Bergmann's clinic when the students were present. He found that "the number of bacteria which settle upon the surface of a wound a square decimeter in extent, in the course of half an hour, is about 60 or 70," and thousands are usually required to produce infection.

There is no danger of infection being produced by the breath of spectators. Air which comes from the lungs is germ free, and even a large class will not infect the air by breathing, but will rather help to free it from bacteria, for the lungs are filters for air laden with micro-organisms. If a surgeon talks while he is operating, he may spray droplets of saliva into the wound *and thus produce infection.* In order to obviate this danger some surgeons wear masks of gauze before the nose and mouth. A conversational assistant is a danger, and a surgeon should direct his remarks away from the wound and not toward it. The surgeon and his assistant should wear caps to keep hair from falling in the wound. The clean shaven face is not a peril to the patient, the face "bearded like the pard" may be. A bearded man should wear a mask.

[1] "Lancet," March 16, 1867; "Brit. Med. Jour.," August 9, 1867.

The more simple the operative technic, the better and the more certain is it to be carefully carried out. Desault said, "The simplicity of an operation is the measure of its perfection." This is as true to-day as when the great French surgeon said it. The fewer assistants that are used the better, and no hands but the surgeons should enter the wound unless others are absolutely required.

In performing any surgical operation cutting is better than tearing by blunt dissection. The former method makes an incised wound, the latter a lacerated wound. In an incised wound there is a minimum amount of damage and there will be rapid repair. In a lacerated wound some necrosis occurs and there is great lowering of tissue resistance, hence a lacerated wound is much more apt to become infected than an incised wound.

Surgical cleanliness may be obtained by either the *aseptic* or the *antiseptic* method. In the *aseptic method*, heat, chemical germicides, or both are used to cleanse the instruments, the field of operation, and the hands of the surgeon and his assistants, the surface being freed from the chemical germicide by washing with boiled water or with saline solution. After the incision has been made no chemical germicide is used, the wound being simply sponged with gauze sterilized by heat; if irrigation is necessary, boiled water or normal salt solution (at 110° F.) is used, and the wound is dressed with gauze which has been rendered sterile by heat. The effort of the surgeon is simply to prevent the entrance of micro-organisms into the tissues. Some micro-organisms must enter, but the number will be so small that they will be destroyed by healthy tissues. The aseptic method should be used only in non-infected areas. If chemical germicides are not used in the wound, there will be a minimum amount of irritation, few cells will be destroyed, the amount of wound-fluid will be small, the surgeon can often dispense with drainage, and repair will be rapid. If a wound is to be closed without drainage, every point of bleeding must be ligated. Many wounds are closed by interrupted through-and-through sutures of silkworm-gut. Some wounds are closed in layers by catgut sutures. If a wound is closed in layers, muscle being against muscle, fascia against fascia, etc., the skin may be closed by interrupted sutures or by Halsted's subcuticular stitch (Fig. 116). If this stitch is employed, the skin staphylococcus does not obtain access to stitch-holes, and stitch-abscesses are not apt to arise. This suture may consist of catgut, silk, or, preferably, silver wire, this latter agent being capable of certain sterilization by heat and exercising a definite inhibitory action on micro-organisms. If a wound is closed without drainage, firm compression is applied over the wound to obliterate any cavity which may exist. Such a cavity is called a *dead space.* If a dead space is allowed to remain wound-fluid will gather, tissue resistance will be lowered, and the wound-fluid, the tissue, or both may become infected. Drainage must be used if the wound is very large, if its shape or structure prevents the obliteration of the cavity by pressure, if there is any doubt as to the perfect cleanliness of the part, if the patient is very fat (for in such individuals fat necrosis predisposes to sepsis and to fat embolism), or if the skin is so thin that we fear pressure will produce sloughing ("A Manual of Surgical Treatment," by Cheyne and Burghard). In some regions of the body wounds are sealed with collodion or iodoform-collodion. If irrigation is not practised and the wound is dressed with dry sterile gauze, the procedure is said to be by the "*dry*" *aseptic method.* In the *antiseptic method* the same preparations are made for the operation as in the aseptic method, but during the operation gauze sponges impregnated with a chemical germicide are used, and the wound is dressed with gauze containing corrosive sublimate or some other chemical germicide. If the wound is not flushed with a chemical germicide, and is dressed with dry antiseptic gauze, the operation is said to be by the "*dry*" *antiseptic method.* The anti-

septic method is preferred in infected areas. Dry dressings are usually preferable to moist dressings in treating aseptic wounds, because they are more absorbent and do not act as poultices, and dry dressings may be used, even when the wound has been flushed. Some surgeons question the value of antiseptic irrigation in a septic wound, but I believe it removes many bacteria and much poisonous matter and also antidotes toxic material. In suppurating areas it is often best to use moist dressings in the form of antiseptic fomentations. Year by year the aseptic method becomes more popular. Surgeons have learned that the most important factor in asepsis is mechanical cleansing by means of soap and water. The chemical germicide plays a secondary rather than a vital part. By mechanical cleansing of the skin great numbers of micro-organisms are removed along with dirt, grease, and epithelium. Many bacteria remain, but vast hordes are washed away, and the danger of infection is greatly lessened by thus diminishing the number of bacteria. If a chemical germicide is used without preliminary mechanical cleansing it is useless, because it cannot destroy bacteria in the epithelium and in masses of oily matter. After mechanical cleansing the germicide is active in destroying the comparatively few bacteria which are naked on the surface. In many regions a strong chemical germicide must not be used (in the abdomen, in the brain, in joints, in the pleural sac, and in the bladder), and in other regions (mucous surfaces and fatty tissue) it is productive of harm rather than good.

Preparation for an Operation.—If the operation is to be performed in a hospital there is, of course, an operating room always ready. If it is to be done in a private house, much careful preparation is desirable. The operating room should be warm, but not too warm. The desirable temperature is 78° to 80° F. Over 80° F. is too warm, it causes vascular relaxation in the patient, and makes the surgeon perspire and wear out. The patient is kept warm by certain special methods. He may be placed on a table heated by hot water or electricity or he may be surrounded by hot-water bags. Any large raw surface is kept covered as far as possible with pads of gauze wrung out of hot salt solution and frequently changed. Protruding intestines are treated in the same way. Every effort is made to avoid soaking the patient's skin with fluids, because as they cool they will chill him. A room in which an operation is to be performed should be well lighted and well ventilated. The northern light is the best. It is advantageous to have an open grate in the room, for then a wood fire can be quickly made to take a chill off the air and ventilation is improved. The morning before the operation the furniture should be removed, the carpet taken up, and the curtains and hangings taken down. If the ceiling and walls are papered, they must be thoroughly brushed. If they are painted, they must be washed with soap and water. Dust is thus removed and the danger of dust falling into the wound is averted. The floor is scrubbed with soap and water. The windows should be opened for many hours to thoroughly dry and freshen the room. On the morning of the operation the windows are closed and newspapers are tacked up so as to cover the lower half of each window. Plenty of light is admitted and the curiosity of neighbors across the street cannot be satisfied. The patient's bed is brought into the room and placed in a position where there will be plenty of light for future dressings, and where the surgeon will have access from either side. In order that there may be access from each side the bed must not be in a corner or against the wall. Never use a big broad bed; use a narrow bed. Never have a feather bed, but insist on Treves's advice being followed, and employ a metal bed with a wire netting and hair mattress.

A piece of carpet or rug is spread upon a portion of the floor and the table is set upon it. The table should be so placed that there will be a good light on the field of operation. There are several tables which are very satisfac-

tory. The best for a private house operation is Lilienthal's (Figs. 24 and 25). This table can be folded into a small compass, can be carried in a case with a handle, and is comparatively light and easily transportable. It can be

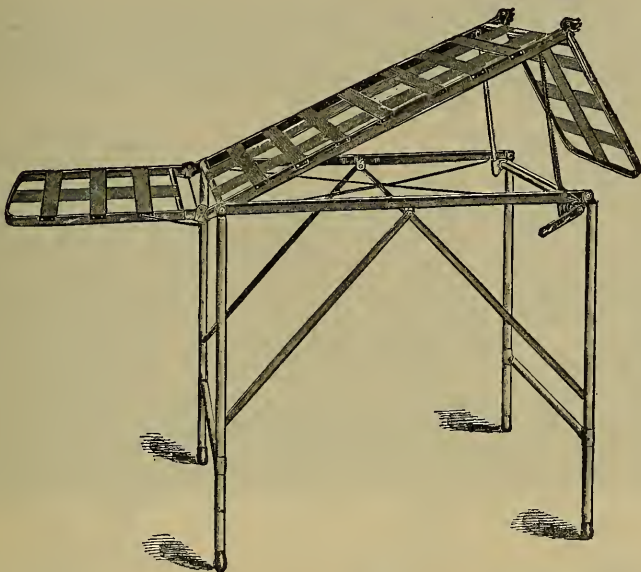

Fig. 24.—Lilienthal's portable operating table.

rapidly set up, is firm, and it enables the surgeon to obtain the Trendelenburg position at any moment. A kitchen table does very well. If a kitchen table is used and the abdomen is to be opened a frame should be at hand which,

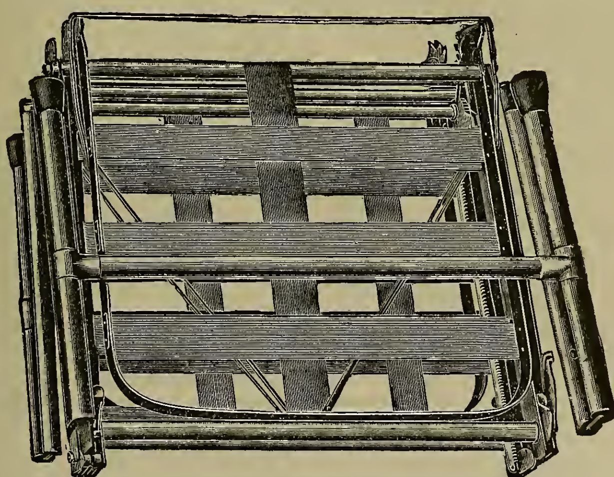

Fig. 25.—Lilienthal's portable operating table, folded.

when slipped under the patient, enables the surgeon to obtain the Trendelenburg position. Dr. Joseph Price was accustomed to use two trestles and a board like an ironing board. In hospital work I use Boldt's table (Figs. 26

and 27). On the table or board is placed a folded comfortable or several folded blankets. A rolled blanket is placed under the hollow of the back to

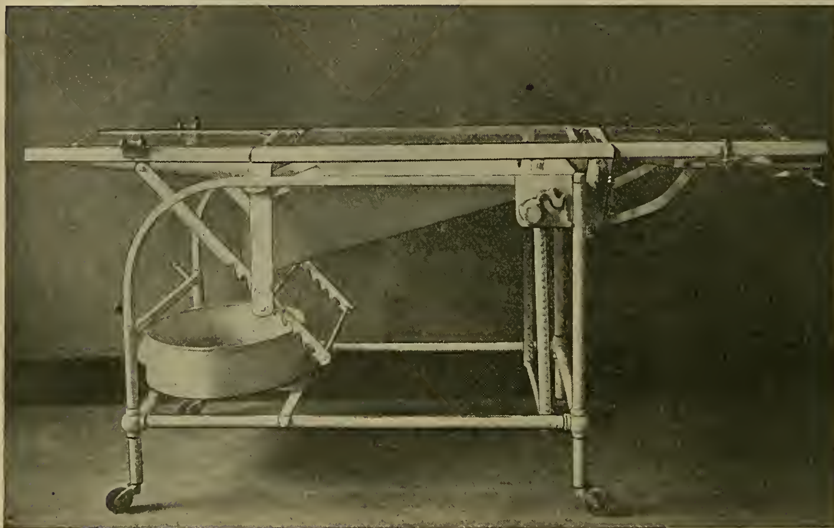

Fig. 26.—Boldt's operating table.

prevent strain of the sacro-iliac joints and postoperative backache. Kelly's pad to catch fluids is laid upon the blankets and is so placed that fluid used in

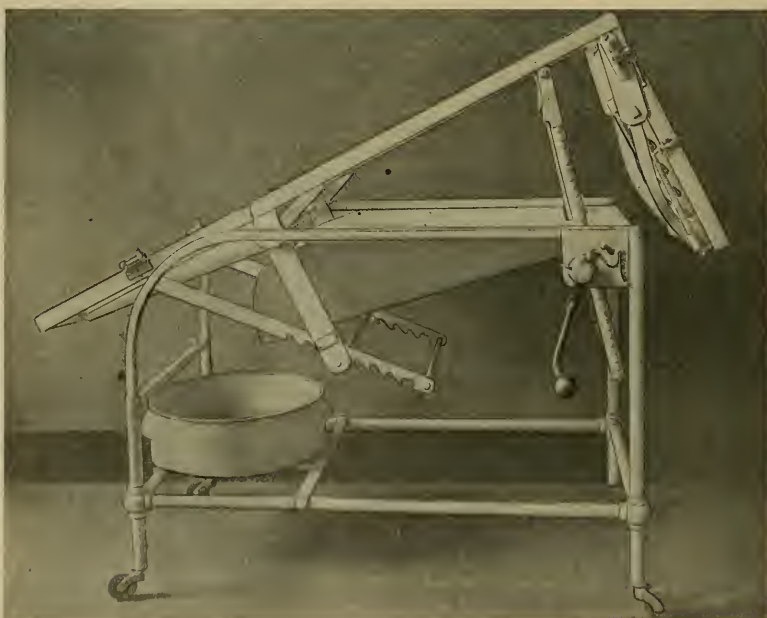

Fig. 27.—Boldt's operating table.

irrigation will flow into it and will be conducted by it to a suitable receptacle.

Around the operating table at proper distances are arranged a table for instruments, ligatures and sutures, a table for dressings, a table for pads, packs, gauze sponges, and a basin of bichlorid, and a table for soap and a basin of water. Ordinary wooden tables may be used if they are covered with towels wet in corrosive sublimate solution. In a hospital special tables are used. They are of iron with glass tops. Ordinary basins may be used, but enameled or glass basins in stands (Figs. 28 and 29) are the most satisfactory. A couple of buckets should be placed on the floor near at hand. Enameled buckets are the best ones to use. The nurses and assistants should have ready the ether cone, wrapped in a clean towel, sterile sheets, sterile gowns, sterile towels, sterile gauze for sponges and dressings, trays

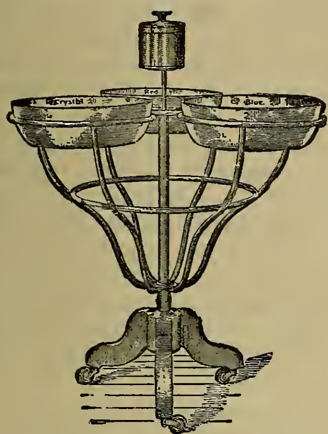

Fig. 28.—Revolving wash-stand.

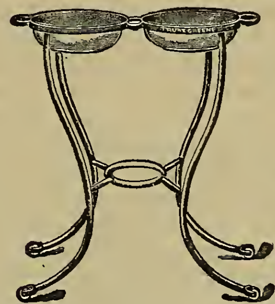

Fig. 29.—Plain double wash-stand.

for instruments (Figs. 30 and 31), iodoform gauze, catgut, silk, silkworm-gut, hot normal salt solution, etc., according to the nature of the operation. The surgeon should pick out the instruments required. The anesthetist should lay out a mouth-gag, tongue-forceps, hypodermatic syringe *in working order*, ether or chloroform, brandy, tablets of strychnin and also of atropin, and a cylinder of oxygen.

Most surgeons have the operation field sterilized the day before the operation, except in an emergency case. For several years I have been doing it in

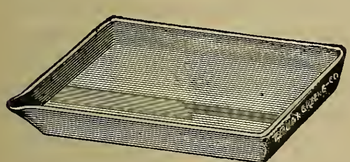

Fig. 30.—Porcelain surgical tray.

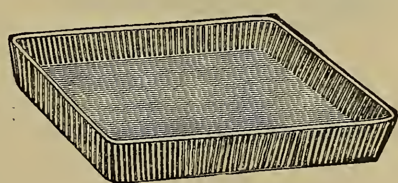

Fig. 31.—Glass surgical tray.

most cases after the patient has been anesthetized, and find this plan more comfortable for the patient, less troublesome, and equally effective.

When the time for the operation arrives, the surgeon and his assistants remove their clothing and put on duck trousers and thin, short-sleeved shirts of white muslin. After sterilizing the hands and forearms they envelop themselves in aseptic or antiseptic sheets or gowns, to protect the patient and themselves. The gowns should have sleeves long enough to cover the forearms and wrists. Sterile muslin caps should always be worn. The caps prevent hair, dandruff, and sweat from falling into the wound. Many operators wear over the mouth and nose a respirator or piece of gauze in order to prevent saliva or mucus being projected into the wound while the surgeon talks.

Danger from the Hands.—It is a difficult or impossible matter to absolutely sterilize the hands, but it is fortunate, as Mikulicz and Flügge say, that most of the bacteria of the skin are harmless. The Staphylococcus epidermidis albus, however, is constantly present in the epidermis. The hands of some persons are more easily sterilized than those of others. For instance, a hairy, creased hand is more difficult to sterilize than a smooth and almost hairless one; a hand grossly neglected, than one reasonably clean. Germs abound in the epidermis, in the fissures and creases, under and around the nails, on hairs, and in ducts of glands. The surface of the hands may be thoroughly sterile at the beginning of an operation and become infected later, because germs in gland ducts are forced to the surface. Hence, in a prolonged operation the surgeon, if he does not wear gloves, should from time to time stop operating and wash his hands, first in alcohol and then in corrosive sublimate solution (Leonard Freeman).

In view of the difficulty of cleansing the hands, every student must be taught how to do it, and he must become impressed with the fact that the surgical hand is to be regarded as reaching to the elbow. The more the fingers enter a wound, the greater is the danger of infection of the wound. The surgeon uses retractors and forceps whenever possible, but in most cases his fingers must at times enter the wound. The fingers of no other person should enter unless absolutely necessary. The basis of all plans of sterilization and the most important part of any plan is mechanical cleansing by scrubbing with soap and water. By this means a quantity of loose epidermis is removed and with it great numbers of bacteria.

Mechanical Cleansing of the Hands and Forearms.—The hands and forearms may be sterilized in several ways. Any method is preceded by mechanical cleansing, which is carried out as follows: Scrub for five minutes with soap and hot running water, giving special attention to the nails and creases in the skin. The water should be as hot as can be borne with comfort, as hot water stimulates the sweat glands and the flow of sweat washes out the ducts. If the ducts are washed out before the operation by copious sweating, during the operation the secretion will be slight. The brush is rubbed both in the long axis of the extremity and transversely. The creases on the back of the hands and fingers will be partially opened by flexing the fingers, and transverse scrubbing will clean the furrows. The furrows on the palmar surface will be opened by extending the fingers, and will be best cleaned by transverse scrubbing (George Ben Johnston). An excellent soap is ethereal soap, which is a solution of castile soap in ether. Castile soap can be used. I am accustomed to use green soap. Some surgeons prefer to use green soap in the form of a tincture. Synol soap has advocates. There is no particular advantage in using soap containing a germicide, as such soap is practically without germicidal power. The brush employed should be kept in a 1 : 1000 solution of corrosive sublimate or should have been recently sterilized with steam and kept in a sterile glass box (Fig. 32). The nails are cut short, are cleansed with an orange-wood stick, which does not scratch them, and the hands are again scrubbed. Very prolonged or very rough scrubbing, especially with harsh agents like marble dust or sand, is actually harmful, as it tends to crack the hands and make them rough and it extensively loosens epidermis which may drop into the wound. Epidermis may contain bacteria within it and may infect the wound.

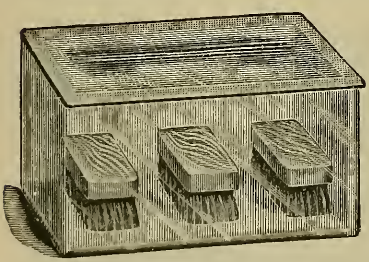

Fig. 32.—Glass brush-box with cover.

Sterilization of the Hands and Forearms.—After mechanical cleansing a germicide is employed to render the parts sterile. Whatever method is adopted it is desirable that it shall not unduly irritate the skin. An occasional operator may use without injury tolerably strong chemicals, but the busy hospital surgeon, who operates perhaps several times or many times a day, cannot use them. Any method which inflames, cracks, or roughens the skin makes future sterilization difficult or impossible, hence such a method is undesirable. Four methods are described here:

Fürbringer's Method.—After washing off the soap in sterile water the hands are dipped in 95 per cent. alcohol and held there for two or three minutes while the forearms, hands, fingers, and nails are being rubbed with alcohol. Alcohol removes the soap which has entered into follicles and creases, removes desquamated epithelium, enters under and about the nails, is germicidal, and favors the diffusion of the corrosive sublimate under the nails and into the follicles, when the hands are placed later in the mercurial solution. Alcohol also hardens epithelium and keeps it from desquamating into the wound. After using the alcohol the hands are then dipped in a hot solution of corrosive sublimate (1 : 1000), and with the forearms are scrubbed for at least a minute, the nails receiving especial care.

The Welch-Kelly Method.—After the hands and forearms have been cleansed mechanically and have been rinsed in sterile water they are immersed for two minutes in a warm solution of permanganate of potassium (a saturated solution in distilled water). This solution causes the cutaneous surface to assume a very dark brown color. The hands and forearms are then immersed in a warm saturated solution of oxalic acid and are held there until decolorized. They are then well washed in sterile water, are next immersed for two minutes in a 1: 500 solution of corrosive sublimate, and finally are rinsed in sterile water and dried on a sterile towel. The solutions for use in the above method should be contained in jars of the shape of a druggist's percolator, so that both the hands and forearms can be immersed at the same time. In this method the permanganate of potash is merely an oxidizer and the oxalic acid is the active germicide. Some persons find that the skin tolerates the plan very well, others, among whom is the author, find the oxalic acid decidedly irritant when used several times in a day.

The Weir-Stimson Method.—This method was suggested by Mr. Rauschenberg, the pharmacist of the New York Hospital, and it was applied practically by Doctors Weir and Stimson. The process is as follows: The hands should be cleansed mechanically as previously directed. Place about a tablespoonful of chlorinated lime in the palm of the hand, place upon the lime a piece of crystalline carbonate of soda (washing soda) 1 inch square and ½ inch thick, add a little water, and rub the creamy mixture over the arms and hands until the rough granules of sodium carbonate are no longer felt. This requires from three to five minutes. At first there is a sensation of heat usually followed by a sensation of coolness. Place the paste under and around the nails by means of a bit of sterile orange wood. Wash the arms and hands in hot sterile water.[1] Remove the odor of chlorin by washing the hands and arms in sterile ammonia water of a strength of from ½ to 1 per cent. (McBurney, Collins, and Oastler, in "International Text-Book of Surgery"). The combination of carbonate of sodium and chlorinated lime is said to set free nascent chlorin, a most efficient germicide. I used this method for several years in the clinic of the Jefferson Medical College Hospital and found it efficient. When employed several times a day it may prove decidedly irritant. It is important that crystalline washing-soda be employed. If the bicarbonate is used, nascent chlorin will not be produced, but hydrochloric acid gas will

[1] "Medical Record," April 3, 1897.

be formed, and the latter gas irritates the skin and is not a satisfactory germicide.

The Sublimate-alcohol Method.—This is the method I personally prefer. It is rapid, efficient, and reasonably non-irritant. It is as follows: Cleanse the hands with soap and water as previously directed. Use 95 per cent. alcohol as in Fürbringer's method (see p. 63). Dip the hands in 70 per cent. alcohol containing 1 part to 1000 of corrosive sublimate, and rub the hands, forearms, and nails with a piece of sterile gauze wet with this fluid for three minutes. Rinse these parts in the fluid and then rinse in sterile water.

The Use of Gloves.—Most surgeons are so impressed with the impossibility of sterilizing the hands that they wear gloves in operations. Over sixty years ago, at King's College, Sir Thomas Watson in a lecture on puerperal fever suggested that obstetricians wear gloves. He said: "In these days of ready invention a glove, I think, might be devised which should be impervious to fluids, and yet so thin and pliant as not to interfere materially with the delicate sense of touch required in these manipulations. One such glove, if such shall ever be fabricated and adopted, might well be sacrificed to the safety of the mother in every labor" ("Watson's Lectures on Physic").

Fig. 33.—Showing rubber glove applied.

Professor Halsted was a pioneer. He began to use rubber gloves in 1889. Some surgeons used cotton and others silk gloves, but it has been proved that cotton and silk are not impervious to micro-organisms, and that rubber is. The thin, seamless rubber gloves which are now made are very satisfactory. They are sterilized by boiling, are then dried, and are wrapped in a sterile towel. In order to insert the hand in them the hand should be dried, the interior of the glove should be dusted with sterile starch or talc powder, and then the nurse should fold forward the wrist part and hold the glove open while the surgeon inserts his fingers into the proper compartments and pushes the hand in. The custom of filling the glove with sterile fluid and then inserting the hand is troublesome and objectionable, because the fingers soon become sodden like those of a washwoman, the sense of touch is impaired, considerable discomfort is occasioned, and the skin is apt to crack.

If, during an operation, a glove becomes infected, a clean one can be substituted for it. Gloves somewhat impair the sense of touch, but a surgeon soon learns to work with them. If they are to be used, the hands should be sterilized just as carefully as when they are not to be used, because, during the operation, the gloves may tear or be punctured by a needle. I always wear gloves, but that it is absolutely necessary to wear gloves in all cases has not been

proved. Their use does contribute to success in brain operations, abdominal operations, and joint operations. They are of great value in military surgery, for the military surgeon may not have time to prepare his hands, and sterile gloves can be always kept ready prepared.

When a surgeon is obliged to place his fingers in an area of virulent infection he may be poisoned. Gloves will save him from this danger. Again, a surgeon should try to avoid bringing his hands unnecessarily in contact with putrid or purulent matter. Though it may not poison him, it grossly infects the surface, renders subsequent cleansing difficult, and endangers other patients. Gloves will prevent this danger. A surgeon should wear gloves if he is making an examination or performing an operation which is sure to infect the bare hands, and he should wear gloves in an operation if in a previous operation his hands were infected. A surgeon whose hands are very hairy or sweat much will contribute to the patient's safety by wearing gloves.

Fig. 34.—Half-long rubber glove.

Gloves should be worn if the surgeon has a wound or sore upon his hand or chapped hands. When using gloves in a prolonged operation dip the covered hands now and then in corrosive sublimate solution, because the glove may have been punctured or dust may have settled upon it from the air.

Gloves make the hands sweat, and if one should be punctured considerable sweat may emerge from the puncture and enter the wound, and sweat contains bacteria. The entry of any considerable amount of sweat is more dangerous to the patient than are well cleaned naked hands, hence gloves may actually favor the infection they are meant to prevent. When they are used the surgeon must take scrupulous care not to puncture them with a needle, clip them with forceps, or tear them with a ligature or suture.

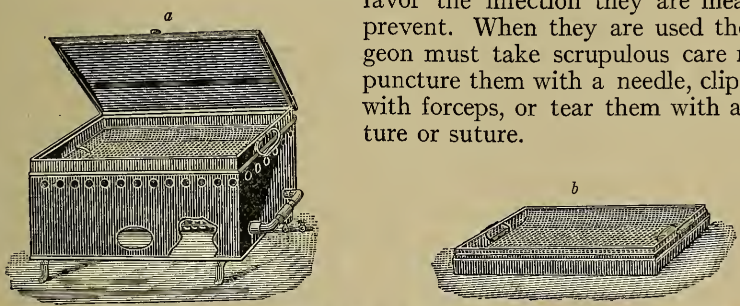

Fig. 35.—*a*, Schimmelbusch's gas-heated apparatus for sterilizing instruments; *b*, wire basket.

The closer they fit the less the danger of puncture, and one should know accurately what size he requires to fit closely and smoothly without being so tight as to make the fingers numb.

Preparation of Gloves.—Wash with soap and water containing a little ammonia, rinse in sterile water, boil for thirty minutes in a 1 per cent. solution of carbonate of soda. Dry the glove and wrap in a dry sterile towel and keep until it is needed. A glove should stand about twenty boilings. The surgeon should carry a number of pairs of prepared gloves in his bag, for the use of himself and assistants in private house operations.

Metal instruments are disinfected by subjecting them to the action of steam in a special sterilizer or, better, by boiling them for fifteen minutes in a 1 per cent. solution of carbonate of sodium. They are wrapped into a bundle by means of a towel or piece of gauze and are dropped into the solution. The blades of knives should first be wrapped in cotton to prevent scratching and dulling. After boiling, the instruments should be rinsed in hot sterile water or in a 5 per cent. solution of carbolic acid and be kept until needed in pans

of sterile water. The carbonate of sodium prevents rusting. In a clinic the boiling is carried out in a Schimmelbusch sterilizer (Fig. 35). In a private house it can be done in a sterilizer such as that shown in Fig. 36, or in a pan, a kettle, or a wash-boiler. A sterilizer with a tray is better than an ordinary pan or kettle, because, when the latter is used, the metal instruments lie in the bottom of the vessel, where the heat is very great and the temper may be impaired. Boiling, unfortunately, destroys to some extent the keenness of cutting instruments, the ebullition throwing them about. After the completion of the operation the instruments should be scrubbed with soap and water, boiled in soda solution, dried, and placed in a closet with glass shelves so that they will be protected from moisture and dust. Instruments can be partially disinfected by keeping them for thirty minutes in a 5 per cent. solution of carbolic acid or, better, in a 2 per cent. solution of formalin. Instruments with handles of wood, bone, ivory, or tortoise shell must not be boiled. Such instruments should not be used. If such instruments are used, they can be partially disinfected by the use of carbolic acid or formalin. Metal instruments, whenever possible, should consist of one smooth piece. Grooves and letters are objectionable, as dirt gathers in such depressions.

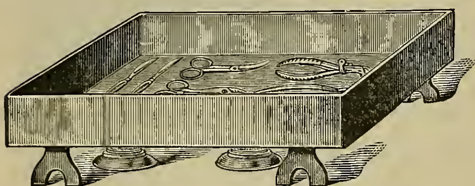

Fig. 36.—Portable sterilizer.

Preparation of the Patient.—Whenever possible give the patient some days' rest in bed before a severe operation. This is not possible in an emergency. It is seldom desirable in the case of a highly nervous and excitable woman. Such a patient is sleepless and frightened and loses ground by delay. In most cases this preliminary rest is advisable. It is particularly desirable in a strong, active working man suddenly translated from labor to bed. We wish to prepare him to meet operative shock. During the wait the patient is apt to adjust himself to his surroundings, he becomes accustomed to diminished activity and to sick-room routine, forms an acquaintance with his nurses and physicians, and, as a rule, becomes less nervous and more calmly confident of the result. He also learns to use the bed-pan and to micturate while recumbent. A patient while waiting is to have a general bath several times. Some weak and emaciated patients are treated and built up for weeks before the operation is attempted. During this preliminary rest the surgeon should study the disease, and study the individual in order to learn his tendencies, peculiarities, etc. The condition of the lungs, the heart, the blood, and the kidneys should be accurately determined. The amount of urine passed in twenty-four hours should be ascertained, and the percentage of urea should be estimated from a sample of the twenty-four-hour urine. The urine is carefully examined for sugar, albumin, casts, acetone, diacetic acid, indican, etc. By the above examinations the surgeon may be able to anticipate and provide against certain calamities. Sometimes such a study leads us to postpone or abandon an operation. Furthermore, such a study gives the information which is necessary in order to intelligently select the proper anesthetic. The presence in the urine of acetone and diacetic acid forbids any but an emergency operation. Sugar or granular and fatty casts in the urine, or a considerable quantity of albumin, make us hesitate to operate.[1] A hemoglobin percentage of under 50 makes us seek to avoid operation in most cases not associated with bleeding. The anesthetist should, during this preliminary period, examine the heart, pulse, and blood-pressure, so as to know the natural

[1] The question of operation on diabetics is discussed on p. 69.

character of each when the patient is free from excitement. Without this preliminary knowledge he cannot accurately appreciate or intelligently interpret some changes induced by the anesthetic. Constipation must be amended by mild laxatives or enemas, and all fermented matter should be removed from the alimentary canal. Constipation increases the probability of wound infection and greatly impairs the comfort of the patient. As previously shown, the putrefactive bacteria in the intestinal canal, which are usually harmless and are what Adami calls "potential parasites," may escape into the tissues. The retention of fermented matter causes catarrhal inflammation and bacteria escape more easily. If they escape they may lead to damage in the wound, and even if wound infection from within does not occur, constipation lessens vital resistance and increases the liability to wound infection from without. Purgatives must not be violent, as anything which greatly depresses a person lessens vital resistance, and powerful purgatives are powerful depressants. The diet should be bland and nutritious, but not bulky. The night before the operation give a saline cathartic, and the morning of the operation employ an enema. Not only do we empty the bowel to lessen the liability to wound infection, but we wish the rectum empty at the time of operation for another reason. It is desirable that the rectum be empty because in shock the absorbing power of the stomach is greatly diminished or is even abolished for the time, and it may be necessary to utilize the absorbing power of the rectum to take up stimulants given by enema. When a patient is under the influence of an anesthetic or when he is profoundly shocked, of course no attempt is made to give stimulants by the mouth. Whenever possible give a general warm bath the day before the operation. It is a common custom the evening before the operation to shave the region if hairy, scrub the entire field of operation, as well as the adjoining regions, with soap and water; wash with alcohol; scrub with hot corrosive sublimate solution (1:1000); apply a layer of moist corrosive sublimate gauze, and place over this dry antiseptic gauze, a rubber dam, and a bandage. Many surgeons apply a poultice of green soap for many hours before applying a chemical germicide, in order to separate masses of epithelium and with them many germs. This method is particularly useful in cleansing the scalp. On removing the dressings to perform the operation, the part is scrubbed with soap and water, washed with sterile water, then with alcohol, and then with corrosive sublimate solution. I have become convinced that the teachers in Johns Hopkins Hospital are right, and that cleansing the day before operation is not necessary except for a brain case. Neither is it desirable, as it often gives the patient a restless night. It is my custom to have a hairy region shaved the day before operation. In all cases the field of operation is disinfected the morning of the operation. Disinfection is again practised when the patient is on the operating table, *after* anesthetization. In emergency cases disinfection can only be practised just previous to the operation. When the field of operation has been prepared, surround it with dry sterile sheets and towels. In a head operation I stitch the towels to the skin to keep them in place and at the termination of the operation remove these stitches. Murphy prevents infection from the cutaneous surface by spreading a specially prepared sterile solution of rubber over the sterilized operation area. The rubber is dissolved in acetone. The incisions are made through the artificial skin of rubber and the rubber is removed when the surgeon is ready to introduce the sutures. Thus infection of the wound with contaminated secretion of the skin glands is prevented. If iodin has been used upon the abdomen, the surgeon must be scrupulously careful not to bring intestine in contact with the skin. If iodin comes in contact with intestine, it irritates the gut and becomes responsible for subsequent adhesions.

If disinfecting an emergency case in which a wound exists, tincture of

iodin, unless well diluted, should not be put in the wound. Hindenburg had a case in which local gangrene followed such an application ("Münchener medizinische Wochen.," July 5, 1911). It is not probable that the very dilute alcoholic solution of iodin used by many to prepare the skin would endanger a wound.

Of recent years iodin has been largely used and warmly praised as a disinfectant for the skin. It was introduced by Grossich in 1908. If iodin is to be used the skin may be scrubbed and shaved the night before, but must *never be scrubbed* within several hours of the impending operation. Were it done, it would swell the surface epithelium and keep the iodin from entering into the skin. Two hours before operation apply iodin, and apply it again when the patient is on the table. In an emergency case the skin is *dry shaved*, the field of operation is painted with a 2 per cent. alcoholic solution of iodin (which is allowed to dry and is not wiped away), and covered with sterile towels or gauze. When the patient is placed upon the table the field is again painted with iodin. This method is of great value in emergency cases, especially in out-patient and accident work. I have abandoned it in the axilla and perineum because the constant moisture of those regions makes iodin inefficient. The method is less efficient in summer than in winter, because in summer the skin is apt to be wet with sweat.

During an operation the patient must be carefully protected from cold by wrapping him in blankets, and often by having him wear specially prepared drawers with feet. After the completion of an operation and the application of the dressings the patient is returned to his room or the ward, care being taken to protect him from cold or drafts.

Disinfection of Mucous Membranes.—It is impossible to thoroughly disinfect mucous membranes. We must not scrub forcibly and we must not use powerful germicides, because they are irritant and also because they may be absorbed. The best that can be done in the *vagina* is to rub lightly, when possible, with a bit of moist absorbent cotton and irrigate with a solution of boric acid or with normal salt solution. Another method is to sponge the vagina with creolin and ethereal soap (1 and 16) and irrigate with hot saline fluid or boric acid.

The *rectum* is prepared by washing out all retained feces by the use of copious high injections and by irrigating with salt solution or boric acid.

The *mouth* is prepared by having snags of teeth and tartar removed and decayed teeth removed or plugged. For several days before the operation scrub the teeth twice a day with a soft brush and castile soap; and every three hours, when the patient is awake, rinse the mouth with peroxid of hydrogen and spray the nares and nasopharynx with a saturated solution of boric acid.

The *urethra* is prepared by administering by the mouth for several days salol or urotropin and by frequent irrigation of the urethra with boric acid solution, normal salt solution, a solution of permanganate of potash (1:6000), or a 1:5000 solution of silver nitrate.

Preparation of a Patient for An Operation Upon the Stomach.—(See p. 1079.)

The Time of Day to Operate.—A hard-and-fast rule cannot be set as to the time of day when operations should be done. Emergency operations must be performed at once without any consideration as to time. It is often necessary, because of other professional obligations, to set an afternoon hour for an operation. Whenever possible, however, if the nature of the case admits of it, operate in the morning and, preferably, in the early morning. By doing this the patient is saved some hours of dread and worry and the surgeon is enabled to operate when he is fresh, active, and alert; in other words, when he is at his best. A tired mind, like a tired hand, tends to become shaky, and a tired mind may mean incorrect observation, careless technic, impaired judgment, disastrous timidity, or calamitous recklessness.

Operations on Diabetics.—Surgical operations upon diabetics are regarded as very dangerous and are employed by most surgeons only in emergencies. In operations upon such subjects gangrene may arise in the wound or diabetic coma may develop. It is important to remember that glycosuria may result from a surgical condition (head injury, sepsis, etc.), and this temporary diabetes may be relieved by operation. I have seen it in appendicitis, and in such cases operation is not contra-indicated, but is imperative. Llewellyn Phillips ("Lancet," May 10 and 17, 1902) refers to the temporary glycosuria produced by injury and sepsis. He thinks that diabetes may directly cause cataract and balanoposthitis, but produces gangrene indirectly by causing nerve degeneration and arteriosclerosis. Phillips points out that a surgical condition and glycosuria may exist independent of and uninfluenced by each other, and many such cases can be operated upon, although operation should be avoided if there is serious disease of some important organ (the liver, for instance). Phillips, in the valuable article referred to, insists that the percentage of sugar is not a measure of the degree of danger; that albuminuria adds greatly to the danger; that the presence of acetone in the urine, and also the presence of ammonia, gives a bad prognosis. Phillips's conclusions as to when to operate and when to refuse operation are as follows ("Lancet," May 10 and 17, 1902): An operation for malignant disease in a diabetic can be performed if the operation would be proper on a non-diabetic individual. Large abdominal tumors can be removed. Cosmetic operations are justifiable if the general health is good and there is not marked arterial disease or nerve degeneration. Operation is justifiable in all emergencies without regard to the condition of the urine. In a diabetic with a surgical malady it is often possible to lessen danger by preliminary treatment. Only an operation of the greatest urgency should be performed if over 1 gm. of ammonia is excreted during twenty-four hours; and if aceto-acetic acid or much albumin is present, every case but the most urgent should be postponed and subjected to medical treatment.

I would add to the conclusions of Phillips that the anesthetic is a danger to the kidneys irritated by the secretion of sugar, and it is desirable, when possible, to use local anesthesia, or, as Robt. T. Morris advises, nitrous oxid and oxygen ("Medical News," June 29, 1901), or spinal anesthesia, or to block the nerves with cocain. In 3 cases I used spinal anesthesia, but in 1 of them the patient died in coma. If sugar diminishes in the urine but increases in the blood, the condition is one of danger. Further, if the urine contains sugar, but neither acetone nor diacetic acid, we should restrict carbohydrates and administer opium or codein. Too strict and too prolonged exclusion of carbohydrates is not justifiable, because it favors the occurrence of acetonuria. If acetonuria exists or arises, a pure meat diet is inadmissible, as it favors diabetic coma. The risk of coma is diminished by giving bicarbonate of soda by the mouth, before and after operation. If coma arises give carbonate of soda intravenously.

Irrigation is often practised in septic wounds, but is not required in aseptic wounds. In a septic wound gentle irrigation is often desirable. Irrigation removes many bacteria and much toxin and antiseptic irrigation perhaps antidotes retained toxins. Irrigation must never be forcible for fear it may disseminate infection. Among irrigating fluids we may mention corrosive sublimate, carbolic acid, peroxid of hydrogen, boric acid solution, acetate of aluminum, and normal salt solution. Hot normal salt solution is the best agent with which to irrigate the peritoneal cavity, the pleural sac, the interior of joints, and the surface of the brain. This solution contains 0.9 per cent. of sodium chlorid.

The Dry Method.—Many surgeons employ Landerer's dry method in oper-

ating aseptically, no fluid being applied to the wound. As the wound is enlarged gauze sponges are packed in to arrest hemorrhage. On the completion of the operation the sponges are removed, bleeding points are ligated, and the wound is often closed without drainage.

Ligatures and Sutures.—In using sutures always remember that they must be tied firmly, but never tightly. A tight suture will cut when the wound swells and will thus fail of its purpose; further, it produces an area of tissue necrosis, which is a point of least resistance in and about which infection is prone to occur. We had far better use many very fine sutures than a less number of thick ones. The individual fine suture is weak, but in numbers they give firm support. A fine suture cannot be tied too tight. If we try to make it tight the attempt is frustrated by the breaking of the suture.

Catgut.—The favorite ligature material is catgut. Catgut undergoes absorption in the tissues. Years ago attempts were made by Scarpa, Crampton, and Physick to use absorbable ligatures. Sir Astley Cooper tried catgut. These attempts failed because the material employed was septic, suppuration ensued, the wound gaped, and the ligature was cast off prematurely. Surgeons remained content with non-absorbable ligatures of silk or linen. These ligatures were not cut short, but a long end was left to each one, and the ends were allowed to hang out of the wound. The ligatures were lightly pulled upon from time to time, and when they loosened or cut through were removed. Catgut is the submucous coat of the intestine of the sheep, and is the material from which violin strings are made. It was reintroduced into surgery by Lister. It is usually obtained in the following manner: The small intestine, after separation from the mesentery, is washed in water, laid upon a board, and scraped by a metal instrument. Thus the mucous coat and the muscular coat are scraped away, and the submucous coat only remains. The submucous coat is cut into strips, and each strip is twisted into a coil. Raw catgut is an infected material. It is difficult to sterilize, because in the twisting many organisms get into the interior of the strand, where it is impossible for antiseptics to reach them. Raw catgut obtained from animals dead of splenic fever contains spores of anthrax. If not thoroughly disinfected catgut is dangerous, and some surgeons consider its cleanliness always a matter of grave question and will not use it. Cases of tetanus after operation have been traced directly to infected catgut. The safest raw catgut is obtained from fresh intestines (as advised by Kuhn), is not twisted, is made into strands in sterile machines so as to prevent handling, and is put up in aseptic bundles. Surgeons' catgut is usually obtained from the dealer in skeins containing 30 yards. It should be rough and yellow. The smooth white variety should not be purchased. It has been rubbed smooth with a piece of glass and bleached with a chemical, and in consequence is weak and unreliable. The smallest size is known as double zero, then come single zero, No. 1, No. 2, No. 3, and No. 4. The usual ligature size is No. 2. Nos. 3 and 4 are only used for tying thick pedicles. Nos. 1 and 2 are used for suturing the dura and peritoneum and No. 1 for tying small vessels in the brain. When catgut is used to tie delicate tissue (omental masses, intestinal surfaces, etc.) it must first be softened by immersing for half a minute in normal salt solution. If this precaution is neglected and wiry catgut is used, the ligature or suture will cut and hemorrhage will occur. The greater the diameter of the gut, the more uncertain is the sterilization. Nos. 3 and 4 are of doubtful cleanliness, no matter what method of sterilization is employed, and a strand though clean upon the surface may be infected in its interior. When a strand which is infected within is used by the surgeon the tissues are not infected promptly, but after some days when the catgut has been partially absorbed and the spores or bacteria within the

strand have been set free. Many late infections are due to catgut infected in the interior of the strand. The smaller sizes I believe can usually be satisfactorily sterilized. I am very uncertain as to the surgical cleanliness of the larger sizes.

If catgut is thoroughly freed from bacteria and the wound in which it is used is aseptic, it is a most satisfactory ligature material, is absorbed in the wound after being cut off short, and produces no trouble, although it does increase wound secretion slightly. The smaller sizes are absorbed in four or five days, No. 2 lasts from nine to ten days, Nos. 3 and 4 from ten days to three weeks. Chromicized catgut is absorbed far less rapidly than plain gut.

One of the following methods of preparation may be used:

Boiling in Alcohol.—The catgut is soaked in ether for twenty-four hours to remove fat. It is then wound on glass spools, transferred to alcohol, and boiled under pressure. The boiling is conducted in a heavy metal jar with a well-fitting screw-top. The jar is half filled with alcohol. The spools of catgut are placed in the jar, the lid of the jar is screwed down, and the apparatus is immersed in boiling water for half an hour. The gut is kept in this jar until needed. Fowler's catgut is prepared by boiling in alcohol. It is placed in hermetically sealed U-shaped glass tubes. Each tube contains alcohol and twelve ligatures. The alcohol is boiled *by immersing the tube in* boiling water.

The *cumol method* is employed by Kelly in the Johns Hopkins Hospital, and is known as Krönig's method. Cumol is a fluid hydrocarbon which boils at 179° C. Catgut is wound upon spools of glass, and these are placed in a beaker glass, the bottom of which is covered with cotton. A bit of cardboard is placed on top of the beaker, and through a small perforation in the cardboard a thermometer is introduced. The beaker is placed in a sand-bath and the bath is heated by means of a Bunsen burner. The temperature is gradually raised to 80° C., and is kept at this point for one hour, in order entirely to remove moisture from the gut. Cumol, at a temperature of 100° C., is poured into the glass, and the heat is increased until the temperature of the cumol is 165° C., which is a few degrees below its boiling-point. For one hour this temperature is maintained. Then the cumol is poured off and the catgut is allowed to remain for a time in the sand-bath, at a temperature of 100° C., in order to dry. It is transferred for keeping into sterile glass jars or test-tubes.[1]

The Claudius Method.—The iodin catgut is prepared by the Claudius method. Mr. Moynihan, of Leeds, makes Claudius catgut as follows: In 10 oz. of sterile water dissolve 1 oz. of crystals of iodid of potassium. When all the crystals are dissolved add 10 oz. of sterile water, and then add 1 oz. of iodin in crystalline form. Dilute the mixture with 4 pints of sterile water. The result is a 1 per cent. solution of iodin and potassium iodid. After the usual preliminary preparation, place the gut in the mixture and keep it in it for for at least eight days before using. It can be kept in it without harm for a number of months. Salkindsohn has modified the Claudius method as follows: Use 1 part of tincture of iodin and 15 parts of proof spirits and immerse the catgut for eight days (J. S. Riddell, in "Brit. Med. Jour.," April 6, 1907).

Silverized Catgut.—Blake advocates this form of gut ("Annals of Surgery," January, 1907). He prepares it as follows: He winds four coils of gut on four glass plates, places the plates in a jar containing a 2 per cent. solution of collargolum and keeps them immersed for a week, the jar being shaken once or twice during the period of immersion. At the end of a week the plates are removed from the silver solution and are placed for from fifteen to thirty

[1] See McBurney and Collins, in "International Text-Book of Surgery," and Clark, in "Johns Hopkins Hospital Bulletin," March, 1896.

minutes in 95 per cent. alcohol, then the gut is wound with aseptic care on glass spools and is kept until wanted in 95 per cent. alcohol.

The *formalin method* was advocated by the late Prof. Senn. The catgut is wound on glass test-tubes and is immersed in an aqueous solution of formalin (2–4 per cent.) for twenty-four to forty-eight hours. It is placed in running water for twelve hours to get rid of the formalin. It is boiled in water for fifteen minutes, is cut in pieces and tied in bundles, is placed in a glass-stoppered jar, and is kept ready for use in the following mixture: 950 parts of absolute alcohol, 50 parts of glycerin, and 100 parts of pulverized iodoform. Every few days the mixture should be shaken.

Senn's process is a modification of Hoffmeister's. Even sterile catgut contains a toxic substance, which increases wound secretion, has a poisonous effect on body cells, and favors to some extent limited suppuration. Senn maintains that to counteract this influence gut should not only be sterile, but should be antiseptic, to inhibit the growth of pyogenic organisms which reach the wound from without during operation or subsequently by the blood.

Dry Heat Method.—Boeckman wraps catgut in paraffin paper, seals it in a paper envelope, puts it in the sterilizer, and subjects it to dry heat. For three hours it is heated to a temperature of 284° F., and for four hours to a temperature of 290° F. The envelope can be carried in the pocket or the instrument bag. When the gut is wanted the end of the envelope is torn off, an assistant with sterilized hands unwraps the paraffin paper, and the gut is dipped for a moment in sterile water to make it pliable.[1]

Corrosive Sublimate Method.—A method which has been largely used is to take raw catgut, keep it in ether for twenty-four hours, soak it for twenty-four hours in an alcoholic solution of corrosive sublimate (1:500), wind it on sterilized glass rods, and place it for keeping in ether or in alcohol.

Johnston's quick method of preparing catgut is as follows: Place it for twenty-four hours in ether; at the end of this period place it in a solution containing 20 gr. of corrosive sublimate, 100 gr. of tartaric acid, and 6 oz. of alcohol. The small gut is kept in this for ten or fifteen minutes, the larger gut from twenty to thirty minutes, but never longer. It is placed for keeping in a mixture containing 1 drop of chlorid of palladium to 8 oz. of alcohol. This gut is strong and reliable. At the time of operation the gut is placed in a solution one-third of which is 5 per cent. carbolic acid solution and two-thirds of which is alcohol.

Preparation of Chromicized Catgut.—Chromicized catgut is absorbed less rapidly by the tissues than ordinary catgut. It is used to tie thick pedicles and large arteries, to suture nerves and tendons, and as a suture material in the radical cure of hernia. Chromicized gut, No. 3 and No. 4, will remain unabsorbed in the tissues from four to six weeks. The gut should be soaked in ether for twenty-four hours, and be immersed for twenty-four hours in a 4 per cent. solution of chromic acid in water. The gut is then dried in a hot-air sterilizer and is disinfected by one of the several methods. The cumol method is satisfactory.

How to Tie Catgut.—Catgut is tied in a reef knot (square knot) and distinct ends are left on cutting. The second knot, if pulled too tightly, may break the ligature. Moist catgut is slippery and is hard to tie. If a large vessel is tied by catgut, a third knot should be used and the ends cut close to the knot. In tying a vessel in the brain or omentum be sure the gut is not wiry; if it is it will tear the vessel and permit renewed bleeding. Wiry gut must be dipped in salt solution for a moment just before using. Really strong catgut can be tied in a surgeon's knot.

Kangaroo-tendon and Its Preparation.—This material is said to be obtained

[1] James E. Moore, in "Phila. Med. Jour.," June 22, 1898.

from the tail of the great kangaroo. It is hard to believe that kangaroos are sufficiently cheap and plentiful to furnish us with it in quantity. It is certainly a tendonous material. It is especially useful for buried sutures in hernia operations; it will be absorbed in the tissues, but only after a long time (sixty to seventy days). Kangaroo-tendon is not grossly infected as is catgut. The material is obtained from a recently killed animal and is promptly dried in the sun. This suture material was introduced by Dr. Henry O. Marcy. It can be prepared in the same manner as the chromicized catgut, and it ought always to be chromicized.

The following method of preparation is recommended by Charles Truax ("Mechanics of Surgery"): Soak the dried tendon until it becomes supple in a 1:1000 solution of corrosive sublimate. Separate the material into individual tendons, place them lengthwise between two towels; dry them; make them aseptic by soaking in a solution of formalin, as we would do with catgut (see above). After washing out the formalin chromicize the tendon by placing it in a fresh 5 per cent. solution of carbolic acid containing 1:4000 parts of chromic acid. When the tendons become "dark golden brown" in color, they are removed from the chromic acid solution, dried between sterile towels, and placed for keeping in 10 per cent. carbolized oil. When wanted, they are removed from the oil, and wiped with a sterile towel saturated with bichlorid solution (1:1000). Kangaroo-tendon is tied in a reef knot. It must be tied firmly, else the knot will slip.

Silk.—This material can be used for both ligatures and sutures; many sizes should be kept on hand. Silk is very strong, soft, extremely supple, and does not swell or irritate the tissue. It can be tied into very firm knots. Ordinary surgical silk is a form of twisted silk—that is, several or many strands are twisted into one. Cable twist or Tait's silk is very strong and is used for tying large pedicles. Braided silk is extremely strong and is made by plaiting together several strands of twisted silk. Floss silk is "a straight fiber slightly twisted" (Truax). Silk is usually tied in a reef knot, but occasionally in a surgeon's knot. White silk may be used, or black silk, which is more easily visible. Silk becomes encapsulated in the tissues. It is not absorbed at all or only after a very long time. It is not a good material for buried sutures, as in the long run it may form a sinus. Fine silk ligatures do not cause sinuses.

Preparation of Silk.—Sutures of silk should be boiled for half an hour before using in a 1 per cent. solution of carbonate of sodium. Some surgeons keep the silk after boiling in sublimated alcohol (1 : 1000) or carbolic solution (5 per cent.), but it is better to prepare it just before using. A convenient method of preparation is to wind the silk on a glass spool, place the spool in a large test-tube, close the mouth of the tube with jeweler's cotton, introduce the tube into a steam sterilizer, and subject it to a pressure of 10 pounds for twenty minutes, repeating the process the next day. These tubes are carried in wooden boxes sealed with rubber corks.

Horsehair and Its Preparation.—This is used for effecting very neat approximation when only light sutures are required; for instance, in wounds of the face. Its chief use is for capillary drainage. It is prepared by washing and then boiling for fifteen minutes in a 4 per cent. solution of carbonate of sodium. It is kept until needed in sublimated alcohol (1 : 1000).

Silkworm-gut and Its Preparation.—This material contains fewer bacteria than catgut and does not swell when introduced into a wound. It is strong, solid, smooth, non-irritating, can be drawn through the tissues with slight force, and does not tend to cut the tissue as does a metallic suture. The designation silkworm-gut is a misnomer; the material is not gut at all, but is obtained from the silk-producing glands. Italy supplies most of the gut used by fishermen, but the gut used by the surgeon comes chiefly from Murcia

in Spain. When the silkworms are just ready to spin they are placed in vinegar and water for a number of hours and are thus killed. Each worm is opened and the silk-producing glands are clearly exposed and each gland is drawn by its ends into a single thread. The threads are dried in the air and assume a reddish color (M. J. Triollet, in "Bulletin des Sciences Pharmacologiques," 1905, No. 5. Quoted in "Lancet," Feb. 3, 1906). "This crude silkworm-gut is sold to the manufacturer and further treated. It is first boiled in alkaline water to remove fat and blood and is then dried in the sun, being protected from dust. It is next polished by means of slightly oiled pumice stone. The gut is then bleached with sulphurous acid and rubbed vigorously with chamois leather to remove dust and sulphur" ("Lancet," Feb. 3, 1906). It is a very valuable material, but is not used for ligatures, as it cannot be tied as firmly as catgut and because when left buried in the tissues the sharp ends may stick and irritate and a point of least resistance may be created. Silkworm-gut is prepared by placing it in ether for forty-eight hours and in a solution of corrosive sublimate (1 : 1000) for one hour, or it can be boiled in plain water for half an hour. It is carried in a long tube filled with alcohol. A few minutes before using the gut is placed in carbolic acid and alcohol (one-third of the solution is a 3 per cent. solution of acid, two-thirds of it is alcohol). Silkworm-gut is tied by the surgeon's knot.

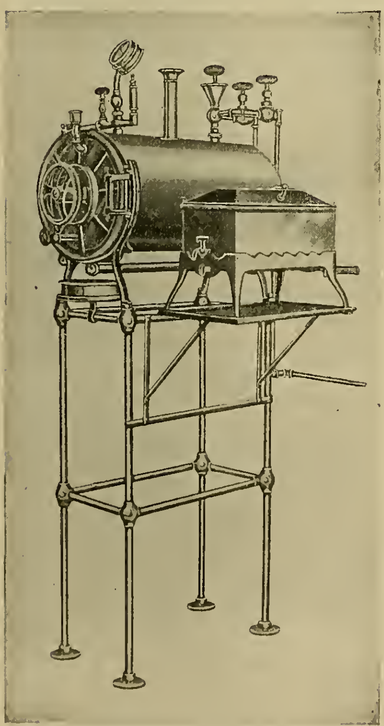

Fig. 37.—Small steam-pressure sterilizer and instrument boiler (Fowler).

Celluloid Thread and Its Preparation.—This material is warmly advocated by Pagenstecher. He calls it celluloid yarn, and prepares it from English gray linen thread. I have used it with much satisfaction. It is strong, smooth, flexible, and the knot holds firmly; it can be sterilized by any method used for raw silk, and sterilization by dry heat actually increases its strength. Its one disadvantage is that it absorbs about 40 per cent. of fluid, but it does not soften. The celluloid is added after the thread has been boiled in a 1 per cent. solution of carbonate of soda, wiped on or wrapped in a sterile towel, and dried in hot air or steam. It is then dipped in a solution of celluloid heated in a hot-air sterilizer, and is packed in sterile boxes (Schlutius, in "Pacific Med. Journal," Jan., 1900; Keen and Rosenberger, in "Phila. Med. Journal," May 10, 1900). Celluloid thread can be used for sutures or ligatures.

Silver wire is prepared by boiling. It is a very useful suture material, as it can be thoroughly sterilized and has a mild inhibitory effect on the growth of bacteria. Some surgeons use it for buried sutures, but many are opposed to using it thus on the ground that it is apt to lead to sinus formation. *Copper, brass,* and *bronze* have a very distinct inhibitory effect on bacteria (C. L. Green, in the "Practitioner," March, 1907), and wire made of any one of these metals is useful. Gold, tin, platinum, magnesium, aluminum, and nickel are devoid of inhibitory power. If iron oxidizes freely it has decided inhibitory

power; if it is so coated that it cannot oxidize it has no inhibitory power. Copper is more powerfully inhibitory than any other metal (C. L. Green, in the "Practitioner," March, 1907). I have used copper wire and brass screws in bone and have used wire of aluminum bronze for various purposes.

Most wounds are closed by interrupted sutures of silkworm-gut, but silk, catgut, chromic catgut, or silver wire can be used. The old continuous suture (glovers' stitch) is rarely used except as a buried suture. An admirable closure can be effected by Halsted's subcuticular stitch, and scarcely any scar results (see page 57). Marcy's buried tendon sutures are much used, especially in hernia operations and in various other operations upon the abdomen.

Dressings are made of cheese-cloth. In order to make *antiseptic gauze* the cheese-cloth is boiled in a solution of carbonate of sodium, rinsed out, and dried; it is then soaked for twenty-four hours in a solution containing 1 part of corrosive sublimate, 2 parts of table salt, and 500 parts of water. It is placed in clean jars with glass lids, and it may be kept moist or dry.

Sterilized or *aseptic gauze* is prepared by boiling in carbonate of sodium solution, etc., as described under Antiseptic Gauze. The gauze is then

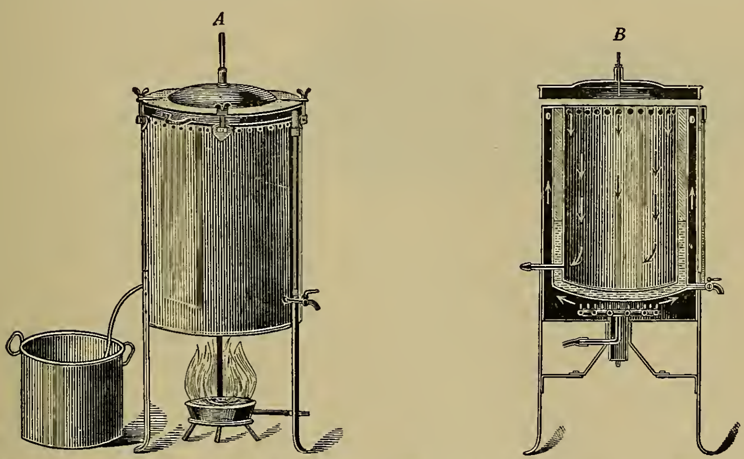

Fig. 38.—Lautenschläger's steam sterilizer for dressings: *A*, Exterior view; *B*, cross-section.

wrapped in a towel and is placed in a steam sterilizer (Figs. 37 and 38) for an hour. It is kept until wanted in sterile glass jars with glass lids.

Sterile absorbent cotton is prepared in the same manner as gauze. Cotton is useful as a dressing to supplement gauze, being placed on the outside of the gauze. It absorbs quantities of serum, but will take up very little pus.

Iodoform gauze is very useful for packing in the brain and abdomen, for packing abscesses and tuberculous areas, and for dressing foul wounds. It is prepared as follows: Make an emulsion composed of equal parts by weight of iodoform, glycerin, and alcohol, and add corrosive sublimate in the proportion of 1 part to 1000 of the mixture. This mixture stands for three days. Take moist bichlorid gauze, saturate it with the emulsion, let it drip for a time, and keep it in sterilized and covered glass jars (Johnston).

Lister's *cyanid gauze* (double cyanid of zinc and mercury) is not certainly antiseptic, and must be dipped into a corrosive sublimate solution (1 : 2000) before using. All forms of gauze can be bought ready prepared from reliable firms.

Some surgeons place *silver foil* upon a wound before applying the gauze (Halsted, page 32). Very small wounds in which drainage is not employed may

be dressed by laying a film of aseptic absorbent cotton over the wound and applying, by means of a clean camel's-hair brush, *iodoform collodion* (48 gr. of iodoform to 1 oz. of collodion). Among other materials sometimes used for dressing wounds the following should be mentioned: Wood wool, absorbent wool, moose pappe, oakum, jute, peat, and sawdust.

Protectives.—A protective is a material placed directly upon wounds to shield them from irritation and infection. The commonly used protectives are Lister's oiled silk protective, gutta-percha tissue, rubber dam, waxed paper, paraffin paper, mackintosh, Cargile membrane, and silver foil. Undoubtedly, many antiseptic agents destroy young cells and in this way hinder repair. The same is true of certain rough dressings.

R. T. Morris showed us that gauze and particularly cotton are injurious to a healing wound. A non-irritant protective laid directly upon a wound may be useful by saving new cells from injury by an irritant germicide and from being pulled away at each change of dressings.

Among the best protectives in common use are Lister's protective, gutta-percha tissue, silver foil, and Cargile membrane. Morris condemns gutta-percha tissue as irritant. He uses thin gold-beaters' skin made from the peritoneum of the ox, which material he calls Cargile membrane, after an Arkansas physician who introduced it into practice. The advantage of this material is that moisture cannot penetrate and new cells do not adhere. I have used it with satisfaction in many cases, but in wounds and ulcers prefer silver foil.

Silver foil, Lister's protective, or gutta-percha tissue is laid directly upon a wound, the dressing being placed above it. Silver foil comes in books and is sterilized by dry heat. Gutta-percha tissue should be sterilized by washing with soap and water, rinsing in sterile water, and soaking in a solution of corrosive sublimate. Lister's protective is employed to save the wound from the irritation of carbolized dressings.

Impermeable Material Over Dressings.—In the United States, if it is desired to place an impermeable material *over* a dressing, a rubber dam is usually employed. A rubber dam before being used should be washed with soap and water and soaked in a solution of corrosive sublimate.

The use of an impermeable material on the outside of the gauze dressing is not nearly so common as formerly. In an aseptic wound dry dressing uncovered by rubber is the most useful plan. When a dressing is covered by an impermeable material it becomes moist, acts as a poultice, and the discharges on the dressing may undergo decomposition.

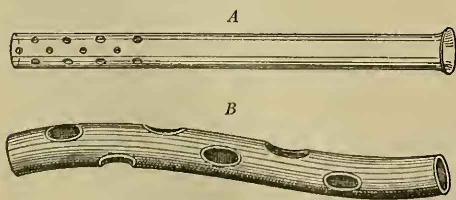

Fig. 39.—Drainage-tubes: *A*, Glass; *B*, rubber.

Drainage is used in all infected wounds, in most very large wounds, in wounds to which irritant antiseptics have been applied, in cases in which large abnormal cavities exist, in very fat people, and in individuals whose skin is so thin that we dare not apply firm pressure (see page 57). Drainage, when needed, is obtained by rubber or glass tubes (Fig. 39), by strands of horsehair, silkworm-gut or catgut, by pieces of gauze, and occasionally in the abdomen by Mikulicz's bag or tampon by which we obtain pressure to arrest hemorrhage and also secure drainage (Fig. 42). Gauze drainage is satisfactory for the removal of serum, but not pus. An objection to the gauze drain is the suffering caused by its removal. Before removal it should be thoroughly moistened and carefully separated from the wound edges to which it is apt to adhere. Sometimes it is

removed a little at a time. If pus is plentiful, especially if it is thick, rubber tubes should be used. The caliber of the tube must be sufficient to permit the pus to flow freely. Rubber drainage-tubes (Fig. 39, *B*) are rendered sterile by boiling in plain water. They are kept until wanted in a mercurial solution. This solution should be changed every few days, because the mercury is apt to be precipitated as sulphid. Glass tubes are sterilized by boiling. A bit of rubber tissue is sometimes used for drainage. The *cigarette drain* is useful in many cases. It drains serum well and is easily removed. It is made by folding up a piece of gauze and surrounding it, except at each extremity, with gutta-percha tissue. Gauze, catgut, etc., are known as capillary drains. When moist they drain serum excellently, but pus very badly or not at all. Pus requires tubular drainage. Drainage-tubes or strands are brought out at a portion of the wound which will be dependent when the patient is recumbent.

Sponges.—Marine sponges are never used to-day; instead we use gauze rolled into balls, the edges and ends being turned in.

Pads and Packs.—Ashton's gauze pads are very useful to push away structures during an abdominal operation and to temporarily pack a wound. Several layers of sterile gauze are taken. Each piece is about 6 in. long and 4 in. wide. A stitch is run round the margins. A piece of tape is sewed in one corner. During the operation the tape protrudes from the wound and is clamped with forceps. This plan saves the pad from being lost or forgotten in the abdomen. Long narrow pieces of gauze make the safest and best packs (*Halsted's packs*), as then a long end always protrudes from the wound during the operation.

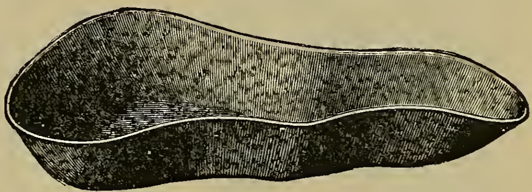

Fig. 40.—Smith's dressing basin.

Change of Dressing.—Dressing should not be changed unless indications call for change. To unnecessarily meddle with a wound is stupid and harmful. In many cases dressings are not renewed until the wound has healed. When a change of dressings is determined upon the surgeon should carefully sterilize his hands and forearms and should have at hand a warm solution of corrosive sublimate, normal salt solution, an irrigator, iodoform, iodoform gauze, scissors, forceps, basins (Figs. 40 and 41), etc. Dressings should be moistened before removal with salt solution or corrosive sublimate solution. If they stick to the part, a spray of hydrogen dioxid projected from an atomizer between the skin and dressings will soon loosen them. Dressings must be changed as soon as soaking with blood or wound-fluid is apparent. If the wound becomes uneasy and painful, or if constitutional symptoms of wound infection arise, the dressings must be removed to permit of inspection of the wound. A change of dressings must be effected with all of the aseptic care employed in a surgical operation. Dressings are not dispensed with until the wound is soundly healed.

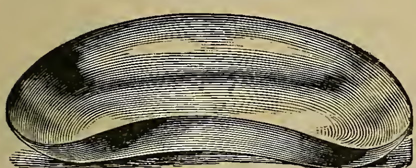

Fig. 41.—Plain dressing basin.

Removal of Stitches.—Buried stitches of animal material are not removed by the surgeon, but are gradually absorbed in the tissues. Buried stitches of silk or silver wire, which are used by some surgeons, although they are not absorbed in the tissues, may never require removal, but in some cases cause sinuses to form, and a sinus from a suture or ligature will not heal until the

suture or ligature is cast out or removed. Sutures of aluminum-bronze wire are absorbed after a long stay in the tissues.

If a catgut stitch is passed through the skin and tied externally the loop in the tissue is absorbed, but the knot and remainder of the loop is on the surface and is not absorbed, but remains adherent to the wound and the surgeon needs only to lift it off with forceps. Catgut is used as a material for cutaneous suturing in the operation of circumcision. When a skin wound is closed by unabsorbable sutures, as it usually is, the surgeon at the proper time takes forceps and scissors and removes the stitches. There is no day after an operation immutably fixed as the proper day to remove stitches. Stitches may usually come out from the sixth to the eighth day, although if there is much tension on the edges of the wound they are allowed to remain several days longer. In large wounds half of the stitches are taken out at one time, the remainder being allowed to remain for a couple of days longer. When a stitch begins to cut, it is doing no good, and it should be removed, no matter how short a time it has been in place. If it is allowed to remain it will cut into the wound, make a stitch-abscess, and cause an irregular suture-line. In order to remove a stitch pick up an end distal from the knot with forceps, lift it lightly, cut one side of the suture close to the skin by scissors, and remove it by pulling in the direction of the side on which the suture was cut (Fig. 43).

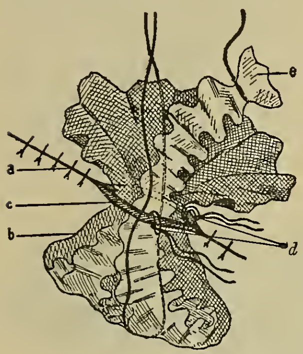

Fig. 42.—Mikulicz's bag: *a*, Abdominal sutures; *b*, gauze bag; *c*, abdominal wound; *d*, loops in the abdominal wall; *e*, gauze strip.

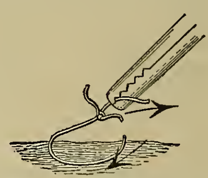

Fig. 43.—Method of extraction of a suture (Esmarch and Kowalzig).

Bandages.—For retaining dressings upon wounds unbleached muslin bandages may be used, but in most cases gauze bandages are employed. Gauze bandages may be applied when dry or wet; normally, they are applied when dry. Gauze bandages soaked in corrosive sublimate solution are antiseptic, do not seal the dressing, hence do not act like rubber dam; can be applied firmly, evenly and rapidly, and are very comfortable.

III. INFLAMMATION

Definition.—When the tissues are injured they react or respond, and this reaction or response is known as inflammation. The process of inflammation was defined by the late Sir John Burdon-Sanderson as "the succession of changes which occur in a living tissue when it is injured, provided that the injury is not of such a degree as at once to destroy its structure and vitality." Professor Adami, in his article upon inflammation in Allbutt's "System of Medicine," points out that this definition really includes too much. He alludes to the hemorrhage which occurs in the liver after a traumatism, and the subsequent changes in the extravasated corpuscles, and points out that these changes are not inflammatory phenomena. This definition, however, includes all inflammatory conditions, is largely employed, is very useful, indicates the cause, and, as Burdon-Sanderson says, makes clear that inflammation is a process and not a state (Adami). Adami's definition is as follows: "The series of changes constituting the local manifestation of the attempt at repair

of actual or referred injury to a part, or, briefly, the local attempt at repair of actual or referred injury." The changes alluded to in Burdon-Sanderson's definition comprise (1) changes in the vessels and the circulation, (2) departure of fluids and solids from the vessels, and (3) changes in the perivascular tissues.

Vascular and **circulatory changes** were formerly thought to be absolutely essential to inflammation in both vascular and non-vascular tissues. In the former they occur in the inflamed tissues; in the latter (cornea and cartilage) they are manifest in neighboring tissues from which the non-vascular area derives its nutritive material. As a matter of fact, in inflammation vascular changes are almost always present; but in a rather trivial corneal inflammation the episcleral vessels may not dilate, and the only white corpuscles which gather in the damaged area are those which come from the lymph-spaces of the cornea. Inflammation in any tissue will not be accompanied by vascular dilatation unless the process reaches a certain stage of severity.

Fig. 44.—Normal vessels and blood-stream.

Fig. 45.—Dilatation of the vessels in inflammation.

Active Hyperemia.—When an irritant is applied to tissue there may be a momentary arterial contraction due to irritation of the nerves, but this contraction is transitory, and is not an inflammatory phenomenon. The first vascular phenomenon is dilatation of all the vessels—capillaries, venules, and arterioles—appearing first and being most pronounced in the small arteries. As a result of the dilatation there are increased rapidity of circulation and increased determination of blood to the part, and the area of hyperemia becomes warmer than is normal. This condition of increased circulatory activity is known as "active hyperemia" (Fig. 45).

Active hyperemia is an increase in the amount of moving blood in a part. Passive hyperemia is an increase in the amount of blood in a part, but not of moving blood, as passive hyperemia or congestion is due to venous obstruction, and the blood is stagnated. Diminution in the amount of blood in a part is *ischemia.* Local anemia is the complete cutting off of the blood-supply of a part.

In active hyperemia more blood goes to the part and more blood passes through it, an increased amount of venous blood comes from the hyperemic

area, the venous tension is increased, and the veins may even pulsate. The capillaries, which under ordinary circumstances contain but few blood-cells (Fig. 44), become filled with corpuscles (Fig. 45), and even the smallest capillaries pulsate. The blood in the veins adjacent to the area of inflammation is of a much lighter red than in health. Many capillaries which were invisible under normal conditions become visible when active hyperemia exists. The capillaries contain no muscle-fiber, and hence these tubes cannot actively contract, except so far as the caliber of the tubes is altered by the contraction or expansion of the endothelial cells of the capillary wall. Contraction and dilatation of the capillaries depend chiefly on the amount of blood sent to or retained in them. In active hyperemia the increased amount of blood sent to the part causes capillary dilatation. As a result of the dilatation the endothelial cells become thinner than before, the cells in consequence of irritation lose some of their power to restrain exudation, and some observers assert that openings are formed between the cells or that previously existing openings enlarge (page 82). Fluid elements rarely leave the blood-vessels during active hyperemia, but they occasionally do. The wheals of urticaria are thus formed (Warren). Active hyperemia is often the first stage of an inflammation, but it is not of necessity followed by other inflammatory changes, and it can be caused by nerve section or nerve stimulation.

Fig. 46.—Retardation of blood and migration of white corpuscles in inflammation.

The duration of active hyperemia is variable. If the irritation was brief, the hyperemia is very transitory. In some cases dilatation with accelerated circulation is scarcely more than momentary, giving way almost immediately to dilatation with retardation. If the irritation is prolonged, hyperemia may last some time before giving way to retardation. In the web of a frog's foot, if an irritant is applied, hyperemia lasts from one-half hour to two hours before it is replaced by retardation.

Clinical Signs of Active Hyperemia.—A hyperemic part, if on or near the surface, is red in color, imparts a sense of heat to the examining hand, the color quickly disappears on pressure and quickly returns when pressure is released. In a congested part the temperature is diminished, the surface is purple, the congested veins are visible, there are edema and a sensation of coldness and numbness. When congestion is purely local the lividity disappears quickly when pressure is applied and returns quickly when pressure is removed. When due to disease of the heart or lungs, lividity disappears and returns slowly. When a local congestion is about to give way to gangrene the lividity disappears very slowly on pressure and crawls back very slowly when pressure is released.

Retardation.—After active hyperemia has existed for a variable time the blood-current begins to lessen in velocity, until it becomes more tardy than in health. This is known as "retardation of the circulation." Retardation is first noted in the venules, next in the capillaries, and last in the arterioles; but arterial pulsation continues. The red cells take the center of the blood-stream, which is known as the axial current. The white corpuscles settle out

of the central stream, separate from the red cells, and float lazily along near the vessel wall, and they are accompanied by many third corpuscles. The white cells show a strong tendency to adhere to the venule walls, and, as a result, accumulate against the inside of, and stick to, these walls and to one another, until the venules are entirely lined with layers of *leukocytes* (Fig. 46). The third corpuscles act in a similar manner and take the peripheral current. In the capillaries some leukocytes gather, but not so many. In the arterioles they adhere during cardiac dilatations, but are swept away by the force of the heart's contractions. Retardation is believed to be chiefly due to paresis of the muscular walls of the arterioles. This causation seems probable when we recall Lord Lister's experiments upon the pigment-cells of the frog's foot. Lister proved that inflammation paralyzes the pigment-cells, and concluded that dilatation at the focus of an inflammation is due to the paralyzing action of an irritant. Dilatation at a distance from the focus is a reflex phenomenon (W. Watson Cheyne). When the vessels are weakened or paralyzed the contractions of the arterioles are feeble or absent, and the blood is no longer urged forward by arterial power. The endothelial cells of the small vessels enlarge distinctly during retardation and develop a condition of stickiness, which leads the white cells to adhere to them, and thus increases resistance to the current of blood and adds to retardation. Fluids pass through the wall of a vessel in this condition more readily than through a healthy vessel, and white corpuscles leave the vessel in large numbers.

Oscillation and Stagnation.—By the accumulation of leukocytes the blood-stream is progressively narrowed and the axial current is impeded. The red blood-cells begin to stick to one another, forming aggregations like *rouleaux* of coin, which masses increase the difficulty the axial current has to contend with, until progressive movement ceases and the contents of the vessels sway to and fro with each heart-beat. This is the stage of *oscillation*. In a short time oscillation ceases and the vessels are filled with blood which does not move, and the vessel walls become irregular in outline or even pouched. This stage is known as "*stasis*" or "*stagnation*." Stasis is chiefly due to paralysis and damage of the vessel walls. Migration ceases when stasis takes place. If stasis persists, coagulation occurs, because the vessel walls have been so injured by the irritant as to be practically dead material, and they are no longer able to prevent clotting of their contents. Finally, in persisting stasis the vessel walls rupture or are entirely destroyed.

Résumé of the Vascular Changes of Inflammation.—We can sum up the vascular changes of inflammation by stating that they consist in a dilatation of the small vessels and a primary acceleration, a secondary retardation, and a subsequent stagnation of the blood-current, exudation of blood-liquor, adhesion of leukocytes to the walls of veins and capillaries, migration of leukocytes, the aggregation of the red blood-cells into intravascular masses, and coagulation of the material remaining in the vessel.

Exudation of Fluids.—It is to be remembered that in the process of nutrition blood-liquor and also white cells pass into the tissues through the walls of veins and capillaries, and during this process certain other materials are passing from the tissues into the vessels. Hence, a diffusible irritant in the vessels may pass into the tissues and a diffusible irritant in the tissues may pass into the vessels. Whenever retardation of the circulation arises there is an increase in the amount of plasma which passes out of the vessels, but in inflammation the exudation into the lymph-spaces is vastly greater in amount and is different in composition. In a slight inflammation, and in the early stage of any inflammation, there is an increase in the fluid exudate, and we speak of the condition as "*serous inflammation*." This fluid is really not serum, but is liquor sanguinis. We find true serum in passive congestion, not in active

inflammation. The fluid of a serous exudation contains very few white cells, and hence little or no fibrin can form in it, and coagulation does not take place in the perivascular tissues; and if the inflammation goes no further, the exudate is absorbed by the lymphatics. A blister is an example of serous inflammation. If the inflammation continues to intensify, the exudation is altered in character—it becomes thicker, turbid and very coagulable, and exhibits a greatly increased bactericidal power. It contains many white cells and fibrin elements, and coagulates in the tissues, because some of the leukocytes break up and set free fibrin ferment, and fibrin ferment causes the union of calcium and fibrinogen and the formation of fibrin. This fluid exudate is known as "*lymph*," or *plastic exudation*, and when it is present we speak of the condition as "*plastic inflammation.*" Lymph can be seen in the anterior chamber of the eye in cases of plastic iritis. Coagulated fibrin in a recent wound causes the edges to adhere or glazes the raw surface. In inflammation of a mucous surface it may appear as a false membrane. In inflammation of serous surfaces it may glue the surfaces together and lessen motion, the fibrinous masses which effect the gluing being called fibrinous or plastic adhesions. Such adhesions within the abdomen may seal a perforation, may cover a raw spot, or may encompass an area of infection and prevent fatal diffusion. Further, fibrin surrounds and entangles bacteria and retards their diffusion. Pyogenic cocci lessen, retard, or prevent fibrin formation or destroy fibrin previously formed. Fibrinous adhesions may, of course, do harm. They may retard or prevent the absorption of exudate; they may narrow and obstruct important structures (bowel, urethra, larynx); they may bind up and cripple an important viscus (liver, heart, or brain). Fibrinous adhesions may be succeeded by dense contracting and constricting bands of fibrous tissue. The lymphatics endeavor to absorb the fluid exudate in inflammation, but become occluded by coagulation, and the area they drain becomes swollen, hard, and "brawny." The slighter the inflammation, the less albuminous is the fluid; the more intense the inflammation, the more albuminous is the fluid. The focus of a severe inflammation feels brawny because of coagulation of a highly albuminous exudate; the periphery of an inflammation is soft and edematous because of the presence there of thin and non-coagulated exudate. Inflammatory lymph contains proteins and other substances. "Of these the more important are ferments, the results of proteolysis (notably fibrin and its precursors and peptones), and in many cases mucin, together with bactericidal substances, and, where bacteria are present, the products of their growth."[1] The amount of the exudation varies with the violence of the irritation, the nature of the irritant, the general condition of the organism, and the state of the tissues which are involved. In dense tissue (bone, periosteum, etc.) the exudation is scanty. In loose tissue (subcutaneous tissue) it is profuse. Profuse exudation may take place into a joint, the pleural sac, the peritoneal cavity, or the pericardium. In such cases the exudation is profuse because the serous membrane has a thin covering of endothelium, contains quantities of vessels, and the vessels receive but a thin covering and obtain but a scant support toward the cavity.

Does the plasma leave the vessels as a simple filtrate? Some maintain that it does. Heidenhain and others claim that it does not, and believe that the endothelial cells play an active part in the process. Heidenhain likens exudation to secretion, because some materials from the plasma pass out and others do not. Adami is inclined to agree with Heidenhain, that the endothelium plays "not a passive but an active rôle." Are there spaces between the endothelial cells of the capillary? It was long taught positively that there are no open spaces between the endothelial cells of the vessel wall and that

[1] Adami, in Allbutt's "System of Medicine."

these cells are held close together by a cement substance. It is now believed by some observers that spaces exist between the protoplasmic strands which hold the cells together, these spaces being closed when the vessel is contracted and open when the vessel is dilated. When these spaces are open fluid passes, and through these doorways leukocytes emerge.

Fig. 47.—Stages of the migration of a single white blood-corpuscle through the wall of a vein (Caton).

Migration and Diapedesis.—Even early in an inflammation a number of white corpuscles pass through the vessel walls; but when the inflammation is well established, large numbers, and when it is severe vast hordes, pass into the perivascular tissues. This process is known as "migration" (Figs. 46 and 47). The leukocytes throw out protoplasmic arms, insert themselves between the cells of the walls of the vessel, and pull themselves through by their power of ameboid movement (Fig. 48). Some observers claim that they do not pass through existing open doors, but force openings which close after them. This is readily accomplished, because the vessel wall is itself damaged, weakened, and convoluted. Others claim that stomata exist between the endothelial cells, the vessel wall being porous like a filter (see page 82). The escape of leukocytes takes place chiefly from the venules, though some migrate through the capillaries and even the arterioles (Fig. 46).

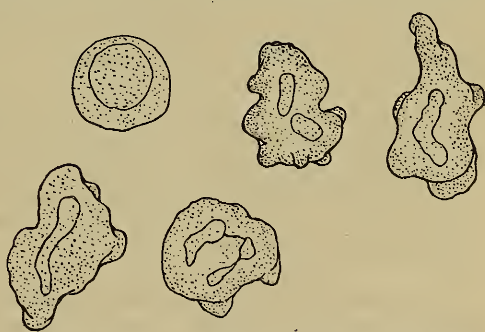

Fig. 48.—Ameboid movements of a leukocyte (Warner).

The leukocytes are influenced to move toward the damaged tissue by the attractive force known as *positive "chemiotaxis,"* a force which draws them toward invading bacteria, to regions of irritation, and to areas of tissue death. Leukocytes may move from very virulent organisms, influenced by what is known as *negative "chemiotaxis."* The migration of a leukocyte requires but a short time. Figure 47 shows the migration of a white blood-cell through a vein wall, the process requiring one hour and fifty minutes. In very acute inflammations red corpuscles also pass into the tissues. Red corpuscles are not capable of ameboid movements, and if they do escape from the vessels the process is passive on their part and not active. This passive escape happens because the capillary walls have been destroyed or because stomata have been greatly enlarged by vascular dilatation. If red corpuscles do pass into the

exudate, as happens in pneumonia, the inflammation is a very severe one, and is called a hemorrhagic inflammation. The escape of corpuscles by a passive process is known as "diapedesis," in contradistinction to the escape of leukocytes by active ameboid movements, a process known as "migration." The white corpuscles usually greatly increase in number in the blood of a person who has an acute inflammation, and the blood-making organs, such as the spleen and lymphatic glands, are often enlarged. An increase of white corpuscles in the blood of an individual is called *leukocytosis* (see page 92).

Blood-plaques.—*Blood-plates*, *blood-plaques*, or *third corpuscles*, may be discovered in freshly drawn blood, but unless they are present in unusual numbers they will rarely be seen in specimens prepared in the usual way. The third corpuscles can be seen by a high-power microscope in the moving blood of the web of a frog's foot. In blood outside of the body they are destroyed as soon as coagulation begins, and in order to see them coagulation must be prevented. Some observers maintain that the third corpuscles are the real fibrin-formers. The blood-plaques, or third corpuscles, are found to be present in increased numbers in inflammation. In health their usual proportion to red cells is as 1 to 20. They are especially numerous at the height of fever processes and during convalescence from an extensive abscess.

Changes in the Perivascular Tissues.—The cells of the perivascular tissue are phagocytes, and when stimulated they enlarge, become more actively phagocytic, and undergo reproduction. The liquor sanguinis which exudes during an acute inflammation coagulates unless prevented by virulent bacteria. It has often been asserted that exudation is Nature's method of supplying nutriment to the cells of the damaged region. Adami points out the apparently contradictory observation that the amount of exudate is in direct proportion to the rapidity of cell destruction, but, nevertheless, concludes that exudation stands in close relation to cell proliferation.[1] From whatever cause, tissue-cells multiply, and this process is known as "*cell proliferation.*"

When a tissue is injured it inflames, and, as Adami points out, the reaction we call inflammation is an attempt to repair injury.

Irritation may lead to degeneration and death of cells; it may lead to growth and multiplication. In many cases both processes are active in the acute stage, the cells at the focus of the inflammation undergoing degeneration and destruction, and those at the boundary undergoing growth and proliferation.

If tissue-cells have been seriously damaged they perish, and new cells are required to replace them. The inflammatory process has led to exudation of plasma and migration of leukocytes into the perivascular tissues. The connective-tissue cells multiply and produce young cells, which are known as "*fibroblasts*," and which eat up many leukocytes. Early in an inflammation polynuclear leukocytes preponderate, later mononuclear phagocytic cells predominate (Opie). The leukocytes contain two enzymes. One is derived from bone-marrow and digests protein in an alkaline medium; the other is derived from lymph-glands and digests protein in an acid medium (Opie). The migrated leukocytes in part surround the inflamed region and retard diffusion of the process. Many enter the diseased area and attack bacteria. Some undergo degenerative changes and liberate fibrin ferment which makes the exudate clot. Some move out of the inflamed area, each one carrying within it tissue débris or a dead bacterium, and many are eaten up by the fibroblasts. There is no real proof that leukocytes proliferate and help directly to form new tissue. This mass of young cells, taking origin from the fixed cells, has been called *embryonic tissue*, because of a fancied resemblance to the cells of the

[1] Adami, in Allbutt's "System of Medicine."

embryo. John Hunter called it *juvenile tissue.* It has also been called *indifferent tissue,* because of the belief that it could be converted indifferently into various tissue according to circumstances. It is also spoken of as *inflammatory new formation.* The cells of embryonic tissue are called *fibroblasts* because they form fibrous tissue.

An exudation may be absorbed by the lymphatics. It may be converted into pus if infected with pyogenic bacteria, or be replaced by cells from the proliferation of fixed tissue-cells, the cellular mass being subsequently vascularized by the extension into it of capillary loops derived from adjacent capillaries. When embryonic tissue is filled with blood-vessels—that is to say, when it is vascularized—it is called *granulation tissue.* Granulation tissue is finally converted into fibrous tissue. The above complicated processes, vascular and perivascular, are not accidents nor haphazard freaks, but are Nature's efforts to bring about a cure.

Dilatation is due to the direct effect of the irritant upon the muscle or its nerve-elements. Retardation and stasis are due to paralysis of the vessel wall, which paralysis causes resistance to the passage of the blood-stream and adhesion of the leukocytes to the vessel wall. The blood-liquor exudes and the leukocytes migrate. Often these efforts of Nature succeed. Acceleration of the circulation may succeed in washing away an irritant from the vessel wall. By bringing quantities of blood to the part copious exudation of plasma is rendered certain. The exudation may wash and remove irritants from the tissues, and the germicidal blood-liquor may destroy bacteria in the damaged area. The migration of corpuscles may prove of great service. The leukocytes surround an area of infection and tend to limit its spread. Leukocytes have phagocytic properties, and energetically attack and often destroy bacteria, and they furnish enzymes which may digest proteins and antitoxins, which antagonize and may neutralize the poisons produced by micro-organisms. Leukocytes aid in forming fibrin. Fibrin formation is of service by helping immobilization and by hindering the spread of bacteria. Leukocytes also aid in separating dead tissue from living, and they remove tissue débris from the area of inflammation. The multiplication of the fixed connective-tissue cells leads to the formation of fibroblasts, and fibroblasts are converted into fibrous tissue, which effects permanent repair (these changes will be alluded to again in the section on Repair).

Nature may fail in her efforts. For instance, an enormous exudate increases stasis and may cause such tension that gangrene results.

Inflammation in Non-vascular Tissue.—A type of non-vascular tissue is the cornea, and the cornea can inflame. The healthy cornea contains no blood-vessels. It is formed of many layers of fibers, each layer running parallel with the corneal surface and forming angles with the fibers of the adjacent layers. Between the layers are communicating lymph-spaces containing connective-tissue cells known as corneal corpuscles. It obtains its nourishment in part from the vessels of the conjunctiva, but chiefly from the vessels of the ciliary body and sclera. When the cornea inflames the episcleral, conjunctival, and ciliary vessels usually dilate and pour out exudate, and the fluid exudate and the leukocytes enter into the corneal lymph-spaces. The exudate coagulates and cell multiplication ensues as in any other inflammation. In mild inflammations the vessels about the cornea may not dilate. Leukocytes, from the lymph-spaces, reach the seat of injury in small numbers, and the fixed cells multiply. De Nancrede points out that in trivial inflammation, which injures but does not destroy the epithelium, leukocytes may not go to the seat of inflammation, the only change being enlargement and multiplication of corneal corpuscles. If new formation takes place, a permanent opacity mars the cornea as a consequence.

Cartilage has no blood-vessels except in regions where growth is very active or where ossification is taking place. Cartilage has no spaces, like the cornea, for a free circulation of lymph. In man canals have not been demonstrated and it is thought that fibrils conduct nutritive fluids, the nutritive plasma flowing between the cells, but there is no direct connection with blood-vessels. The plasma is furnished by the vessels at the margin of the perichondrium. Cartilage can inflame, and an inflammation of this structure is slow in evolution and of long duration. When inflammation occurs the cartilage cells enlarge and their nuclei proliferate, the intercellular substance softens and cartilage cells may be cast off. After a long time vessels may invade the inflamed cartilage and fibrous tissue forms from the perichondrium, but in some cases a loss of substance is not repaired.

Inflammation of Mucous Membrane.—It may be catarrhal, suppurative, croupous, or diphtheritic. In a *catarrhal inflammation* the increased blood-supply causes an excessive flow of mucus. The submucous tissues present the ordinary changes of inflammation and quantities of epithelial cells are cast off from the surface. Fibrous tissues may form in the submucous tissue and thus cause permanent thickening (strictures, etc.).

Suppurative inflammation is usually preceded by catarrhal inflammation. In this condition there is a discharge of mucopurulent fluid and ulcers are apt to form. A trivial loss of substance permits of regeneration, but a considerable loss is repaired by fibrous tissue, which by its bulk and by contracting may interfere greatly with the functional usefulness of an organ or a canal.

A *croupous inflammation* is one in which quantities of epithelial cells are cast off the surface and there forms upon the surface a highly fibrinous exudate (false membrane).

In *diphtheritic inflammation* the mucous membrane is destroyed and the false membrane invades the submucous tissue. Diphtheritic inflammation is due to a specific bacillus.

Classification of Inflammations.—The various forms of inflammations are—(1) *Simple* or *common*, that which is due to any ordinary traumatic, chemical, thermal, or actinic cause, and not to bacteria. An instance of simple inflammation is traumatic periostitis or sun dermatitis. It does not tend particularly to spread. Often the cause of a simple inflammation is momentary in action; (2) *infective* or *specific*, that which is due to micro-organisms, as the streptococcus of erysipelas. An unsuccessful attempt has been made to charge all inflammations to bacteria. It is true that bacteria can generally be found in inflammatory areas, but that they are the only causes of inflammation is accepted by few. Infective inflammations often tend to spread widely; (3) *traumatic*, which is due to a blow or an injury; (4) *idiopathic*, which is without an ascertainable cause. There is certainly a cause, even if it cannot be pointed out, and the term "idiopathic" means that we do not know the cause; (5) *acute*, which is rapid in course and violent in action; (6) *chronic*, which follows a prolonged course; (7) *subacute*, which is intermediate in violence and duration between acute and chronic; (8) *sthenic*, characterized by high action; it occurs in strong young subjects; (9) *asthenic* or *adynamic*, occurring in the old, the debilitated, and the broken down. In such an inflammation there is no certain limitation of the inflammation by leukocytes, and there is an indisposition on the part of the tissue-cells to form fibroblasts; (10) *parenchymatous*, affecting the "parenchyma," or active cells of an organ; (11) *interstitial*, affecting the connective-tissue stroma of an organ; (12) *serous*, characterized by profuse non-coagulating exudation (as in pleuritis) or by marked inflammatory edema; (13) *plastic*, *adhesive*, or *fibrinous*, characterized by an exudation which glues together adjacent surfaces, as in peritonitis; (14) *purulent*, *phlegmonous*, or *suppurative*, when pyogenic cocci are present

and multiply; (15) *hemorrhagic*, when the exudate contains many red blood-cells, as in strangulated hernia and in the pustules of black small-pox; (16) *croupous*, when an inflammation produces upon the surface of a tissue a fibrinous exudate which cannot be organized into tissue, and which is due to the action of micro-organisms. An exudate of this character was called by the older surgeons "*aplastic lymph*." It occurs most usually on mucous membrane; (17) *diphtheritic*, which differs from croupous in the fact that the false membrane is in the tissue rather than upon it; (18) *gangrenous*, an inflammation resulting in death of the part, the gangrene being due to the tension of the exudate or the virulence of the poison; (19) *healthy*, when the tendency is to repair; (20) *unhealthy*, when the tendency is to destruction; (21) *latent*, an inflammation which for some time does not announce itself by any obvious symptoms, as the inflammation of Peyer's patches in typhoid fever; (22) *contagious*, when its own secretions can propagate it; (23) *dry*, without exudation; (24) *hypostatic*, arising in a region of passive congestion (as a bed-sore); (25) *malignant*, due to a malignant growth; (26) *catarrhal*, affecting a mucous membrane; (27) *neuropathic*, due to impairment of the trophic functions of the nervous system, as in perforating ulcer; and (28) *sympathetic* or *reflex*, due to disease or injury of a distant part, as when orchitis follows mumps.

Extension of Inflammation.—Inflammation extends by continuity of structure, by contiguity of structure, by the blood, and by the lymphatics. Extension by continuity is seen in phlebitis. Extension by contiguity is seen when a cutaneous inflammation advances and attacks deeper structures. Extension by the blood is seen in the formation of the small-pox exanthem. Extension by the lymphatics is witnessed in a bubo following chancroid.

Terminations of Inflammation.—Inflammation may be followed by a return of the tissues to health, and this return may take place by delitescence, by resolution, or by new growth. By *delitescence* is meant abrupt termination at an early stage, as when quinsy is aborted by the administration of quinin and morphin, and the production of a sweat; *resolution* means the gradual disappearance of the symptoms when inflammation has passed through its regular stages; and *new growth* means that an inflammation has lasted a considerable time, with ample blood-supply and without suppuration, and has gone on to the formation of fibroblasts, granulation tissue, and fibrous tissue. Inflammation may be followed by death of the inflamed part or necrosis. Death of the part may be due to suppuration, ulceration, or gangrene.

The **causes of inflammation** are—*predisposing*, or those residing in the tissues, and rendering them liable to inflame; and *exciting*, or those which directly awake the process into activity. The first may be thought of as furnishing inflammable material; the second may be regarded as sparks of fire.

Predisposing causes are those which impair the general vigor, injure the blood, weaken the tissues, or lower nutritive activities. Among these causes are shock, hemorrhage, nervous irritation, gout, rheumatism, diabetes, Bright's disease, alcoholism, and syphilis. Plethora renders a person liable to sthenic inflammations (those characterized by high action). Tissue debility renders one prone to adynamic or asthenic inflammations. Nerve injury predisposes to inflammation, either from damage to trophic nerves and consequent failure in tissue nutrition and resistance or because analgesia exists and irritants which reach the region are not recognized and are allowed to remain. For instance, if the conjunctiva is in a condition of analgesia, the presence of foreign bodies is not noticed and destructive inflammation may result from their non-removal.

After removal of the Gasserian ganglion the cornea is devoid of sensation, the flow of tears is lessened, dust gathers in the eye, and if not removed by irrigation or kept out by a shield, inflammation and disastrous ulceration will ensue.

Exciting Causes.—The exciting causes of inflammation are—*traumatic*, as blows and mechanical irritation; *chemical*, as the stings of insects, the rubefacient effects of mustard, venom of serpents, products of bacteria, ivy poison, etc.; *thermal*, heat and cold; *specific*, the micro-organisms, causing, for instance, tuberculous peritonitis or erysipelas; and *nervous*, nerve stimulation certainly being capable of producing hyperemia and sometimes even inflammation. Inflammation due to nerve stimulation is seen in herpes zoster and in the swollen and discolored skin over an inflamed joint (Adami). Inflammation may also be induced by electric currents, by the *x*-rays, by radium rays, and by the actinic rays of sunlight and of electric light.

Some writers insist that every inflammation is due to the action of micro-organisms, but this statement lacks proof. They maintain that inflammation is a destructive microbic process which cannot bring about repair, and that repair begins only when inflammation ends. As Adami points out, the advocates of this view argue that swelling, pain, and discoloration point to the existence of inflammation; that repair can take place when these phenomena are absent, hence inflammation is not present when repair begins. As a matter of fact, swelling, discoloration, and pain are phenomena often but not invariably associated with inflammation; and in inflammation one or all of these phenomena may be absent. Because these signs are not discovered is no proof that inflammation does not exist. I believe that inflammation is not always due to microbes and is not always a destructive process, but may be from the start conservative and reparative. It is the reaction of the tissue to injury and is the first step on the road to repair.[1]

Symptoms of Acute Inflammation.—Inflammation, if at all severe, announces its presence by symptoms which are both *local* and *constitutional*.

Local Symptoms of Acute Inflammation.—The most prominent local symptoms were known centuries ago to the famous Roman, Celsus, who stated them as "*rubor, calor cum tumore et dolore*"—redness and heat with swelling and pain. As set forth to-day, the local symptoms are: (1) heat; (2) pain; (3) discoloration; (4) swelling; (5) disordered function; and (6) muscular rigidity, which is noted in inflammation of certain regions and structures.

Heat is due to the passage of an increased quantity of blood through the damaged area and to the arrival at the surface of the body of warm blood from internal parts. Although an inflamed part may be, and usually is, warmer than the surrounding parts, its temperature is never greater than the temperature of the blood. This increase of heat is especially noticeable when we, for instance, touch an arm affected with erysipelas and contrast the sensation obtained with that obtained by placing the hand on the sound arm. The diseased arm feels much warmer to the examining hand than does the sound arm, but its temperature is not above the general body temperature. An extremity in health, as is well known, shows on the surface a temperature below that of the blood; in an inflamed state the temperature may nearly equal that of the blood. Heat is always present in inflammation of a superficial part. The surgeon examines for heat by placing his hand upon the suspected area and then placing the same hand upon a corresponding portion of the opposite side of the patient in order to note the contrast. If great accuracy is desired, a surface thermometer is used.

Pain is a constant and conspicuous symptom. It is due to stretching of or pressure upon nerves from exudate; to irritation of nerves; or to inflam-

[1] See Adami's masterly article in Allbutt's "System of Medicine."

mation of the nerves themselves, producing cellular changes. Pain is associated with *tenderness* (pain on pressure), it is aggravated by motion and by a dependent position of the part, and it varies in degree and in character. In serous membranes it is acute and lancinating, like dagger-thrusts; in connective tissue it is acute and throbbing; in large organs it is dull and heavy; in the bone it is gnawing or boring; in the skin and mucous membrane it is itching, burning, smarting, or stinging; in the urethra it is scalding; in the testicle it is sickening or nauseating; in the teeth it is throbbing; and in inflammation under dense fascia it is pulsatile. Pain in inflammation after presenting itself in one form may change in character. If a pain becomes markedly throbbing, suppuration may be anticipated. Pain does not always occur only at the seat of trouble, but may be felt also at some distant point. Usually there is also pain at the seat of disease. Sometimes no pain is complained of in that region. I have seen pain in the right sciatic region dependent upon a chronically inflamed appendix, no complaint having been made of pain in the abdomen. This is known as a "*sympathetic*" or *referred pain*, and is due to the fact that the area to which pain is referred receives its nerve-supply from the same spinal segment as does the inflamed area; in other words, there is a nervous communication between the inflamed part and a distant area. In many cases of sympathetic pain a nerve-trunk refers the sense of pain to its peripheral distribution, but sometimes pain is referred to an adjacent nerve, a distant nerve, or even, perhaps, to a nerve on the opposite side of the body. Tenderness, however, is detected at the seat of trouble, whether or not it exists at the seat of referred pain.

Pain of hepatitis is often felt in the right shoulder. Pain at the point of the right shoulder or in the shoulder-blade is felt also in gall-stones, cholecystitis, and in cancer of the liver. The pain arises in filaments of the pneumogastric from the hepatic plexus.

Pain of coxalgia is often felt on the inside of the knee, because the obturator nerve, which sends a branch to the ligamentum teres, also sends a branch to the interior and to the inner side of the knee-joint.

Inflammation of an eye with increased tension causes browache. *Inflammation of the anus, uterus, tubes,* or *ovaries* may cause sacral backache. *Pain of rectal inflammation* may be referred to the back of the sacrum, down the thighs, to the penis and to the perineum. I have seen pain in the heel as a symptom of rectal cancer. *Pain of inflammation of the sacro-iliac joint* may be referred to the sciatic nerve and its branches. *Inflammation of the prostate and neck of the bladder* causes pain in the head of the penis, and often pain in the lower abdomen and loin. *Inflammation of a testicle or epididymis* cause pain in the groin, and often also in the abdomen, back, and thighs. *Renal calculus and pyelitis* cause pain in and retraction of the testicle, and pain in the loin, groin, or thigh.

If the covering of an organ is involved, pain becomes more violent; for instance, hepatitis becomes much more painful when the perihepatic structures are attacked. Inflammation without pain is known as "latent" (as the inflammation of Peyer's patches in typhoid). The sudden disappearance of inflammatory pain, when not due to the administration of opiates, suggests the possibility of gangrene, because analgesia exists in gangrene. The characteristics of inflammatory pain are that it comes on gradually, has a fixed seat, is continuous, is attended by other inflammatory symptoms, and is increased by motion, by pressure, and by a dependent position of the part. If there be no tenderness in a part, the source of the pain is not local inflammation; but tenderness may exist when there is no local inflammation, as in an area to which pain is referred from a distant part. Pain of an inflammation which does not involve a nerve does not correspond to an exact nervous dis-

tribution. If pain corresponds exactly to the area of a nerve's distribution, the cause of it is acting on the nerve-trunk or on its roots. If the cutaneous surface is involved, the lightest touch causes pain. The surface may be extremely hyperesthetic even when it is not inflamed, the condition resulting from deep-seated or distant inflammation. Areas of hyperesthesia of the skin of the abdomen are noted in various visceral inflammations. Such hyperesthesia is due to referred impressions. If touching the skin produces no pain, but deep pressure does produce it, the deeper structures are the source. Pain in muscle and ligament is developed by motion; in muscle, by contraction, but not by passive movements with the muscle relaxed; in ligament pain is developed by active or passive movements which stretch the ligament. If, for example, a man with a stiff neck has pain on the right side of the back of his neck on voluntarily turning his face toward the left shoulder, but is without pain when his face is turned by the surgeon, who, conversely, induces pain by turning the patient's face far to the right, this condition indicates the trouble to be muscular. If, however, no pain arises on turning the face to the right, but it is manifest on turning the face actively or passively to the left, the pain is in those ligaments which stretch when the face is turned to the left.[1] In inflammation of the synovial membrane even gentle passive motion in any direction causes pain.

The pain of colic differs from that of inflammation. It is sudden in onset, intermits, recurs in paroxysms, and is relieved by pressure. The pain of inflammation is gradual in onset, is continuous, and is made worse by pressure. The pain of neuralgia is often preceded by cutaneous anesthesia of the skin of the part, is very paroxysmal, comes on suddenly, darts through recognized nerve-areas, the attack lasts some hours, and is apt to recur at a certain hour. It presents no general tenderness, as does inflammation, but there may be several points which are acutely sensitive to pressure (Valleix's *points douloureux*). The tender spots of Valleix are met with in *inveterate* neuralgia, and occur at points where nerves "pass from a deeper to a more superficial level, and particularly where they emerge from bony canals or pierce fibrous fasciæ."[2]

Pain is often of great value by calling attention to parts diseased; but it may be a terrible evil, racking the organism and even causing death. If pain continues long, it becomes in itself formidable: it prevents sleep, it destroys appetite, and it deteriorates the mind, and one of the surgeon's highest duties is to relieve it. The *physiognomy or expression of physical pain* presents the following characteristics: Heavy fulness about the eyes, dropping of the angles of the mouth, and the aspect of fatigue. The victim of pain may be restless, but in severe inflammation he is apt to assume some fixed posture. He may be anemic. There may be widespread tremor, muscular twitches, or muscular rigidity. The absence of the physiognomy of pain in a person who complains of great agony is a strong indication that the patient exaggerates the gravity of his sufferings or deliberately deceives.

Discoloration arises from determination of blood to the part; hence the more vascular the tissue, the greater the discoloration. A non-vascular tissue presents no discoloration, though we usually find discoloration adjacent in the zone of blood-vessels which furnish the tissue with nutriment. Discoloration in vascular tissue is most intense at the focus or center of the inflammation. Discoloration varies in tint and in character according to the tissue implicated and the nature of the inflammation. It may be circumscribed or diffuse. Arborescent redness means a distribution in dendritic lines. Linear discoloration signifies redness running in straight lines, as in phlebitis. Punctiform discoloration occurs in points, and is due to vascular rupture. Maculiform redness resembles an ecchymosis or blotch. Dusky discoloration points to suppuration.

[1] "Surgical Diagnosis," by A. Pearce Gould.

[2] Anstie, "Neuralgia and Diseases which Resemble It."

Inflammation of the throat and skin produces scarlet discoloration; inflammation of the sclerotic coat of the eye and of the fibrous coat of muscle produces lilac or bluish discoloration; inflammation of the iris produces brick-dust, grayish, or brown discoloration; erysipelas causes a yellowish-red discoloration; secondary syphilis causes a copper-hued discoloration; and tonsillitis causes a livid discoloration. A tuberculous ulcer is of a purple color on the edge. Gangrene is shown by a black discoloration. A scorbutic ulcer is surrounded by an area of violet color.

Redness as a sign of inflammation must be permanent and joined with other symptoms. Redness due to inflammation disappears on pressure, but returns when the pressure has been removed. If redness is due to staining of the surface by dye, pigmentation, or extravasation of blood, pressure will not blanch the spot. If on taking off pressure the redness of inflammation rapidly returns, the circulation is active; if, on the contrary, it very slowly reappears, the circulation is very sluggish and gangrene is threatened. Subcutaneous hemorrhage gives rise to a purple-red color which does not fade when subjected to pressure. Stains of the surface by dyes fail to disappear on pressure, are distributed over a considerable surface, show a hue which is uniform throughout, are obviously superficial, are not associated with other signs of inflammation, and can be washed away.

A. Pearce Gould, in his excellent little work upon "Surgical Diagnosis," tells us that the color of a hyperemic surface may furnish important information. Lividity may mean failure of the heart and lungs, or simply venous congestion in the part. In lividity from obstruction of the lungs or heart the color slowly returns after pressure has driven it out. In lividity due to local congestion the color quickly returns when pressure is released and the dilated veins are often distinctly visible. Of course, in a local trouble, when the circulation becomes impaired to such a degree that gangrene is threatened, the lividity fades very slowly on pressure and reappears very slowly on the release of pressure.

Swelling or *tumefaction* is due in small part to vascular distention, but chiefly to effusion and cell multiplication. The more loose cellular material a part contains, the more it swells; hence the eyelids, scrotum, vulva, tonsils, glottis, and conjunctivæ swell very greatly when inflamed. A swelling is soft or edematous when due to uncoagulated effusion; is brawny and doughy when due to coagulated effusion; is hard and elastic when produced by proliferating cells. Swelling may do good by unloading the vessels and acting like a blister or local bleeding, or it may do great harm by pressing upon the vessels and cutting off the blood-supply. Swelling of the conjunctiva, or chemosis, may cause sloughing of the cornea, and swelling of the prepuce may cause gangrene. A swelling may do harm by obstructing an aperture, as in edema of the glottis, when the larynx becomes blocked; or by compression of a normal channel, as in the swelling of the perineum when the urethra is compressed. The cutaneous surface over a swollen area may become covered with blisters or blebs. This condition is noted particularly after burns and fractures.

Disordered function is always present in inflammation. It may be manifested by *increased tenderness* or sensibility; a slight touch, it may be, producing torturing pain. This condition is called *hyperesthesia*. Parts almost or entirely destitute of feeling when healthy (as tendons, ligaments, and bones) become highly sensitive when inflamed. It may be manifested by *increased irritability*. In dysentery the colon repeatedly contracts and expels its contents; the stomach does likewise in gastritis; and the bladder acts similarly in cystitis. Spasmodic twitching of the eyelids occurs in conjunctivitis, and twitching of the muscles of a limb after fracture and amputation.

Impairment of Special Function.—In inflammation of the eye, when an attempt is made to look at objects the lids close spasmodically, and even a little light causes great pain and lacrimation (photophobia). In inflammation of the ear noises cause great suffering, and even when in a quiet room the patient has subjective buzzing and roaring in his ears (tinnitus aurium). In coryza the sense of smell, in glossitis the sense of taste, in dermatitis the sense of touch, and in laryngitis the voice may be lost. In inflammation of the brain the mind is disordered; in arthritis the joints can scarcely be moved; and in myositis it is difficult and painful to employ the muscles.

Derangement of Secretions.—In dermatitis the sweat is not thrown off; in hepatitis bile is not properly secreted; and in nephritis urea is not satisfactorily removed. The secretions may undergo important changes of composition. The sputum in pneumonia is rusty, and dysentery causes a discharge of bloody mucus.

Derangement of Absorbents.—In the height of an inflammation the absorbents are blocked and clogged by coagulated exudate, and they cannot perform their offices.

Muscular rigidity is sometimes an important sign of inflammation. If a joint is inflamed, the muscles which move the joint are rigid and the joint is more or less immobile. In inflammation of the peritoneum the abdominal muscles are rigid, and the respirations become shallow, frequent, and thoracic. In pleuritis the intercostal muscles of the inflamed side become rigid and the respiratory excursion of the chest is limited. Rigidity serves to lessen motion, prevent pain, protect the part, and so gives physiological rest.

Constitutional Symptoms of Acute Inflammation.—The chief constitutional symptoms of acute inflammation are elevated temperature and leukocytosis. Constitutional symptoms may be absent, and often are in moderate or limited inflammations; but in severe, extensive, or infective inflammations the symptom group known as *fever* is certain to exist. This is known as *symptomatic*, or *inflammatory fever*, and it arises in non-septic cases from the absorption of aseptic pyrogenous exudate, and in microbic inflammations from the absorption of pyrogenous toxic products of bacterial action. In young and robust individuals an acute non-microbic inflammation causes a fever characterized by full, strong pulse, flushed face, coated tongue, dry skin, nausea, constipation, and possible acute delirium (the *sthenic type* of the older authors). In broken-down and exhausted individuals an ordinary inflammation, and in any individual a bacterial inflammation, may cause a fever with typhoid symptoms (the *typhoid*, *asthenic*, or *adynamic type*). Fibrin ferment is obtained from the white corpuscles; it is liberated as the corpuscles break up in the exudate, and acting on the liquor sanguinis cause the union of calcium and fibrinogen and the formation of fibrin. The absorption of fibrin ferment many believe causes aseptic fever (see page 129). Inflammatory blood contains an increased amount of albumin and salts. If a person with inflammatory fever is bled, the blood coagulates rapidly, the clot sinks, and there is found on the surface a cup-shaped coat, made up of liquor sanguinis and white cells, known as the "*buffy coat*"; but this is not really a sign of inflammation, and occurs normally in the blood of the horse. The buffy coat forms when blood contains a great number of leukocytes, because these leukocytes sink more slowly than do the red corpuscles. Cupping occurs because the white corpuscles sink more slowly by the side of the tube than far from the sides.

Leukocytosis.—In many inflammatory and infectious diseases leukocytosis is noted. It probably indicates an attempt on the part of the organism to protect itself from noxious materials. Leukocytosis is usually much more marked if pus exists than if the exudation is serous or fibrinous.

"The degree of leukocytosis may be considered a general index to the in-

tensity of the infection and to the strength of the individual's resisting powers in reacting against it. It follows, therefore, that intense infections occurring in individuals whose resisting powers are strong, produce a decided increase; but the presence of an infection of like intensity in one whose resisting powers are greatly crippled fails to cause leukocytosis, for in such an instance the organism is so overpowered by the effects of the morbid process that it is incapable of reacting" ("Clinical Hematology," by J. C. DaCosta, Jr.). We see from the above that gangrene or any other virulent infection may be accompanied by a low leukocyte count, and when pus is surrounded by a thick wall the leukocytes may be normal or nearly normal in number. An increased proportion of polymorphonuclear leukocytes strongly suggests body reaction against infection, and an increase of eosinophiles aids us in recognizing deep-seated pus when the leukocyte count is normal or but slightly increased.

The introduction of salt solution into the peritoneal cavity leads to the gathering of numbers of white cells, and the resistance of the serous membrane to infection is increased. Horse-serum that has been boiled is said by Petit to be a valuable material to draw polynuclear leukocytes to a part ("Med. Record," June 22, 1907). It has been injected into the peritoneal cavity the evening before an operation (30 c.c.); it has been poured into the cavity at the termination of an operation; the gauze used for drainage after an appendicitis operation has been soaked in it.

There is no fixed number of leukocytes which causes us to affirm the presence or absence of gangrene or pus. Most serious inflammations show marked inflammatory leukocytosis and an increase in the relative proportion of polynuclear cells. Typhoid shows no leukocytosis and even a mixed infection shows comparatively little increase of polynuclear cells. The same is true of tuberculosis. The same man should make all the counts on one patient; at least five hundred cells should be counted and several examinations ought to be made.

Chronic Inflammation.—This condition results from the action on the tissues of some mild but long-acting irritant. It progresses slowly and does not produce symptoms of severity either in the part or the body at large.

Causes.—Blood diseases, as rheumatism and gout; infective diseases, as tuberculosis and syphilis; retained pus in an ill-drained abscess; blocking of the duct of a gland; the retention of a foreign body in a part; the flow of an irritant secretion (as saliva from a fistula); repeated identical traumatisms of an occupation, etc. W. Watson Cheyne tells us that chronic inflammation is not due to the ordinary pyogenic organisms (see Cheyne's article on Treves's "System of Surgery").

Tissue Changes.—These changes are practically the same as in acute inflammation, but take place far less rapidly. Vascular dilatation, exudation, and leukocytic migration are often trivial. Cell proliferation is always conspicuously marked. It is maintained by Cheyne and others that typical granulation tissue does not form, the tissues of the part being replaced directly by fibrous tissue. The amount of fibrous tissue produced is relatively very great. This tissue may cause permanent thickening, or may contract and thus diminish the size of a part. Contraction is very considerable in cirrhosis of the liver and in interstitial nephritis.

Symptoms.—Pain varying in intensity and character; tenderness; great swelling, which in some cases is followed by shrinking, and is usually indurated or brawny. As a matter of fact, great swelling is the most usual symptom. Sometimes there is a trivial amount of heat. There is rarely discoloration unless the skin is itself inflamed, but usually the surface veins are distinctly, and sometimes they are greatly, distended. There are no constitutional symptoms attributable purely to the inflammation. If there are such symp-

toms, they are due to the disease which induced the inflammation or to interference with the function of an organ because of the fibrous mass. (For the treatment of chronic inflammation see articles upon special regions and particular structures.)

Treatment of Acute Inflammation.—The first rule in treating an inflammation must be to remove the exciting cause. If this cause is a splinter in the part, take out the splinter; if it is a foreign body in the eye, remove the foreign body; if urine is extravasated, open and drain; take off pressure from a corn; pull out an ingrown nail; and remove microbes from an infected area by draining, irrigating, and perhaps by applying antiseptics. The rule, remove the cause, applies to a chronic as well as to an acute inflammation. If the cause of an inflammation was momentary in action (as a blow), we cannot remove it, for it has already ceased to exist. After removing the cause, endeavor to bring about a cure by local and constitutional treatment.

Local Treatment of Inflammation.—It must be remembered that the division of inflammation into stages is natural, and not artificial, and that a remedy which does good in one stage may do harm in another. Certain agents are suited to all stages of an acute inflammation, namely, *rest* and *elevation*. In many inflammatory conditions nature seeks to immobilize, protect, and rest the part by increasing the tension of adjacent muscles. By this muscular rigidity inflamed joints are fixed and rested. Rigidity of the intercostal muscles in pleuritis limits chest motion and pain; rigidity of the abdominal muscles in peritonitis limits abdominal movements and lessens suffering.

Rest.—Physiological rest is of infinite importance, and is always indicated in acute inflammation. In the exercise of function blood is taken to a part and an existing inflammation is aggravated. Further, as Billroth has pointed out, rest prevents the dissemination of infection, because motion exposes fresh surfaces to inoculation and breaks down protective barriers of leukocytes. Its principles were first thoroughly studied by Hilton.[1] Baron Larrey, the celebrated military surgeon of the Napoleonic Empire, anticipated many modern views on this subject. He insisted on the necessity of rest in the treatment of wounds; he believed that rest permitted Nature to perform her work unhampered; he was accustomed to leave a "first dressing," if properly applied, undisturbed for several or even for many days. He believed it advisable to associate with rest well adjusted and judicious compression made by bandages, especially flannel bandages. (The author, on Baron Larrey, in "Johns Hopkins Hospital Bulletin," July, 1906.) The means of securing rest differ with the structure or the part diseased. When rest is used, do not employ it too long. *Rest in bed* diminishes the amount of blood sent to an inflamed part and lessens the force of the circulation; hence it antagonizes stasis. It has been shown that the heart beats at least fifteen times per minute less when the patient is recumbent than when he is erect. The saving of strength and the benefit of the local condition are thus seen to be enormous. In fact, the heart saves at least twenty-one thousand beats a day. In every severe inflammation insist on the patient going to bed.

In *cerebral concussion* rest must be secured by quiet, by darkness, by the avoidance of stimulants and meat, by the application of ice to the head, and by the use of purgatives to prevent reflex disturbance and the circulation of poisons in the blood. In *inflamed joints* rest must be obtained by proper position, associated in many cases with the adjustment of splints or plaster of Paris, or the employment of extension.

In *pleuritis* partial rest can be secured by strapping the affected side with adhesive plaster, or by using a bandage or a binder to limit respiratory movements. In *fractures* Nature procures rest by her splints—the *callus*—and

[1] "Lectures upon Rest and Pain."

the surgeon procures rest by his splints—firm dressings or extension. In *cancer of the rectum* and *intractable rectitis* a colostomy secures rest for the inflamed and damaged bowel. In *enteritis* opium gives rest to the bowel by stopping peristalsis. In *cystitis* rest is obtained by the administration of opium and belladonna, which paralyze the muscular fibers of the bladder. The use of the catheter gives rest to the bladder by removing urine. A cystostomy allows complete rest by permitting the bladder to suspend its function as a reservoir of urine. In cystitis from *vesical calculus* rest is obtained by incising the bladder, removing the stone, and draining, or by crushing and evacuating the stone. In *inflamed mucous membrane* rest from the contact of irritants is secured by touching the membrane with silver nitrate, which forms a protective coat of coagulated albumin. Opening an *abscess* gives its walls rest from tension. In *inflammations of the eye* light must be excluded to obtain complete rest, but tolerably satisfactory rest is given in some cases by the use of glasses of a peacock-blue tint. In *aneurysm* the operation of ligation cuts off the blood-current and gives rest to the sac. In *hernia* the operation gives rest from pressure. Instances of the value of rest could be multiplied indefinitely.

Relaxation is in reality a form of rest, and consists in placing the part in an easy position. In *synovitis of the knee* semiflexion of the knee-joint lessens the pain. In *muscular inflammation* relaxation relieves the pain.

Elevation partly restores circulatory equilibrium. A *felon* is less painful when the hand is held up in a sling than when it is dependent. A *congestive headache* is worse during recumbency. A *gouty inflammation* in the great toe is more painful with the foot lowered than when it is raised. A *toothache* becomes worse on lying down.

Certain agents are suited to the stage of vascular engorgement, increased arterial tension, and beginning effusion. These agents are—(1) local bleeding or depletion; (2) cold.

Local Bleeding.—Local bleeding, or *depletion*, is the abstraction of blood from the inflamed area. This abstraction relieves circulatory retardation and causes the blood to move rapidly onward. The corpuscles clinging to the vessel walls are washed away, the capillaries shrink to their natural size, and the exudate is absorbed. In other words, local blood-letting increases the rate of the circulation, though not its force.

The *methods of bleeding locally* are—(*a*) puncture; (*b*) scarification; (*c*) leeching; (*d*) cupping.

Puncture is recommended in inflammation, not only because it abstracts blood locally, but also because it gives an exit to effusion under fibrous membranes. It is very useful in relieving tension—for instance, in epididymitis. It is performed with a tenotome and with aseptic precautions. If numerous punctures are made, the procedure is termed "multiple puncture." This is very useful when applied to the inflamed area around a leg ulcer. The late Prof. Joseph Pancoast was very fond of employing multiple punctures, designating the operation "the antiphlogistic touch of the therapeutic knife."

Scarification or Incision.—By means of scarification we bleed locally, evacuate exudate, and relieve tension. One cut or many cuts may be made, and these cuts may be deep or may not go entirely through the skin, according to circumstances. Multiple incisions are useful when applied to inflamed ulcers, tissues in danger of gangrene, and to almost any condition of great tension. Scarification is of notable value when edema of the glottis exists. Free incision is of great benefit in periostitis and in threatened gangrene. In osteomyelitis the medullary canal must be promptly opened.

Leeching.—Leeches must not be applied to a region plentifully endowed with loose cellular tissue, as great swelling and discoloration are sure to ensue. These regions are the prepuce, labia majora, scrotum, and eyelids. Leeches

should never be applied to the face (because of the scar), near specific sores or inflammations, nor over a superficial artery, vein, or nerve. A leech is best applied at the periphery of an inflammation and between an inflammation and the heart. To leech at the inflammatory focus only aggravates the trouble. Before applying leeches, wash the part and shave it if hairy. Place the leech in a test-tube or an inverted wine-glass, inserting the tail or thick end first, and invert the tube so that the leech's head will come in contact with the prepared skin. The leech is restrained in the tube until it "takes hold" and begins to feed, when the tube is removed. If the leeches will not bite, smear the part with milk or a little blood. Never pull off a leech; let it drop off. It will usually drop off when full, but if it refuses to do so, sprinkle it with salt. After removing a leech, employ warm fomentations if continued bleeding is desired. Sometimes the bleeding persists or recurs. Weill and Mouriquand ("Press. Médicale," Paris, No. 1, 1911) report 6 cases of severe bleeding. Bleeding can usually be arrested by styptic cotton and pressure. In some rare cases the bleeding continues in spite of pressure. This is due to the fact that the tissue contains a considerable quantity of a material secreted from the throat of the leech, which material prevents coagulation of blood. In such a case excise the bite and the area of tissue adjacent to it, and suture the wound. Leeching leaves permanent triangular scars. The Swedish leech, which is preferred to the American, draws from 2 to 4 drams of blood. After a leech has been removed, if we desire to use it again, place it in salt water. This causes it to vomit the blood which it has taken up. Leeching has both a constitutional and a local effect. It is at present used comparatively rarely, but it is employed by some practitioners over the spermatic cord in epididymitis, on the temple in ocular inflammation, and over the right iliac region to relieve pain in mild cases of appendicitis.

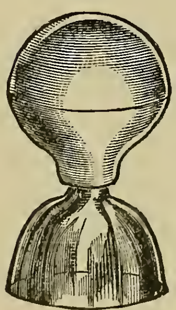

Fig. 49.—Rubber bulb cupper.

Cupping.—Dry cups deviate blood from a deeply placed inflamed area to the surface. Wet cups actually remove blood.

Dry cups are applied without first incising the skin. One or more may be applied. A special instrument is sold in the shops for the performance of dry cupping. It consists of a glass bell, with a globular and hollow top of rubber (Fig. 49). The rubber is emptied of air by squeezing. The glass bulb, the edges of which have been greased, is pushed upon the skin, and the compression is relaxed upon the rubber bulb. A partial vacuum is created, and an area of skin and subcutaneous tissue full of blood rises into the glass bell.

Cupping can be easily performed by means of a tumbler. The edge of the glass is greased; a bit of blotting-paper wet with alcohol is placed in the bottom of the tumbler and lighted. After a brief period the glass is inverted and placed upon the skin, which has been dampened with warm water. As the air in the glass cools the tissues rise into the partial vacuum.

Wet cups draw blood, and the skin should be cleansed before they are applied. In wet cupping apply a cup for a moment, remove it, incise or puncture the skin, and replace the cup to draw the requisite amount of blood. Incisions may be made by an ordinary scalpel, a lancet, or a scarificator, a cup being then applied. An excellent scarificator is shown in Fig. 50. In this instrument concealed blades are thrown out by touching a spring. Baron Heurteloup devised an instrument (Fig. 51) in which the incision is made by a scarificator. The blood is drawn out by a pump, the tube being placed upon the cut area and the withdrawal of the piston creating a vacuum. This instrument is known as the "artificial leech." After scarification and the application

of the cup, the partial vacuum draws blood into the cup; when the wounds cease to bleed the cup is removed, and if further bleeding is thought desirable, the clots are wiped away and the cup is again applied, and after its removal warm fomentations are used. Wet cupping is of value in pleuritis, pericarditis, and nephritis.

Cold is a very powerful and useful agent if used judiciously and applied at the proper time. It is valuable because of its reflex effect upon the vessels of the inflamed area rather than because of direct action upon the cells of a part. It should only be used early in the case, that is, before stasis occurs. It is not to be used in the later stages of inflammation, for it will then only aggravate the existing state; in fact, when there is considerable exudation cold does actual harm.

Cold acts by constricting the vessels of a hyperemic area, thus lessening the amount of blood sent to the part, and preventing the evolution of the process into the stage of stasis and exudation. Further, it prevents the migration of leukocytes, retards cell-proliferation, relieves pain and tension, and lowers temperature. If cold is too intense, if it is kept too long applied, if it is used too late in an inflammation, if it is used upon an old or feeble patient, or if it is employed when there is much exudation or a condition of tissue strangulation, it does actual harm. It lessens the nutritive activity of cells, constricts

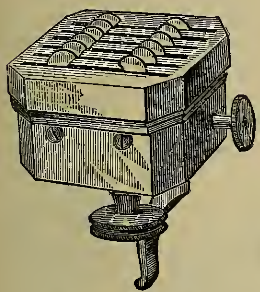

Fig. 50.—Scarificator.

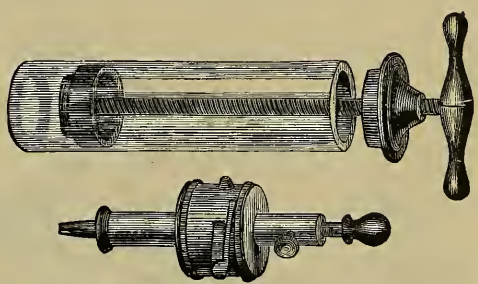

Fig. 51.—Heurteloup's artificial leech.

the lymph-spaces and channels, increases existing stasis, hence lowers the vitality of the tissues, and may cause gangrene. If the parts are constricted, as in strangulated hernia, or if they are compressed by a large exudate or fed by diseased blood-vessels, or if the patient is old or exhausted, cold is particularly apt to cause gangrene. Cold should not be used in a bacterial inflammation. In such an inflammation it is desirable that quantities of active leukocytes should come to the part. These phagocytes destroy bacteria and circumscribe the inflammatory focus. Cold keeps much blood and hence many leukocytes out of the part, lessens the ameboid activity, and prevents migration of the leukocytes which do succeed in arriving. Hence, cold actually favors the spread of a microbic process. Furthermore, it lessens leukocytosis and thus lessens the protective reaction of the tissues. De Nancrede, in his "Principles of Surgery," points out that in an inflammation stasis soon arises at the focus of the inflammation, and there is an area of stasis surrounded by a zone of hyperemia. Cold benefits the hyperemic zone, but aggravates the stasis. De Nancrede cautions us as follows: "Judgment is, therefore, requisite to decide whether the evil at the focus will not outweigh the good exerted at the periphery."[1] De Nancrede further points out that cold must not be used intermittently; but if employed at all, must be continuously applied. If cold is applied intermittently, there will be a reaction whenever it is removed, and this reac-

[1] "Principles of Surgery."

tion causes increased hyperemia. Hence, cold must be "continued in action to prevent reaction." If during the employment of cold the skin becomes purple and congested and the circulation feeble, at once discontinue the use of it, as its continuance will be dangerous.

Cold may be used as wet cold or as dry cold.

Wet cold is easily applied, but it is much more depressing than dry cold, is likely to produce discomfort, macerates the skin, and may lead to the formation of excoriations, etc. A part can be subjected to wet cold by the application of evaporating fluids or the use of a siphon. When wet cold is used inspect the part at frequent intervals, and discontinue the treatment if evidences of stasis become positive. Evaporating fluids are extensively employed. If such a fluid is used, never cover the part with a thick dressing. If this should be done, the fluid will not evaporate with sufficient rapidity to produce cold. A piece of thin muslin or flannel should be moistened with the fluid and laid upon the part, and be kept constantly moist by the application from time to time of small quantities of the liquid. Lead-water and laudanum is used extensively, and probably owes its chief value to the fact that it produces cold on evaporation. Lead-water and laudanum is composed of 1 oz. of laudanum, 1 oz. of liquor plumbi subacetatis, 1 pint of water. Liquor plumbi subacetatis dilutus may be used without laudanum. It is thought that the addition of laudanum tends to allay pain. Coplin demonstrated by a series of laboratory experiments that lead-water and laudanum is a germicide. A solution of ammonium chlorid may be used in the strength of 1 oz. of the drug to 2 quarts of water. If ammonium chlorid is used for more than a short period of time, it is prone to cause the formation of blisters, which are irritable and painful. Cheyne and Burghard use the following formula: ½ oz. of ammonium chlorid, 1 oz. of alcohol, and 7 oz. of water. Plain spring-water, iced water, or a mixture of alcohol and water may be used. The *siphon* is occasionally used. If there is a wound, the fluid which comes in contact with it must be aseptic or antiseptic. We may use sterile water, sterile salt solution, a solution of boric acid, or a solution of acetate of aluminum. In conjunctivitis, cold is applied to the eye by means of linen or muslin soaked in iced water, laid upon the closed lids, and changed frequently.

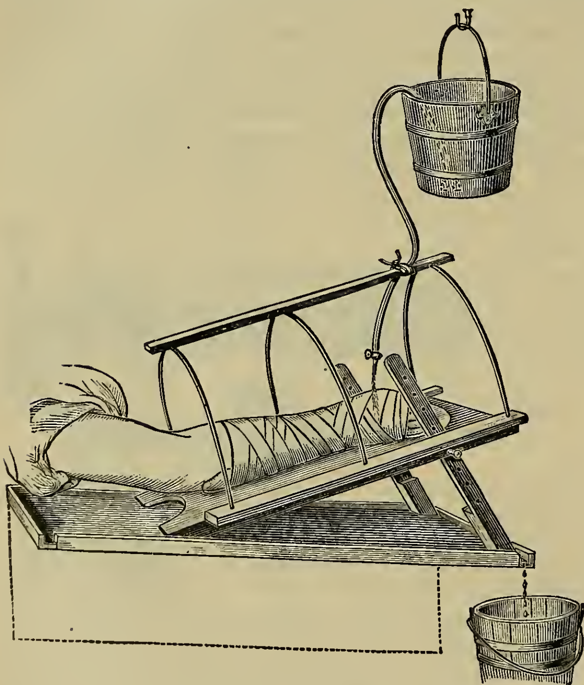

Fig. 52.—Siphon (Esmarch).

To apply wet cold by means of a siphon, the part is covered with one layer of wet linen or muslin, and is laid upon a rubber sheet folded like a trough and

emptying into a bucket. A vessel filled with cold water is placed upon a higher level than the bed. A wet lamp-wick is now taken, one end is inserted into the water of the vessel, and the other end is laid upon the part. Capillary action and gravity combine to keep the part moist. A rubber tube may be used instead of a wick. If a tube is employed, tie it in a knot or clamp it so that the fluid is delivered drop by drop (Fig. 52). Ordinary water or iced water can be used. If the water be too warm, it can be reduced to about 45° F. by adding 1 part of alcohol to every 4 parts of water. A mixture of 5 parts of nitrate of potassium, 5 parts of chlorid of ammonium, and 16 parts of water produces great cold.

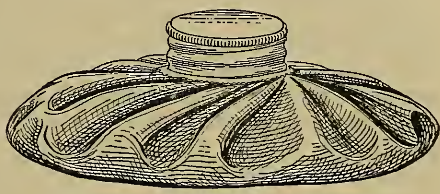

Fig. 53.—Ice-bag (W. E. Ashton).

Dry cold is more manageable and more generally useful than wet cold. It is applied by means of a rubber bag or a bladder filled with ground or finely cracked ice, several folds of flannel being first laid over the part. The flannel collects the moisture from the "sweating" bag and thus prevents maceration of the skin. Further, it saves the tissue from being subjected to too much direct cold and enables us to obtain the beneficial reflex effect. The ice-bag of India-rubber is widely used. We can venture to apply by means of the ice-bag a greater degree of cold than it is proper to apply by the use of fluids, as dry cold is not so likely to induce gangrene as is moist cold. If there is much tenderness, the weight of an ice-bag causes pain, and it is best to suspend it from a frame, so that it lightly touches the part. The frame is the same as is used to keep the bedclothes from contact with a fractured leg, and can be easily made from barrel-hoops. During the time an ice-bag is being used the part must be inspected at brief intervals to see that the circulation is not unduly depressed. The ice-bag is frequently used in joint inflammation, in intracerebral inflammation, in epididymitis, in acute myelitis, and by many in the earliest stage of appendicitis (see page 1016, where the author expresses his disapproval of such a method of treatment). If a joint is sprained, the immediate application of an ice-bag is of great service. A part can be encircled with a rubber tube through which iced water is made to flow (Fig. 54). Even when this apparatus is used the part should first be wrapped in flannel. Leiter's tubes, which are tubes of lead made to fit various regions and which carry a stream of cold water, can also be used. A piece of flannel must be placed between the tube and the skin. The temperature of these tubes can be lowered to any desired degree by lowering the temperature of the circulating fluid. Cheyne and Burghard wisely caution us to use a fluid at a temperature not

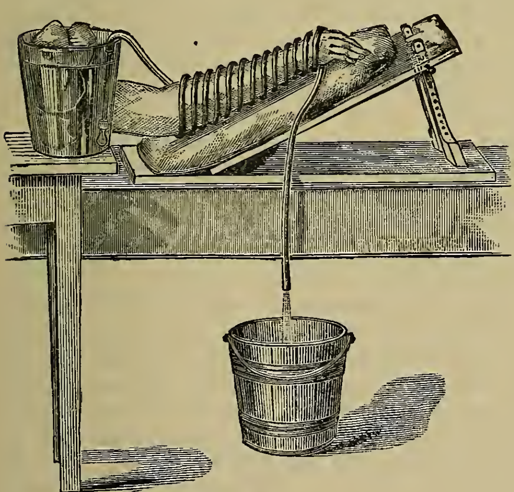

Fig. 54.—The Esmarch cooling coil.

under 50° or 60° F., to inspect the part every three or four hours, and not to employ the tubes longer than twenty-four hours.

Heat is employed by some early in an inflammation. It is rarely beneficial at this stage, except when applied by a hot-air apparatus for the treatment of an injured joint. It is true that a degree of heat which does not actually destroy the tissues will contract the vessels as does cold; but this degree of heat will not be borne by the patient unless but a limited portion of a superficial part is involved.

Certain agents are suited to the stage of fully developed inflammation, when there is a great deal of swelling due to effusion and cell-proliferation. The indication in this stage is to abate swelling by promoting absorption. This is accomplished by (1) compression; (2) local use of astringents and sorbefacients; (3) the douche; (4) massage; (5) heat.

Compression is especially beneficial in fully developed or in chronic inflammation, but it will do good even in the early stages. Compression is of great usefulness; it supports the vessels and causes them to drink up effusion, and it strongly rouses the absorbents. This agent is valuable in most external inflammations with marked swelling, and is particularly beneficial in chronic inflammation. In *erysipelas* of an extremity the part should be elevated and the extremity bandaged from the periphery to the body. In *ulcers*, especially those with hard and blue edges, the use of Martin's elastic bandage or of straps of adhesive plaster gives decided relief. In *chronic inflammation of a joint* elastic compression is of great value. In *epididymitis*, after the acute stage, the testicle may be strapped with adhesive plaster. In *lymphadenitis* compression by a weight or by a bandage is very generally employed. In *fractures* compression not only antagonizes spasm, but also combats the swelling and pain of inflammation. Compression must be judicious; it must never be forcible, and it must not be applied to a limb without including the distal portion of the extremity (never, for instance, strongly compress the elbow without including the hand, nor the palm without bandaging the fingers). Injudicious compression causes severe pain and great edema, and may produce gangrene.

Astringents and Sorbefacients.—Astringents may have direct value in inflammation of the skin, but it is not likely that they have any effect on deep-seated inflammation. When used in evaporating lotions in an earlier stage of inflammation the cold does good rather than the drug. Lead-water and laudanum is extensively employed and it is thought to somewhat allay inflammatory pain. The mixture certainly gives comfort in cutaneous erysipelas. It is very doubtful if lead-water is of any service at any stage of a deep-seated inflammation or in any fully developed inflammation. If used after the first stage it must not be applied as an evaporating lotion, because cold will do harm. Pieces of lint are soaked in the fluid and placed upon the part, and a bandage is applied. The wet lint which has been placed upon the part is covered with oiled silk or a rubber-dam before the bandage is applied. If used in the latter manner, the body-heat is retained in the part. If greater heat is required, a hot-water bag can be placed outside of the bandage. Lead-water, though germicidal, is seldom used in treating wounds, and hot lead-water should not be applied to an area of cutaneous inflammation, as heat increases congestion and does harm to a cutaneous inflammation.

Saturated watery solution of Epsom salt is of real value in inflammation. It is applied as a wet compress covered with rubber-dam. It is moistened every two or three hours and renewed in twenty-four hours, the skin being washed at the time of renewal. In many cases it allays pain and abates swelling. Its use was suggested by Tucker ("Jour. Experimental Med.," May 25, 1907).

Tincture of iodin is astringent, sorbefacient, counterirritant, and germicidal. It must not be used pure. For application to adults it should be diluted with an equal amount of alcohol, and for children with 3 parts of alcohol. In using iodin, paint it upon the part with a camels'-hair brush and fan it dry, applying one or more coats. The repeated application of iodin to the skin is of great benefit in inflammation of the glands, muscles, tendons, joints, and periosteum. Iodin is apt, after a time, to vesicate, and must not be used in full strength, because it is irritant. It is of special value in chronic inflammation. In deep-seated inflammation it acts as a counterirritant.

Nitrate of silver is a non-irritating astringent of considerable value in inflammation of mucous membranes. It forms a protective coat of coagulated albumin, and is much used in treating the throat, mouth, and genital organs. In urethral inflammation a protein compound of silver known as protargol may be used.

Ichthyol is a drug of decided efficiency in reducing inflammatory swelling. It is usually employed in ointments, the strength being from 25 to 50 per cent. It is best exhibited with lanolin. When rubbed in over inflamed glands, joints, and lymphatic enlargements, it is of great value. In children a 25 per cent., and in adults a 50 per cent., ointment should be rubbed in thoroughly twice a day. In inflammatory skin disease, synovitis, thecitis, frost-bite, bubo, chilblain, and in many other conditions, acute or chronic, the use of ichthyol is indicated. The odor of ichthyol is highly disagreeable, and when ordered for a refined person it had better be deodorized. For this purpose Hare uses oil of citronella, 20 minims to 1 oz. of ointment.

Mercurials.—Blue ointment, pure or diluted to various strengths, is extremely valuable. It is spread upon lint and kept applied over areas of fully developed inflammation. It is especially useful in acutely or chronically inflamed joints, glands, tendons, etc. Blue ointment is strongly irritant, and will soon blister or excoriate a tender skin. It is very beneficial in periostitis, and is employed by many surgeons in chronic inflammations.

The **douche** consists of a stream of water falling upon a part from a height. The water may be poured from a receptacle or may run through a tube, and may be either hot or cold. Alternating hot and cold streams are very popular in inflammations of joints and tendons, especially in chronic inflammation. This mode of application is known as the "Scotch douche." It restores the tone of the blood-vessels and plasma-channels and promotes the absorption of inflammatory exudate. If the part is very tender, the water should be squeezed upon it from sponges. In a sprain of a joint, after a time, when thickening has occurred, pour upon the part daily, from a height, first a pitcherful of very warm water, then a pitcherful of very cold water; then dry the part and use friction with a hand greased with cosmolin. Hot vaginal douches are generally employed in pelvic inflammations.

Massage is a procedure not employed frequently enough. It is very useful in some acute inflammations, though in these it must be gentle. It is of great service in the treatment of sprains of joints and fractures of bones. It is influential for good in chronic inflammations at the period when rest is abandoned. It acts by promoting the movements of tissue-fluids (blood, lymph, and areolar fluid), stimulating the absorbents, strengthening local nervous control, and thus improving nutrition. Passive motion in joints acts as massage.

Heat may be used continuously or intermittently, and may be either moist or dry. A considerable degree of heat will act like cold and contract the vessels. The degree necessary to cause vascular contraction would not destroy the tissue, but would produce discomfort, which discomfort would become unbearable during the continuance of the application. Therefore,

heat is rarely used in the earliest stage of an acute inflammation. It is hard to state exactly when heat should be substituted for cold. Certainly when retardation and stasis are manifest it is to be preferred. Moderate heat should be used when inflammation is not very superficial. In a cutaneous inflammation heat usually does harm, because it increases the congestion of an inflamed superficial part. In deep-seated inflammations heat to the surface acts as a revulsive or counterirritant. Thus a poultice to the chest may do good in the first stage of pneumonia, and cauterization of the skin near a joint may benefit an acute synovitis. The use of heat for purposes of counterirritation will be discussed under the head of Counterirritants. A moderate degree of heat applied over a fully developed and not too superficial inflamed area dilates the vessels, especially the veins, of the skin and superficial tissues. Thus circulation is re-established in an area filled with stagnant blood or blood which is scarcely moving and the inflamed region is drained, fluid exudate is absorbed, tension is lessened, the lymph-spaces and vessels distend, and lymphatic absorption becomes active. The application of heat increases the ameboid activity and the migratory tendency of the leukocytes, phagocytes gather in great numbers and surround an area of infection, and those which have taken up bacteria or tissue débris hurry away. Heat also, in all probability, causes antibodies to escape from the leukocytes and enter the blood-serum. Furthermore, heat favors leukocytosis. Thus, we see, that heat tends to help the building of protective barriers about an area of infection and aids the protective reactions of the body. Heat notably lessens the pain of inflammation. It is often used purely to relieve pain.

The *forms of heat* are—(1) fomentations; (2) poultices; (3) water-bath; (4) dry heat.

Fomentation is the application to the skin of a piece of flannel containing a hot liquid. A basin is warmed and over the top of the basin a towel is placed. A piece of flannel folded in two or three thicknesses is laid upon the towel and boiling water is poured upon it. By twisting the towel the water is squeezed out of the flannel. Great care must be taken to squeeze the water thoroughly out of the flannel, otherwise the skin may be scalded. The hot flannel is laid upon the skin over the disordered part. A rubber-dam larger than the flannel is placed over it, a mass of cotton is laid upon the rubber-dam, and a bandage is applied. The fomentation must be changed within an hour unless a hot-water bag has been placed outside the bandage, in which case it need not be changed for two hours or more. The flannel which is dipped into the hot liquid is known as a "stupe." The turpentine stupe is made by wringing out the flannel as above and then putting upon it from 10 to 20 drops of turpentine. Instead of fomenting the part, steam may be thrown upon it. Fomentations are used chiefly for their reflex influence over deep congestions or inflammations. The liquid of a fomentation may, if desired, contain corrosive sublimate, carbolic acid, or other agents. A fomentation containing an antiseptic is known as an antiseptic fomentation. An *antiseptic fomentation* or, as it is often called, an *antiseptic poultice* is made and applied as follows: Gauze is used instead of flannel, and is laid upon the towel over the basin as previously described. A very warm solution of corrosive sublimate (1:1000) of concentrated boric acid solution, or a 2 per cent. solution of acetate of aluminum, is poured upon the gauze, the material is partly wrung out, placed upon the part, covered with a rubber-dam, and upon it a hot-water bag is placed. Fomentations are very useful in relieving pain in any stage of an inflammation and act also as counterirritants. Fomentations are used in preference to ordinary poultices if there is any probability of a surgical operation becoming necessary, because skin to which an old-fashioned poultice has been applied cannot be satisfactorily sterilized. The antiseptic fomentation is of great service in

removing sloughs from foul wounds and ulcers. It is the only form of poultice which is admissible when the skin is broken.

Poultice or Cataplasm.—A poultice is a soft mass applied to a part to bring heat and moisture to bear upon it. Poultices can be made of ground flaxseed, of slippery-elm bark, of arrowroot, starch, bread and milk, potatoes, turnips, etc. The poultice should be placed upon the part and be covered outside with oiled silk, a rubber-dam, or waxed paper. A mass of cotton is applied outside of the rubber and the poultice is held in place by a bandage or binder. It can be kept very warm for a considerable period by placing upon it a bag filled with hot water. If a hot-water bag is not employed, a poultice should be changed every two hours. Spongiopilin, when moistened with hot water, is a good substitute poultice. Lint soaked with hot water and covered with some impermeable material does very well. A poultice containing opium is known as a "sedative" poultice. About 2 gr. of opium to the ounce of poultice-mass may relieve pain. Flaxseed is a vegetable material, adheres to the skin, enters the mouths of glands and follicles, undergoes decay, can be removed only with great difficulty, and is a very objectionable material to use if there is any breach of surface continuity or if it is possible that an incision will be required. The preparation of an antiseptic *poultice* or fomentation is described above. Poultices must not be kept on the part too long, as they will cause vesication, especially in adynamic conditions. If a poultice is causing vesication, remove it and do not replace it, or replace it after sprinkling the part and the poultice with powdered oxid of zinc. If suppuration exists or is seriously threatened, do not waste time by using poultices, but incise at once. Incision may prevent suppuration by relieving tension, affording drainage, and permitting the local use of antiseptics. If pus exists, it cannot be evacuated too soon. To use poultices and delay incision is often productive of irreparable harm. After incision of a purulent focus it is common practice to apply an antiseptic fomentation in order to draw quantities of leukocytes to the part and thus limit the spread of infection and stimulate granulation.

Hot-water Bath.—The continuous warm bath is now rarely employed except in burns and cases of phagedena, when it often proves curative. In these cases an antiseptic agent may be dissolved in the water. Continuous immersion in a warm bath is regarded favorably by some surgeons for the treatment of sloughing wounds and large purulent areas. The immersion of a part from time to time in water as hot as can be tolerated is useful in fully developed and in chronic inflammation. Such immersion benefits an inflamed joint, lessening the pain, swelling, and stiffness.

Dry heat is applied by a metallic object dipped in hot water and laid upon the part; by Leiter's tubes, through which hot water flows; by the hot-water bag or by the hot-air apparatus. Some surgeons use the hot-water bag in cases of mild appendicitis in order to favor the limitation of the area of infection. The hot-water bag is often soothing and beneficial when laid upon an inflamed joint, or on the perineum or the hypogastric region in cystitis. A bag of hot sand, a hot brick, or a bottle or can of hot water may be used instead of the water-bag. The hot-air apparatus is of very great service in the treatment of chronic inflammation, and particularly of inflamed joints (*vide* dry hot-air apparatus).

Treatment When Suppuration is Threatened.—When suppuration is threatened, ordinarily hot fomentations or antiseptic fomentations must be used, and the part must be kept at rest. As previously explained, the flaxseed poultice is inadmissible. When suppuration is threatened, the use of heat causes the collection of multitudes of leukocytes, which tend to limit the area of infection and destroy bacteria. Even when suppuration is not prevented, heat aids in the rapid breaking down of the diseased tissue at the focus of

the inflammation and causes hordes of leukocytes to gather and encompass the suppurating tissue, and these leukocytes prevent the spread of the infection.

In most cases, when suppuration is obviously inevitable or seriously threatened, a *free incision* will be of greatest benefit.

Irritants and Counterirritants in Inflammation.—*Irritants* attract an increased supply of blood to the part whereon they are applied, and are used for their local effects. *Counterirritants* are used to affect by reflex influence some distant part. In chronic inflammation irritants may do good by promoting the blood-supply, thus favoring the removal of exudates (liniment for rheumatism and synovitis, and nitrate of silver for ulcers). Counterirritants are powerful pain-relievers when used over an inflamed structure; they bring blood to the surface, and are thought by many writers to cause anemia of internal parts, the site and area of anemia depending on the site, the area, and the duration of the surface irritation. Some recent studies seem to suggest that counterirritation produces hyperemia of the superficial part, compensatory anemia of surrounding regions, and anemic edema of the subcutaneous tissue and muscles (W. Wecksberg, "Zeit. f. klin. Med.," Bd. xxxvii, H. 3 u. 4). Nancrede dissents from the statement that counterirritants cause anemia of internal parts; and he maintains that they irritate deeper parts and cause more external blood to be taken to them. He claims that a blister applied to the chest produces a hyperemic area in the pleura, and refers to Furneaux Jordan's opinion that direct irritation to the surface over a joint adds to synovial hyperemia, and that consequently in joint inflammation counterirritants should be applied above and below a joint, but not directly over it. As a matter of fact, we know clinically that powerful counterirritation directly over an inflamed superficial joint is occasionally followed by an aggravation of the trouble, and that in pericarditis blistering directly over the pericardium may, as pointed out by Brunton, make the condition worse. Counterirritants not only relieve pain in the earlier stages of inflammation, but they also promote absorption of exudate in the later stages, and are particularly valuable in chronic inflammations. Great benefit is obtained by blistering old thickened ulcers, and by painting the chest with iodin to relieve pleuritic effusion. Frictions, besides their pressure effects, act as counterirritants. Frictions may relieve skin pain, and are associated with the application of stimulating liniments in the treatment of stiff joints. A mustard plaster is a valuable counterirritant in an acute deeply seated inflammation. Tincture of iodin is extensively used in chronic inflammation.

There is no more efficient method of relieving pleural effusion than by the application of a succession of blisters. Blisters are also used in the treatment of inflamed joints, pericarditis, pneumonic consolidation of the lung, acute and chronic rheumatism, etc.; and are applied back of the ears or at the nape of the neck in congestive coma or meningitis. A blister can be produced in a few minutes by soaking a bit of lint in chloroform, and after applying it to the surface, covering it with oiled silk or with a watch-glass. Equal parts of lard and ammonia will blister in five minutes. It is easier to blister with cantharidal collodion or blistering paper. Before applying a blister, shave the part if it be hairy; then grease the plaster with olive oil and apply it. Blistering plaster is left in place six hours in the case of an adult, but only two hours in the case of an old person or a child; the plaster is then removed, and if a blister has not formed, the part must be poulticed for a few hours. When a blister is obtained, open it with a needle which has been dipped in boiling water. If the surgeon wishes the blister to heal, it should be covered with a piece of lint smeared with cosmolin or with zinc ointment. If it is to be kept open for a time, cut away the stratum corneum and dress with cosmolin, each ounce of which contains 6 drops of nitric acid.

Pustulation can be effected with tartar-emetic ointment or with Vienna paste. Tartar-emetic ointment was formerly used on the scalp in meningitis. Vienna paste consists of 5 parts of caustic potash and 6 parts of lime made into a paste with alcohol. It is applied for five minutes, and is then washed off with vinegar.

The actual cautery is the most powerful of counterirritants. It is chiefly used in chronic inflammation of joints, bone, nerves, and the spinal cord. The application is, of course, very painful, and it is best to give an anesthetic before using the cautery. The Paquelin cautery is the instrument used. This is a hollow platinum point which, after being heated in the flame of an alcohol lamp, is kept hot by forcing through it the vapor of gasolene (Fig. 226). The point is used at a white heat. One area or several may be seared. The cautery is drawn lightly two or three times over each spot we wish to burn. The object is to destroy only the superficial layers of the skin. After the cauterization is completed, lint wet with iced water is applied for several hours to allay pain, and then hot antiseptic fomentations are used until the slough separates.

If the wish is to prevent healing after separation of the slough, dress the sore with cosmolin, each ounce of which contains 6 drops of nitric acid. It is not wise to cauterize deeply directly over a superficial joint.

Constitutional Treatment of Inflammation.—Certain remedies are used in inflammation for their general or constitutional effects; these remedies are—(1) general bleeding; (2) arterial sedatives; (3) cathartics; (4) diaphoretics; (5) diuretics; (6) anodynes; (7) antipyretics; (8) emetics; (9) mercury and iodids; (10) stimulants; (11) tonics.

General Bleeding, Venesection, or Phlebotomy.—Venesection is suited to the early stages of an acute inflammation in a young and robust subject. The indication for its employment is increased arterial tension, as shown by a strong, full, rapid, and incompressible pulse in a vigorous young patient. General blood-letting diminishes blood-pressure and increases the speed of the blood-current, thus amends stasis, causes the absorption of exudate, and the washing of adherent white corpuscles from the vessel wall; furthermore, it reduces the whole amount of body blood and thus forces a greater rapidity of circulation, decreases the amount of fibrin and albumin, lowers the temperature, arrests cell-proliferation, and stops effusion.

This procedure was in former days so highly esteemed that it settled into a routine formula to be applied to every condition from yellow fever to dislocation. The terrible mortality of the cholera epidemics from 1830 to 1835 led practitioners to question the belief that bleeding was a general panacea, and from this doubt there was born in the next generation violent opposition to blood-letting in any disease. Like most reactions, opposition has gone too far, the pendulum of condemnation has swung beyond the line of truth and sense, and thus is universally neglected or broadly condemned a powerful and valuable resource. Many physicians of long experience have never seen a person bled; its performance is not demonstrated in most schools, and but few patients and families will permit it to be done; but when properly used it is occasionally beneficial. It is applicable, however, only to the young, strong, and robust, and not to the old, weak, or feeble. It is used for violent acute inflammations of important organs or tissues, and not for low inflammations or for slight affections of unimportant parts. It is used in the early, but not in the late, stages of an inflammation. It is used when the pulse is frequent, full, hard, and incompressible, but not when it is slow, small, soft, compressible, and irregular. It is used when the face is flushed, but not when it is pallid. It is not used in fat persons, drunkards, very nervous people, or the sufferers from adynamic, septic, or epidemic diseases. It is of value in some few cases of congestion of the lungs, pneumonitis, pleuritis, meningitis,

prostatitis, cystitis, and other acute inflammatory conditions. It is particularly valuable in any subject when uremia exists, or when there is distention of the right side of the heart. The method of bleeding is described on page 462.

After bleeding the patient should be put on arterial sedatives, diuretics, diaphoretics, anodynes, and, if necessary, purgatives. A favorite mixture of Prof. S. D. Gross was the antimonial and saline, 40 gr. of Epsom salt, $\frac{1}{10}$ gr. of tartar emetic, 2 drops of tincture of aconite, and 1 dram of sweet spirits of niter, in enough ginger syrup and water to make $\frac{1}{2}$ oz.; given every four hours.

Arterial Sedatives.—Drugs of this character are of great use before stasis is pronounced; but if used after stasis is established they will increase it. If stasis exists it may be relieved by blood-letting, local or general, and then arterial sedatives can be given. Either local bleeding or venesection abolishes stasis and lowers tension, and arterial sedatives maintain the effect and hold the ground which is gained. The arterial sedatives employed are aconite, veratrum viride, gelsemium, and tartar emetic. These sedatives lessen the force and the frequency of the heart-beats, and thus slow and soften the pulse, and are suited to a robust person with an acute inflammation, but are not suited to a weak individual in an adynamic state.

Aconite is given in small doses, never in large amounts. One drop of the tincture in a little water is given every half hour until its effect is manifest on the pulse, when it may be given every two or three hours. Large doses of aconite produce pronounced depression, and are dangerous. Aconite lowers the temperature, slows the pulse, and produces diaphoresis.

Veratrum viride is a powerful agent to slow the pulse and to lower blood-pressure; it produces moisture of the skin, and often nausea. It is given in 1-drop doses of the tincture every half hour until its physiologic effects are manifested, when the period between doses is extended to two or three hours. Ten drops of laudanum given a quarter of an hour before each dose of veratrum viride will prevent nausea.

Gelsemium is an arterial sedative. It is given in doses of 5 to 10 drops of the tincture every three or four hours.

Tartar emetic lowers arterial tension and lessens the pulse-rate. This drug is not generally employed; if it is used with the greatest care it is no better than some other agents, and if it is not so used it will cause dangerous depression. The dose is from $\frac{1}{20}$ to $\frac{1}{10}$ gr., given in water every three hours until the physiological effects are manifest.

Cathartics.—Purgation is of great value in inflammation. By it putrid material is removed from the intestine, fluid containing poisonous elements is drawn from the blood, and the liability to infection of the tissues is lessened. Purgation is a powerful aid in removing serous effusions and other exudates. The administration of purgatives is, of course, not to be a routine procedure in inflammatory states. The bowels may be acting so freely that no cathartic is required. Treatment in an inflammation should be inaugurated, if constipation exists, by giving a cathartic. The tongue affords important indications as to the necessity for purgation. Castor oil can be given in capsules, or in the froth of beer, or the juice of half a lemon is squeezed into a tumbler, 1 oz. of oil poured in, and the rest of the lemon is squeezed on top, thus making a not unpalatable mixture. Aloin, podophyllum, the salines, and calomel in 3- or 5-gr. doses, followed by a saline, have their advocates. In threatened peritonitis the salines are used by some surgeons, a teaspoonful of Epsom salt and a teaspoonful of Rochelle salt being given hourly until a movement occurs. In this condition, however, purging may prove disastrous. In the course of inflammation, from time to time, if there be constipation, a coated tongue, and foulness of the breath, there should be ordered 1 gr. of calomel with 24 gr. of bicarbonate of sodium, made into twelve powders, one being given

every hour; if the bowels are not moved by the time the powders are all taken, a saline should be given. If a violent purgative effect is desired, as in meningitis, croton oil or elaterium may be ordered. If constipation is persistent, give fluidextract of cascara sagrada daily (20 to 40 drops), or a pill at night containing $\frac{1}{4}$ gr. of extract of belladonna, $\frac{1}{4}$ gr. of extract of nux vomica, $\frac{1}{10}$ gr. of aloin, $\frac{1}{4}$ gr. of extract of physostigma, and $\frac{1}{2}$ drop of oil of cajuput. Enemas or clysters may be used in some cases. A very useful enema is composed of 1 fl.oz. of oil of turpentine, $1\frac{1}{2}$ fl.oz. of olive oil, $\frac{1}{2}$ fl.oz. of mucilage of acacia, in 10 fl.oz. of water. Soap and turpentine is very satisfactory. Soapsuds and vinegar in equal parts make a serviceable clyster. A combination of oil of turpentine, castor oil, the yolk of an egg, and water can be used. Asafetida, 30 gr. to the yolk of 1 egg, makes a good enema to amend flatulence. An ounce of alum in 1 quart of water is valuable for the same purpose.

Diaphoretics.—These agents are very useful. A profuse sweat removes much toxic material from the blood and in the beginning of an acute inflammation, such as tonsillitis, may abort the disease. Dover's powder is commonly used, but pilocarpin is preferred by some. Camphor in doses of from 1 to 5 gr. is diaphoretic, and so are antimony and ipecac. Acetate and citrate of ammonium, opium, alcohol, hot drinks, heat to the surface (baths, hot bricks, hot-water bags), serpentaria, and guaiac are diaphoretic agents.

Diuretics are useful in fevers when the urine is scanty and high-colored, and are valuable aids in removing serous effusions and other exudates. Among the diuretics may be mentioned calomel in repeated large doses, cocain, alcohol, infusion of digitalis, the nitrites, squill, turpentine, copaiba, and cantharides. The liquor potassæ and the acetate of potassium are the best agents to increase the solids in the urine. The liquor potassii citratis in doses of 1 to 4 fl.dr. is efficient. Large drafts of water wash out the kidneys. If the heart is weak, citrate of caffein is a good stimulant diuretic, and hot coffee is very serviceable in promoting the secretion of urine. The injection of hot salt solution into the rectum and under the skin favors diuresis, and the intravenous infusion of salt solution is a very powerful diuretic (see page 465). The application of heat to the loins promotes the secretion of urine. Sodiotheobromin salicylate (diuretin) is an uncertain but often valuable diuretic, in doses of 10 gr., every two or three hours.

Anodynes and Hypnotics.—Drugs may be required to allay pain or procure sleep. Dover's powder, besides being diaphoretic, is anodyne. Opium acts well after bleeding or purgation. If it causes nausea, it should be preceded one hour by the administration of 30 gr. of bromid of potassium. Opium is given by the mouth or by the rectum. Morphin is given by the mouth or hypodermatically. Opium is used when there is pain, but its use is not to be long persisted in if it can be avoided. It is given in doses measured purely by the necessities of the case. If opium disagrees, try the combination of morphin with atropin. After an operation antipyrin or phenacetin will often quiet pain and secure sleep. When a person feels "so tired he can't sleep," alcohol in the form of whisky or brandy must be given. Sleeplessness not due to pain is met by chloral, trional, veronal, the bromids, or sulphonal. Chloral is dangerous in conditions of weak heart or exhaustion. Bromids must be given in large doses to be efficient. Sulphonal must be given about four or five hours before sleep is expected, in doses of from 10 to 20 gr. in hot milk or hot mint-water. Trional is safe and very satisfactory. It is given in doses of 15 to 25 gr. in hot water.

Antipyretics.—Arterial sedatives, diaphoretics, and purgatives lower temperature, and have previously been alluded to (see page 106). There are two great classes of febrifuges—those which lessen heat-production and those which increase heat-elimination. In the first group we find quinin, salicylic acid and the salicylates, kairin, alcohol, antimony, aconite, digitalis, cupping,

and bleeding. In the second group we find alcohol, nitrous ether, antipyrin, acetanilid, phenacetin, opium, ipecac, cold to the surface, and cold drinks. In surgical inflammations it is rarely necessary to employ heroic means to lower temperature. Quinin is but a feeble antipyretic for non-malarial fevers, and that it shall be one at all requires a dose of 20 gr. or more. Salicylic acid is not advisable unless there is hyperpyrexia or unless the patient has acute rheumatism. If 30 or 40 minims of guaiacol are painted on the skin of the abdomen, it will cause a notable but brief drop in a febrile temperature. After a short period of lowered temperature there is commonly a chill and a rapid rise. Cardiac depression may arise after giving an antipyretic, and such an agent as antipyrin is dangerous to the weak and adynamic. In truth, all of the coal-tar derivatives are dangerous when used as antipyretics. As a matter of fact, fever is a condition in which the animal organism is endeavoring to oxidize and render inert certain poisonous materials, and antipyretic drugs lessen oxidation and actually make the patient worse. It is a suggestive fact that bacteria are said to multiply more rapidly when kept at about the normal body temperature than when kept at fever heat (102° F. or more). The mere discomfort of fever may be much mitigated by antipyretic drugs, but the fever process is not benefited by them. No attempt should be made to lower temperature by cold or antipyretic drugs, unless with the high temperature there are the nervous phenomena of hyperpyrexia.

Emetics may do good when the patient suffers from a parched, coated tongue, a dry and hot skin, nausea, and gastric oppression, but it is very rarely in these days that we employ them.

Mercury and the Iodids.—Mercury is an alterative, that is, an agent which favorably affects body nutrition without causing any recognizable change in the fluids or the solids of the body. Mercury lessens blood plasticity, hinders the exudation of liquor sanguinis—thus furnishing less food to the cells in the perivascular tissues—and retards cell-proliferation. Further, by a stimulant action on the absorbents it promotes the breaking up of an existing inflammatory exudation, and hence limits damage from excess of new formation. The time at which mercury is best given is when violent symptoms have abated, the guides being a reduced temperature and a moist skin. Mercury is often given in conjunction with the local use of sorbefacients (ichthyol or mercurial ointment). When possible, the administration of mercury is associated with compression of the inflamed part. Mercury is sometimes given until the gums are slightly touched, but it is not given to the point of salivation. When the breath becomes offensive and the gums tender on snapping the teeth, or when griping and diarrhea begin, the dose should be reduced or the drug should be stopped (see Ptyalism). In iritis mercury is used to get rid of the plastic effusion which is causing pupillary fixation and opacity. In keratitis the gums should be touched *slightly*. In orchitis, after the subsidence of the acute symptoms, mercury should be employed. In pericarditis, meningitis, and in many chronic and lingering, and in all syphilitic inflammations, this drug can be used.

Some persons will be salivated by very minute doses of mercury, either because of idiosyncrasy or previous saturation. Others can take enormous doses without any appreciable constitutional effect. The action of mercurials can be favored by a combination with ipecac or with tartar emetic.

In giving mercury, if a prompt effect is desired, give 3 gr. of calomel every three hours until a metallic taste is noted in the mouth. If the case is not so urgent, gray powder is a good combination. Children are given calomel and sugar or mercury and chalk. If it is desired to give the drug for some time, corrosive sublimate is a suitable form, and small doses will actually increase the number of red blood-corpuscles. Corrosive sublimate is to be given alone

or combined only with iodid of potassium. The green iodid of mercury is a drug suitable for prolonged administration. During a prolonged course of mercury it will often be necessary to give at the same time a little opium to prevent diarrhea and griping. A rapid effect can be obtained by rubbing daily with a gloved hand 1 dr. of the oleate of mercury or ½ dr. of the ointment into the groins, the axillæ, or the inside of the thighs. Suppositories of mercurial ointment induce rapid ptyalism. Hypodermatic injections of corrosive sublimate or gray oil may be used, and must be thrown deeply into the muscles of the buttock or back. Old people, those who are exhausted, anemic, and broken down, and the tuberculous bear mercury badly. If it be given to them at all, it must only be in small amounts and for a brief time.

Alkaline iodids are useful in removing the products of inflammation; they can be given for a long time, and admirably supplement mercurials. Iodid of potassium can be prescribed in combination with corrosive sublimate as follows:

R.	Hydrarg. chlor. corros.	gr. ij;
	Potass. iodidi	ℨv et ℈j;
	Syr. sarsaparillæ comp	q. s. ad f℥viij.—M.

Sig.—Two fluidrams in water, after meals.

Iodid of potassium, well diluted, is given on a full stomach; it is never given concentrated or before meals. A convenient mode of administration is to procure a concentrated solution of the iodid of potassium, remembering that every drop equals about 1 gr. of the drug, and give as many drops as may be desired in half a glass of water after meals. If the medicine disagrees, add to each dose, after it is put in water, 1 dr. of the aromatic spirit of ammonia. Extract of licorice is a good vehicle for the iodid. If the mixture in water disagrees, the drug should be given in milk. Capsules are satisfactory, but a drink of water should be taken just before and again just after taking a capsule, to protect the stomach from the concentrated drug. Iodid of sodium may agree when iodid of potassium does not. When the iodids disagree they produce *iodism.* The first indications of iodism are a bad taste in the mouth, running of the eyes and nose and sneezing, followed by a feeling of exhaustion, absolute loss of appetite, nausea, tremor, and skin eruptions (acne, hemorrhages, blebs, hydroa, etc.). If iodism occurs, stop the drug and give the patient Fowler's solution in increasing doses, laxatives, diuretic waters and also nutritious food, and stimulants if depression is great. Sometimes belladonna does good in obstinate cutaneous disorders induced by the iodids.

Remedies Directed Against Special Morbid States.—If inflammation is associated with rheumatism, gout, scurvy, syphilis, tuberculosis, or any other constitutional disease or predisposition, appropriate treatment should be instituted to control the disease or combat the predisposition, and at the same time the area of inflammation should be locally treated. Syphilis is treated by the internal use of mercury; in some cases the iodids are also given; scurvy, by vegetable juices and potash salts; rheumatism, by the alkalis or salicylates; gout, by colchicum or piperazin; tuberculosis, by the fats, tonics, and open-air life.

Stimulants.—The chief stimulants used are hot black coffee by the stomach or bowel; hot normal salt solution by the bowel, beneath the skin, or in a vein, alcohol by the mouth or rectum; and strychnin or atropin hypodermatically. The use of *alcoholic stimulants* is called for by conditions rather than by diseases, being indicated by the state of the patient rather than by the name of the malady. For a brief acute inflammation in a robust young person alcohol is not needed; but all who are weak or exhausted, be they young or old, all who are aged, those who are accustomed to alcoholic beverages, those

who have high temperature or failure of circulation, and those who labor under septic inflammations or adynamic processes require alcohol, and it should be given with a free hand. In an acute malady, a feeble, compressible, rapid, or irregular pulse, and great weakness of the first sound of the heart are indications that alcohol is required. Low, muttering delirium is a strong indication for stimulation. There is no *dose* of alcohol for these states; it is given for its effect. Two ounces of brandy or whisky may be needed in a day, or perhaps many ounces. If the breath of the patient smells strongly of the alcohol, he is getting too much. If delirium increases after each dose, alcohol is doing harm. Alcohol is contra-indicated in acute meningitis. In acute illness use whisky, brandy, champagne, or alcohol and water. During convalescence there may be used a little port, claret, or sherry wine, or malt liquor. These agents will promote appetite, digestion, and sleep.

Strychnin is a very valuable stimulant. It can be given in doses of $\frac{1}{30}$ to $\frac{1}{20}$ gr. three times a day, but after a few days seems to lose its stimulant effect.

Atropin is one of the best remedies for exhaustion of the vasomotor system. The dose is $\frac{1}{100}$ gr. hypodermatically.

Tonics.—The use of tonics is indicated during convalescence from acute and throughout the course of chronic inflammations. There may be used iron, quinin, and strychnin in the form of elixir; iron alone, as in the tincture of the chlorid; quinin in tonic doses (6 to 8 gr. daily); or Fowler's solution of arsenic. An excellent pill consists of—

R.	Acid. arsenos	gr. j;
	Strychnini	gr. ss;
	Quinini	gr. xlviij;
	Ferri reduct	gr. vj.—M.

Ft. in pil. No. xxiv.
Sig.—One after each meal.

Bitter tonics before meals improve the appetite. One of the best tonics is tincture of nux vomica in gradually increasing doses.

Antiphlogistic Regimen.—This term comprises the necessary directions relating to diet, ventilation, cleanliness, etc.

Diet.—When, in the early stages of an acute inflammation, the patient cannot eat, there must be administered a cathartic before food is given. Nausea is combated by calomel and soda, drop-doses of a 6 per cent. solution of cocain, iced champagne, iced brandy, chloroform-water, hot water, and counterirritation of the epigastric region. Sucking ice may check nausea, but it often makes the patient uncomfortable, because he sucks in air with the melted ice. Sucking ice does not quench thirst. When the process is depressive from the start, and in any case after the earliest stage, feeding is of vital moment. The great tissue waste calls for large quantities of nutritive material, but the impaired digestion demands that the food shall be easily assimilable; hence it is taken in liquid form, small quantities being frequently given. Albumin-water is an agreeable beverage of some nutritive value. Milk contains all the elements required by the body, and is the food of foods. If it disagrees, it should be mixed with lime-water, or to each dose an equal amount of Vichy or soda-water may be added. Peptonized milk is a valuable agent. Some people can take boiled milk who cannot take cold unboiled milk. Some patients, however, digest raw better than boiled milk. Peptonized milk has been to a great extent superseded by pancreatinized milk. It is given cold, either alone or mixed with a carbonated water. Koumiss is retained in some cases when the stomach rejects all other foods. This fermented milk is nutritious, stimulant, and very useful. One part of milk, 2 parts of cream, and 2 parts of lime-water make a nutritious and digestible mixture. Milk punch is largely used. Whey

may be used when plain milk cannot be taken. Eggs are highly nutritious, but are apt to disturb the stomach; they may be given as egg-nog, or simply soft-boiled, or the yolk can be beaten up in a cup of tea, or raw eggs may be given in sherry or brandy. When considerable nausea exists the yolk of an egg may be added to 1 oz. of lemon-juice and 2 dr. of sugar, the glass being filled with carbonated water. Beef-tea is certainly a stimulant, but it is not a food. It contains the excrementitious elements of the beef. It is prepared by cutting up 1 pound of lean beef, adding to it a quart of water, and then simmering, but not boiling, down to a pint, finally filtering and skimming the liquid. The dose is a wineglassful seasoned to taste. Beef juice is nutritious. It is prepared as follows: A thick and tender beefsteak is partly broiled over a hot fire, the outside is browned and the juice is retained within the meat. The steak is cut into pieces to fit a lemon squeezer or meat-press (the instrument having been warmed by previously dipping it in hot water). The juice is expressed by squeezing and may be given warm, seasoned with salt and pepper, or may be taken after it has been frozen. Fresh meat juice may be used plain or pancreatinized. The meat juices obtained in the shops have little nutritive value. Bouillon and beef extracts have slight nutritive value. Meat jellies (calf's foot being the one commonly used) have some though little nutritive value by producing a certain amount of energy which, were they not given, would of necessity be furnished by protein. Hence, meat jelly saves or spares protein (Bauer). Clam-juice and clam-broth are palatable and slightly nutritious. They are retained in many cases when any other food would be rejected. The broth is to be given hot and the juice either hot or cold. Coffee is a valuable stimulant in febrile conditions. When the stomach entirely rejects food day after day, nutritive enemata are given. There is dispute as to their value, because it is certain that the large intestine does not digest by juices of its own manufacture, and no protein matter can be absorbed without previous digestion. If undigested protein matter is introduced it undergoes putrefaction, causes irritation, and liberates toxins which are absorbed. It seems equally certain, however, that the large bowel does absorb water as part of its physiological duty and that it can absorb alcohol, saline fluid, grape-sugar, certain drugs, and perhaps digested albumin and fat. Undigested albumin and fat should never be given by enema. These materials should be pancreatinized before injection or should be mixed with pancreas and then injected, the peptones being formed in the bowel. Nutritive enemata are given at a temperature of 90° to 95° F. They should not be bulky (not over 7 or 8 oz.), because a large enema is usually quickly expelled. They should not be given oftener than three or perhaps four times a day, because too frequent administration irritates the rectum and enemas will not be retained by an irritated rectum. During the period that rectal enemata constitute the method of feeding the rectum should be washed out once a day by a high enema of warm salt solution; this cleansing enema is given one hour before a nutritive enema. A useful enema is Leube's meat and pancreas—3 oz. of pancreas and 8 oz. of meat are rubbed together by a pestle, tepid water is added, and the mixture is injected. It undergoes digestion in the large bowel. Bidwell's formula is as follows: 2 oz. of milk, 2 oz. of strong beef-tea, yolk of 1 egg, 1 dr. of pancreatic solution, prepared one hour before using and kept during the interim at a temperature of 100° F. Brandy can be added just before using. Enemata of salt solution greatly relieve thirst. When the sufferer feels able to eat a little, any good soup, strained and skimmed, should be ordered. As the patient gets better he may be fed on scraped meat, broth containing crumbs, tapioca with cream, custard, milk-toast, sweetbreads, chops, oysters, chicken, etc., until he gradually reaches ordinary diet.

The *temperature* should be taken at regular intervals, and the condition of the gastro-intestinal tract should be observed. The *urine* must be examined

at intervals, and the daily amount passed must be known. If insufficient urine is being passed, increase the amount of fluid, particularly of water, given by the mouth. If the urine is scanty and the patient is nauseated by drinking water, give enemata of hot saline fluid or employ hypodermoclysis. The *pulse* and *heart* must be frequently observed, and cardiac weakness must be combated by suitable stimulants.

Ventilation and Cleanliness.—The ventilation of the apartment is of the greatest importance. Every day the windows should be opened widely for a time, the patient, of course, being protected from chilling and kept out of a draft. When the windows are open the air of a room can be quickly changed by swinging the door to and fro. A constant access of fresh air must be secured, and the temperature kept as near as possible to 68° F. If high fever exists, the sick man must be cleaned and be sponged off with alcohol and water every day. It is important that the bed-clothing be clean and that the sheet be unwrinkled, as otherwise bed-sores may form.

Treatment of Chronic Inflammation.—The subject of chronic inflammation has been referred to previously. The local treatment comprises rest, relaxation, elevation, counterirritation, massage, passive movements, the douche, the application of sorbefacients, the use of compression, incision, and, perhaps, certain special methods, as the induction of passive hyperemia by Bier's method, or baking the part in a hot-air oven. The patient should be placed under proper hygienic and climatic conditions; the diet must be judiciously regulated; drugs are given symptomatically or to combat some constitutional tendency or disease (see articles upon Special Regions and Diseases).

Bier's Hyperemic Treatment of Inflammation.—Years ago Laennec asserted that cyanosis is antagonistic to tubercle. Rokitansky emphatically supported the contention that people with marked valvular disease of the heart are seldom attacked by pulmonary tuberculosis. Such lesions, of course, dam back the blood in the lungs. Farre and Travers point out the great liability to pulmonary tuberculosis of patients with anemic lungs because of stenosis of the pulmonary artery (Edward Adams, in "N. Y. Med. Jour.," February 26, 1910). The discovery of how to utilize this knowledge in treatment was made by Professor Bier, of Berlin. Bier believes that hyperemia in inflammation is a reaction on the part of the organism; that it is Nature's effort to remove an irritant and to supply increased nutritive material, hence that it is desirable and should not be combated by cold, but should be favored by every means in our power. Bier endeavors to increase the hyperemia of an inflamed region, or to produce hyperemia in an area of disease. He regards hyperemia as beneficial, stasis as harmful; hence he causes or increases hyperemia and combats stasis. Stasis lowers tissue resistance and may cause gangrene. The increase in the amount of moving blood in a part means an increase in the number of phagocytes and the amount of germicidal blood liquor. By the method of treatment recommended by Bier the surgeon induces venous, passive, or obstructive hyperemia by means of an elastic band or a cupping glass, active or arterial hyperemia by means of hot air.

Obstructive Hyperemia by Means of the Elastic Bandage.—The constrictor should be the soft broad bandage of an Esmarch apparatus. Figure 55 shows it applied around the arm. The bandage must not be so tight as to cut off the pulse at the wrist or to cause unpleasant sensations, pain, or very rapid distention of the subcutaneous veins (Meyer and Schmieden). When edematous swelling arises we may be unable to feel the pulse. Then our guide must be the sensations of the patient. If the treatment causes pain or increases existing pain, at once discontinue it (Waterhouse, "Brit. Med. Jour.," December 16, 1911). The part below the band should become bluish red and warm, but never white under the influence of the constriction. When the bandage is in

place an area of inflammation shows an increase of redness, heat and swelling, and a diminution of pain. If pain was not present before, the bandage must not produce it. Should it do so it is too tight. In chronic conditions the bandage is usually employed daily and for two, three, or four hours at a séance. When used for three hours or longer temporary edema may arise. In acute cases it is used for twelve, fifteen, or twenty hours a day. Prolonged application may make the skin sore unless a flannel bandage is applied before the band is used, unless the site of application is shifted daily, and unless the skin during each intermission is well rubbed with alcohol. The bandage is always applied well above the inflamed region, and that region is exposed free from dressings in order that its condition during treatment may be observed. If edema occurs, the band must be removed and the edema relieved by elevation and massage. If the inflammation is accompanied by marked edema, incisions are required. Treatment by the bandage may prevent pus formation. If pus forms it must, of course, be evacuated.

Fig. 55.—Shows elastic bandage in place around the arm, its ends tied with tapes which are attached to the bandage. This is the style of bandage usually found upon the market. If the bandage is to remain on for a number of hours, it is advisable to apply a strip of adhesive plaster, to guard against the tapes becoming undone. Note the engorgement of the subcutaneous veins of the forearm, showing the effect it is desired to produce by the bandage (Meyer and Schmieden).

Obstructive Hyperemia by Means of the Cupping Glass.—Endeavor to make the skin bluish red, but not white. Cupping glasses are used not only to treat areas of inflammation, but to aid in emptying sinuses and abscesses which have ruptured or have been incised. Figures 56–59 show cupping glasses.

I am satisfied from personal experience that Bier's method of treatment is of great value in acute inflammation as well as in chronic inflammation, and that it is not used as often as it should be. I have used it with success in several cases of ununited fracture. It is an improvement on the method of Thomas, of Liverpool, for inducing hyperemia about the ends of the fragments. He did it by repeated percussion with a mallet. Barker has recently advocated Bier's treatment for ununited fracture. I have never used it for purulent affections of large joints, a condition in which Bier finds it highly useful (Bier and Baetzner, in "Practitioner," Jan., 1912). He empties the joint with a trocar, washes it with carbolic solution, puts on dressing, but does not immobilize. Bier retains the band from twenty to twenty-two hours a day. As soon as acute symptoms subside he uses hot air. The reduction of the daily period of hyperemia is brought about gradually before substituting hot air. I have seen very gratifying results from the Bier treatment of gonorrheal joints. I believe that this treatment gives the best chance of cure without deformity and with

retained function. It is valuable for joint tuberculosis, although very numerous brief applications are necessary. It is beneficial for thecitis, areas of suppuration after incision, and chilblains. Waterhouse suggests its use to prevent

Fig. 56.—The simplest form of suction glass. The rubber bulb is attached directly to the glass. This glass is used in the treatment of furuncles of smaller size and sinuses (Meyer and Schmieden).

Fig. 57.—Illustrating an ordinary suction apparatus for the finger (felon, etc.) with a convexity at the lower surface, designed to receive the pus (Meyer and Schmieden).

suppuration in a crushed limb. The treatment is contra-indicated in spreading inflammation—for instance, erysipelas.

Bier claims that arterial hyperemia induced by hot air is particularly useful in chronic inflammation, as it favors the absorption of exudates and of

Fig. 58.—Shows glass of simpler configuration; a rubber tube connects glass with bulb; the same can be readily detached, thus rendering easy the sterilization of the glass by boiling. In the tube a three-way stop-cock is inserted. This cup is used for treating furuncles of larger dimensions, etc. (Meyer and Schmieden).

adhesions. It will hasten the separation of sequestra. Venous hyperemia produced by the elastic band or the cupping glass is claimed to be of great value in infections. It may abolish the infection, prevent suppuration, and hasten the process to a conclusion. It does certainly lessen pain and favor

absorption. The elastic band may be used upon an extremity, a testicle, the scrotum, and the head. In other regions cupping glasses are used, a partial vacuum being established in the glass by means of a pump or a rubber bulb.

Sir Almroth Wright's Views Upon Inflammation and Its Treatment.—Wright maintains that a free supply of blood and lymph is necessary for repair, that both the blood and lymph should contain a sufficiency of protective materials, and that it is essential that numerous active leukocytes enter the area of disease.

When there is a large serous effusion and few leukocytes, a condition met with often in tuberculous pleurisy, repair does not take place.

In abscess the leukocytes are dead and the material obtained from dead leukocytes retards healing. If the fluid exudate does not contain protective material the process extends.

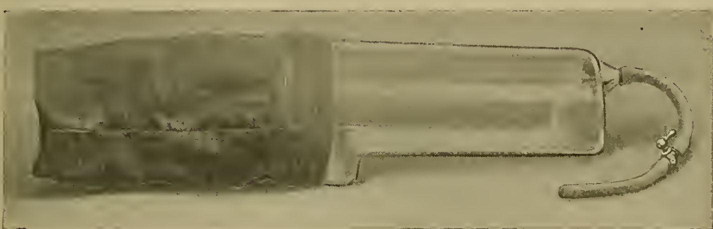

Fig. 59.—Constructed for the treatment of the hand. A soft-rubber band wound around the cuff makes it fit air-tight around the arm (Meyer and Schmieden).

Repair is retarded by induration, or by the formation of a fistula or a sinus.

If there is a small amount of fluid exudate, there is little protective substance thrown into the inflamed part and repair is retarded.

If there be a large effusion and few leukocytes, cure is favored by removing the fluid. This is done in abscess and in serous effusion. If there is too little lymph in the part salt solution and citric acid should be used locally, and citric acid should be administered internally. The administration of proper bacterial vaccines will increase the protective qualities of the lymph. (See Wright, "The Pathology of Inflammation," and the résumé of his views in "Progressive Medicine," Sept. 1, 1908, p. 31.)

IV. REPAIR

A damaged tissue reacts to the injury and Nature attempts to effect repair. It is held by many that inflammation is a destructive process and repair is a constructive process; that repair is constantly effected in an aseptic wound without many of the evidences of inflammation; that repair does not proceed from inflammation, but is retarded or prevented if inflammation occurs. As before stated, we agree with Adami, that inflammation is reaction to injury and the effort of Nature to repair the injury. As Adami points out, the attempt to repair may fail, the reaction to injury being excessive or not powerful enough; but even should the attempt fail, the conservative intention exists. "What is the development of cicatricial tissue but an attempt at repair? What other meaning can be ascribed to the increased bactericidal power of the inflammatory exudate as compared with that of ordinary lymph and blood-serum? Why do leukocytes accumulate in a region of injury? Why do some of them incorporate bacteria and irritant particles, and others bring about the destruction of these without necessarily

ingesting them? All these are means whereby irritants are antagonized or removed, and reparation and return to the normal sought after."[1]

Repair is favored by good general health, asepsis of the wound, coaptation of wound edges, and rest. It is retarded or prevented by infection, gaping of the wound, frequent or forcible motion, and impairment of the general health.

Albuminuria and *diabetes* particularly obstruct repair. R. T. Morris points out that sugar in the blood is hygroscopic, removes water from the tissues, and thus obstructs repair; and also that the wound fluids contain sugar and are good culture-media ("Med. News," June 29, 1901).

Healing By First Intention.—A wound may "heal by first intention." This mode of healing, which is known as "primary union," occurs without suppuration, and is observed in the healing of an aseptic wound. If infection occurs, primary union will not take place. The phrase "by first intention" comes down to us from the past. It was properly thought that Nature intends to repair a wound, and first intention signifies the first, best, the most desirable way in which it can be accomplished. In a small aseptic incision, in which no considerable vessels are cut, repair will take place very rapidly after the edges have been approximated and the wound dressed. In fact, the wound edges may be held firmly together in twenty-four hours. In such a wound a small amount of blood flows from the capillaries between the edges of the wound, and this blood clots. A trivial amount of exudate and some few migrated corpuscles pass into the clot and into the tissues. The fixed connective-tissue cells and the endothelial cells of the vessels multiply, and form embryonic or juvenile tissue. The cells are epitheloid cells and are known as fibroblasts. The fibroblasts eat up many of the leukocytes and multiply, so that the new cells from one side of the wound finally interlace with the new cells from the other side. Nearby capillaries become irregular in outline; at certain points bulging occurs, and at these points new capillaries develop, extend into the mass of fibroblasts, and join new capillaries of the opposite side. The reparative material is now said to be organized; it has become granulation tissue. The fibroblasts become spindle shaped and develop into interlacing fibers (Fig. 60). The tissue is now fibrous tissue; it contracts strongly, and finally most of the capillaries are obliterated by pressure. In such a slight wound the reaction to injury is chiefly noted in the cells of the part, and the vessels and leukocytes play but a small part in repair.

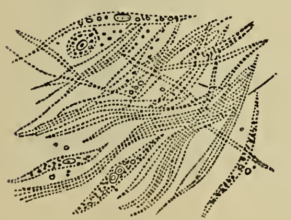

Fig. 60.—Cells developing into fibers (Bennett).

The exudation is so scanty that there is practically no swelling unless it arises from venous obstruction. The vessels are so slightly affected that there is no redness. The final step in healing is contraction of the fibrous tissue and the covering of the surface with epithelium, which springs from the epithelial cells upon the edges. This final process is called "cicatrization," and consists in the formation from fibroblasts of new fibrous tissue and the contraction of the new tissue. The "immediate union" of some writers never occurs. This term means the union of microscopic parts to their counterparts without any effort at repair. A first union is effected always by clotted blood and coagulated exudate, next by proliferating cells, and finally by fibrous tissue. A wound healing by first intention exhibits no evidence of inflammation. There is some slight tenderness, but no actual pain. A certain amount of swelling arises because of exudation of fluid from the blood, and the coagulation of this fluid makes the wound edges hard. Venous obstruction leads in some cases to a considerable fluid swelling. A wound may heal by first intention even though some

[1] Adami, in Allbutt's "System of Medicine."

bacteria are present, if the part has a good blood-supply and the patient is in good health. Active leukocytes and germicidal blood liquor may prevent infection. In a more extensive incised wound many vessels are cut. After oozing ceases the vessels are closed by clots continuous with the clot between the sides of the wound. An exudation of plasma from the blood-vessels and of lymph from the lymph-spaces takes place. Leukocytes in great numbers invade the wound edges and the exudate, and the exudate clots. Thus, an infection may be surrounded and limited. This mass of blood-clot, plasma-clot, and leukocytes used to be known as "coagulable lymph." The leukocytes actively eat up the clot, and by the end of the third day occupy the space formerly occupied by the clot. Embryonic tissue is formed by multiplication of the fixed connective-tissue cells and endothelial cells. These cells are called fibroblasts. They multiply and grow into the mass of leukocytes, eating up many of the leukocytes, and finally join the fibroblasts of the other side of the wound. Some leukocytes enter into the lymph-spaces. New capillaries form from the capillaries at the wound margins. By the end of the first week the fibroblasts begin to assume various outlines, sending out poles or branches or becoming spindle shaped. These spindle-shaped cells become fibers, and the fibers of the new tissue interlace and strongly contract. Thus the edges are pulled firmly together. Finally, new epithelium, derived from epithelium at the wound edges, forms and grows over the wound (Figs. 61–63). In order to obtain primary union the surgeon ought to cleanse the wound, and all his procedures must be thoroughly aseptic and bleeding should be carefully arrested. The parts are then accurately coaptated by sutures, aseptic or antiseptic dressings are applied, and special care is taken to secure *rest.* In a large wound special methods to secure drainage are required (page 76). In a small wound the spaces between the stitches give exit to the trivial quantity of wound fluid. The use of irritant germicides in a wound greatly increases the amount of discharge and renders necessary the introduction of material for drainage. Even a comparatively small wound requires drainage for the first twenty-four hours. During the first twenty-four hours after a large wound begins to heal by first intention the discharge of bloody serum is most plentiful, but after this period it becomes very scanty and soon ceases entirely, and can be much diminished in quantity on the first day by the application of pressure. Warren says that after a hip-joint amputation over a pint of bloody serum flows out during the first twenty-four hours. In an aseptic wound, as a rule, one-half of the stitches are removed on the sixth or seventh day and the remainder on the eighth day, but for two weeks more the wound should be rested and supported, as the new tissue is not very resistant to infection. *Aseptic fever* always arises when much exudation is poured out and it is slowly and imperfectly drained. Aseptic fever is due to the absorption of aseptic pyrogenous material (see page 129). If an incised wound becomes infected, the pyogenic organisms, by liquefying the intercellular substance, destroy the bond of union which is forming between the wound edges. As a consequence, the wound edges are soon widely separated by pus.

What used to be known as "*healing by blood-clot*" is healing by first intention. If there is a considerable gap between the edges of an aseptic wound, and the gap is filled with a blood-clot, healing goes on in the same manner as when the gap is narrow, although more corpuscles, more exudate, and more fibroblasts are required to effect repair.

Healing By Second Intention.—Healing of a wound in which there is a large cavity in the tissue or in which the edges have gaped apart is known as healing by granulation, or "healing by second intention." It is called healing by granulation because the granulations (areas of vascularized embryonic tissue) are visible. It is effected in the same manner as "healing by first

intention," the processes in the two cases being practically identical if pus is absent. As a matter of fact, in healing by granulation there is usually wound infection. As a result of infection intercellular substance is peptonized, many reparative cells are cast off, and repair can be effected only after the formation

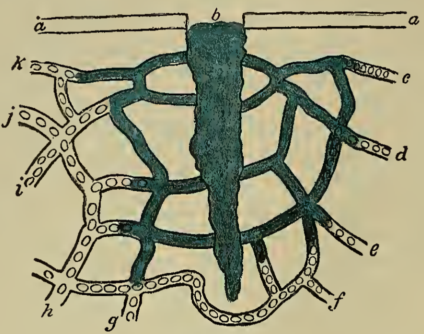

Fig. 61.

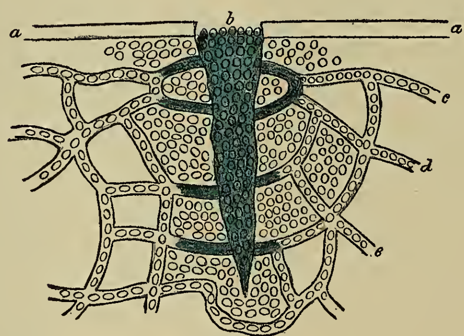

Fig. 62.

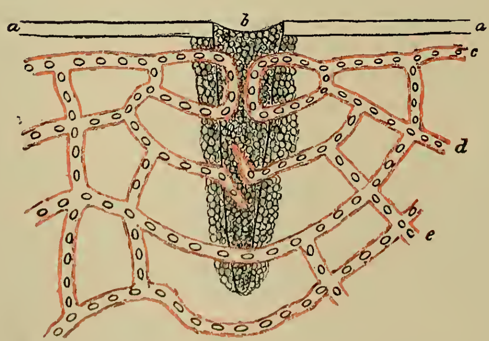

Fig. 63.

Figs. 61–63.—Healing by first intention: *a*, Skin; *b*, fibroblasts; *c*, *d*, *e*, capillaries. Fig. 61, Clot in the vessels continuous with clot between the edges of the wound. Fig. 62, Migration of leukocytes into the perivascular tissues and into the clot between the edges of the wound. Fig. 63, Formation of new capillaries (after Pick).

of enormous numbers of fibroblasts and the expenditure of considerable time. It requires much longer for an infected wound to heal than for an incised wound to be repaired, and an infected wound can heal only by granulation. A short time after the infliction of a wound the oozing ceases, because thrombi form in

the vessels and clot gathers in tissue-gaps and interstices. Exudation begins and leukocytes migrate into the exudate and into the walls of the wound. In an hour or two the surface of the wound becomes distinctly glazed or glistening, because of the formation and coagulation of fibrin. The exudation is at first thin and red, and it soon becomes so profuse as to wash away the discolored fibrin coat. Usually, in a few days the discharge becomes purulent. The connective-tissue cells, especially the endothelial cells of the vessels, proliferate and form fibroblasts, and the fibroblasts multiply to close the wound. From adjacent capillaries new capillaries form. This formation takes place as follows: A portion of a capillary thickens and a whip-like process comes off from the thickened part. This process fuses with a second filament budded from another or from the same capillary, or runs straight out as a terminal vessel. The filaments after a time are hollowed out from within, protoplasmic tubes are formed, and endothelial cells develop from the protoplasm. In some cases a tubular prolongation comes off from a capillary directly. Figures 63 and 64 show the formation of a capillary. In a wound healing by granula-

Fig. 64.—Development of a blood-vessel in mesentery of an embryo (Warren).

tion these newly formed capillaries run among the fibroblasts, and some of them run perpendicularly to the surface, or a loop forms and reaches the surface. The surface of a granulating wound is covered with migrated leukocytes, and directly under these are fibroblasts covering the new vascular strings or loops. Vascular strings or loops coated with fibroblasts are called granulations (Fig. 65 shows a granulating surface). When the discharge becomes purulent, many leukocytes and fibroblasts are destroyed, inflammation increases, exudation becomes profuse, and cellular multiplication widespread and rapid in order to make up for the cells lost by microbic action. Gradually the gap is filled. As it is being filled the older fibroblasts in the deeper layers of the edges and base of the wound are converted into *cicatricial*, *fibrous*, or *scar tissue* (Fig. 66). As the granulations rise to a higher level at the surface the area of fibrous tissue becomes broader at the base and margins, and this young fibrous tissue contracts. By contracting it draws the edges of the wound nearer together, and thus lessens the area of the surface which must be covered with epithelium.

When the granulations reach the level of the cutaneous surface the epithelial cells at the margin of the wound proliferate, and young epithelial cells, constituting a bluish or opalescent film, grow over the granulations. Epithelium comes only from epithelium. Granulations are never converted into epithelium. The epithelial covering comes only from the epithelium at the wound margins, unless there be epithelial remains in the wound; for instance, an undestroyed papilla, sweat-duct, or hair-follicle. The process of covering the surface with epithelium is known as *epidermization.* The epidermization of a large area always consumes considerable time and sometimes Nature fails to accomplish it. In such cases skin-grafting is employed (*q. v.*). Before, during, and for a time after epidermization the fibrous tissue of the walls and base of the wound contracts. Thus the wound margins are pulled and held nearer together, the gap to be bridged is diminished in size, the danger of tearing apart of the epithelial layer is lessened, many capillaries are destroyed by pressure, and

Fig. 65.—Blood-vessels in granulation (Gross).

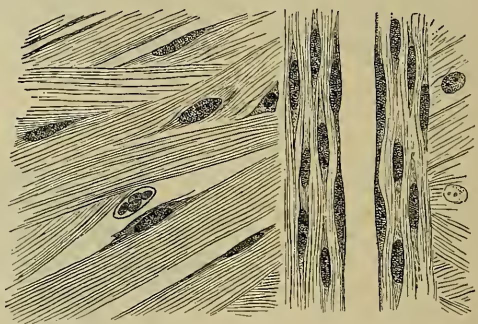

Fig. 66.—Cicatricial tissue; × 670 (Fowler).

the scar becomes firm, white, and puckered. *Cicatrization* consists in the conversion of immature connective tissue into mature fibrous tissue and in the contraction of the new fibrous tissue. Cicatrization is hurried in a healthy granulating wound by the application of an 8 per cent. ointment of scarlet red. It is kept in place only twenty-four hours. To keep it longer will irritate the wound edges. If infection is severe, destruction will exceed repair and healing will not occur. In such a case there is coagulation necrosis of granulation tissue, and the wound becomes covered with tissue remains (aplastic lymph). If granulations rise above the cutaneous level, healing will not take place, because the epithelium cannot then grow over the raw surface. A wound in this condition is said to possess *exuberant granulations*, or *proud flesh.* In some cases the granulations are *pale* from insufficient blood-supply, and in others *edematous* from venous congestion. Contraction of the fibrous tissue may be insufficient because there is adhesion to deep unyielding fascia or to periosteum. Excessive contraction is frequent after burns and often produces terrible deformity. The scars or cicatrices of burns contain much elastic tissue derived from cell protoplasm. Infected wounds and ulcers heal by second intention.

Healing By Third Intention.—This consists in the union of two granulating surfaces, the granulations of one side fusing with the granulations of the other side. It is seen in the union of collapsed abscess-walls. The surgeon occasionally seeks to obtain union of a wound several days old by third intention by approximating two granulating surfaces. If the surfaces are aseptic, he will often succeed. The procedure of approximation is known as *secondary suturing.* It is not unusual to pack a wound with iodoform gauze to control oozing. When this is done it is customary to pass the sutures, but not to tie them. After a few days the gauze is removed and the sutures are

tied. This plan renders healing much more rapid than would be possible by the process of healing by second intention.

Cicatrices, or Scars.—The newly formed connective tissue which constitutes a scar will be present in large amount if more granulations were formed than were really necessary for repair or if a considerable defect was repaired.

A recent scar contains fibrous tissue, many fibroblasts, and numerous blood-vessels, but no nerves, lymphatics, or elastic fibers. The skin above recent scars is usually red because of the numerous vessels beneath it and the layer of epidermis is well developed. In old scars fibroblasts have disappeared and fibrous tissue really constitutes the cicatrix. Some blood-vessels disappear and the diameters of those remaining are much reduced. These vascular changes result from contraction of the cicatrix. Delicate elastic fibers appear in old scars. They appear at the end of the second month in wounds healed by first intention, at the end of the third or fourth month in wounds healed by second intention, and they take origin directly from cell protoplasm and not from fibrous tissue (Minervini, in "Virchow's Archiv," vol. clxxv, No. 2). No genuine lymphatics exist in old scars, but occasionally nerve filaments are present. Some dermal papillæ are found after a time, but skin glands, skin muscle, and hair-follicles remain absent.

An old scar is smooth, whiter than the surrounding skin, somewhat creased or wrinkled, and deficient in tactile sense. The scar of a healed tuberculous ulcer is irregular, livid, and often actually corrugated. The scar of a healed syphilitic ulcer is at first coppery red and then glistening white and depressed. The scar of an old ulcer of the leg and of the skin about it is often darkened by pigmentation.

A cicatrix may be discolored by retained foreign bodies, for instance, grains of gunpowder.

During scar formation shreds of epidermis may be displaced and included in granulation tissue. Subsequently they are included in fibrous tissue, and may then give rise to transplantation (*implantation*) dermoids or to epithelial tumors (see page 379). A scar may be deformed, for instance, may be greatly depressed and adherent to underlying bone, and in certain situations such a scar will fix the jaws or any other joint. The *vicious cicatrix* is a great excess of scar tissue and results from delayed healing by second intention. Such cicatrices are particularly common after burns and tuberculous ulcerations. In some cases the scar is irregular and lumpy, in other cases it is thickened at certain parts and discolored and resembles keloid.

A cicatrix may block a natural orifice, as the mouth or nostril; may produce great deformity, for instance, the head may be drawn upon the chest or shoulder by a contracting scar in the neck, fingers may be grown together after a burn, or a hideous depression may exist on the forehead after an injury, or the face may be fearfully contorted by contracting cicatrices. A scar may produce great disability by blocking the jaws, obstructing the rectum or urethra, or fixing a joint or certain muscles of an extremity.

Most scars are insensitive, some are hypersensitive. The hypersensitive scars are usually thin and pale. The itching, burning, or tingling appreciated in a sensitive scar are located, as a rule, at the junction of sound skin and newly formed epidermis. Sometimes acute neuralgic pain exists in and about a scar due to pressure upon nerve filaments.

A scar may inflame or ulcerate, warts may spring from its cutaneous surface, keloid may arise from the fibrous tissue, carcinoma may come from the epithelial elements (Marjolin's ulcer), sarcoma from the connective-tissue elements.

Healing of Subcutaneous Wounds.—Blood fills the tissue gap and the blood clots. Plasma exudes and corpuscles migrate into the clot and the

tissue about it. The clot is eaten up by the leukocytes. The connective-tissue cells and the endothelial cells of the adjacent tissue proliferate and form fibroblasts, and fibroblasts multiply and replace the clot. The area of fibroblasts is vascularized by the formation of new capillaries, fibrous tissue forms and strongly contracts.

Healing of Wounds In the Non-vascular Tissues.—After a trivial injury of the cornea a few leukocytes gather from the lymph-spaces and a few of the fixed cells proliferate. When the cornea is more severely wounded, an increased flow of lymph occurs. The nerves are irritated, vessels adjacent to the cornea distend, and many leukocytes invade the lymph-spaces. The corneal corpuscles multiply and alter in shape. The product of the process may be transparent if fibrin is absorbed and leukocytes pass away, because proliferating corneal corpuscles form transparent tissue. The surface epithelium is replaced by proliferation of the deep layer of corneal epithelium. If the wound has penetrated the posterior portion of the cornea, it becomes filled by proliferating epithelium from the membrane of Descemet. In a severe injury of the cornea endothelial cells and corneal corpuscles proliferate, vessels grow in from the corneal margins toward the seat of inflammation, fibrous tissue forms, and permanent opacity results.

Repair in cartilage, when it occurs at all, is very slow and is accomplished in the same way as repair in the cornea. Any severe injury is repaired by white fibrous tissue, furnished by the cells of the perichondrium, and the scar is permanent.

Cell-division.—The multiplication of connective-tissue cells in repair may be by direct, but is usually by indirect, cell-division. *Direct cell-division* consists in division of the nucleus followed by division of the entire cell.

Indirect cell-division, or *karyokinesis*, takes place after remarkable changes in the nucleus. The membrane of the nucleus disappears; the nuclear network becomes first close and then more open; and the cell becomes round, if not so before. The network of the nucleus, now consisting of one long fiber, takes the shape of a rosette; next it takes a star form —the aster stage; two V's next form—the equatorial stage; an equatorial line appears and widens, and each one of the V's retreats toward a pole. Thus two new nuclei are formed, each polar V passing in inverse order through the previous changes of shape, and the protoplasm of the original cell collecting about each nucleus (Fig. 67).

Fig. 67.—Forms assumed by a nucleus dividing (Green, from Flemming).

Repair of Nerves.—A nerve-fiber consists of a core known as the axis-cylinder, which is the essential element in function. About the axis-cylinder is an almost liquid material, known as the medullary sheath or white substance of Schwann, or myelin. The myelin is surrounded by a firm sheath known as the neurilemma (sheath of Schwann, primitive sheath, neurilemma). On the inner surface of the sheath of Schwann, or between it and the white substance of Schwann, are nuclei which are supposed by some to be peripheral nerve-cells (neuroblasts). The neurilemma is absent in the brain and cord. The continuity of the white substance of Schwann is interrupted at frequent

intervals, and these breaks in the myelin are called nodes of Ranvier. Numbers of fibers of the kind just described, bound in bundles by connective tissue and surrounded by a fibrous sheath, constitute a nerve. It is known that a nerve may regenerate and completely regain function after division; that regeneration is strongly favored by suturing the ends together; and that if the ends of a divided nerve are more than 1 inch apart, regeneration will rarely take place unless they are sutured together. The method by which regeneration is affected has been much disputed and is still involved in uncertainty. If a nerve is divided, the peripheral segment at once loses its function and then undergoes degeneration (Wallerian degeneration). The degeneration begins within twenty-four to forty-eight hours and affects the entire peripheral segment. The axis-cylinder perishes, the myelin runs into globules and is absorbed, leaving an almost empty sheath; the nuclei of the inner surface of the neurilemma proliferate for a time, but cease to do so before the myelin is completely absorbed. The sheath shrinks and looks empty, but here and there are collected masses of proliferated nuclei and protoplasm. Degeneration takes place in days, but regeneration requires months. Regeneration takes place by the multiplication of pre-existing nerve-fibers, and not by the transformation of connective tissue into nerve structure. The ends of a divided nerve, it is true, become united by connective tissue formed by the proliferation of fibroblasts, but this connective tissue is only a bridge to carry nerve elements across the gap between the proximal and peripheral segments. The common view is that regeneration takes place as follows: The new axis-cylinder of the peripheral segment is a prolongation of the old axis-cylinder of the proximal segment, projected in the following manner: A fiber, which is at first devoid of myelin, is prolonged from a proximal axis-cylinder; it divides into many cylinders, which pierce the granulation tissue between the separated ends and enter into the empty sheaths of Schwann of the distal segment or insinuate themselves between these sheaths (Ranvier, Réclus, Senn). The above is the view entertained by those who teach that the new axis-cylinders come entirely and only from the prolongation of old axis-cylinders of the proximal segment, that the distal segment is passive in the process until "neurotised" (Vanlair), and that regeneration is impossible in the distal segment unless it is in approximation with the proximal segment or within easy reach of the prolongations of the axis-cylinders from above. Another view is that the axis-cylinders, myelin, and neurilemma are formed from cells which exist in the distal segment, and that juvenile axis-cylinders and medullary sheaths are formed in the peripheral portion and then effect a junction with like structures of the central segment. The last-mentioned view is advocated by Mayer and Eichhorst, Tizzoni, Cattani, and others, and Ballance and Stewart have published a most valuable monograph advocating it ("The Healing of Nerves"). The nuclei proliferate and form a mass of protoplasm within the old sheath, which protoplasm subsequently joins the proximal segment. Such a protoplasmic fiber has "conduction and irritability" (Raymond's "Human Physiology"), but there is as yet neither myelin nor axis-cylinder. "The fiber is responsive to mechanical stimuli, but not to induction shocks, which latter property returns only after the axis-cylinder is developed. The medullary substance later appears and forms a tube; and still later the axis-cylinder is formed, having its origin in the central end of the nerve" (Ibid.). The views of Ballance and Stewart may be set forth as follows: When a nerve-trunk is divided, the peripheral segment degenerates whether it has been sutured to the proximal segment or not, and the portion of the proximal segment near the wound also degenerates. The injury produces at once an effusion of blood, migration of leukocytes takes place into and about the wound at the proximal segment, but leukocytic invasion of the entire distal segment is noted. After three days

connective-tissue cells begin to replace the leukocytes, and after two weeks the excess of leukocytes is no longer observed, proliferated connective-tissue cells having taken their place (Ballance and Stewart, "Healing of Nerves," page 94). The proximal segment in the neighborhood of the wound and the entire distal segment are invaded by proliferating connective-tissue cells. The connective-tissue cells completely absorb the fatty myelin and axis-cylinders. The cells of the neurilemma actively multiply, and connective-tissue cells lying among chains of neurilemma cells become spindle-shaped and "the degenerated nerve-trunk therefore becomes hard, fibrous, and cirrhosed" (Ibid.).

In the proximal end of a divided nerve an *"end-bulb"* is formed. This was long supposed to be due to the prolongation of nerve-fibers from the central fibers and a turning backward because they could not cross the gap. As a matter of fact, the ends of the divided fibers curl up; on and in this scaffold-like arrangement new fibers are placed, they having been produced by the neurilemma cells which have taken on "neuroblastic function" (Ballance and Stewart). When a nerve has been sutured, the earliest signs of regeneration "occur at the end of three weeks" (Ibid.). Short lengths of new fibers are laid down within old neurilemma sheaths. The new axis-cylinder "is seen to consist in the deposition along one side of a spindle-shaped neurilemma cell, of a thin thread which grows in length until it projects beyond the limits of the parent cell and stretches on toward its next neighbor in the same longitudinal row" (Ibid.). The new medullary sheath is "laid down by a process of secretion" (Ibid.) along the sides of the neurilemma cells.

Ballance and Stewart go on to point out that if the central theory of regeneration is true, not a trace of regeneration could occur in the distal segment when the two segments have not been united by sutures, and yet such regeneration *does* occur, although slowly, the new axis-cylinders and medullary sheaths not attaining full size. "Evidently some stimulus afforded by the conduction of impulses is necessary in order to permit of their full development" (Ibid.). In the notable study quoted at such length are some experiments on the "conduct and fate of transplanted nerve." When the gap is wide between the two ends, a portion of fresh nerve-trunk may be inserted to bridge it. The transplanted piece degenerates; it is invaded by leukocytes, and proliferating connective-tissue cells, medullary sheaths, and axis-cylinders are destroyed, but regeneration may subsequently occur; "but when it does occur, it is not from the activity of the cells of the graft itself." Blood-vessels enter the degenerated graft at each end and they are accompanied by chains of neurilemma cells, which form axis-cylinders and medullary sheaths. The graft is merely a scaffold. Verga (quoted "Journal de Chirurgie," April, 1910) opposes the notion that the peripheral end plays any part in regeneration and advocates the view that all regeneration comes from the central end.

The studies of Ballance and Stewart persuade us that regeneration does occur in the distal part independently of the proximal part, although full development does not take place unless there is a junction with the central part. As to the exact method of regeneration we still feel somewhat uncertain. When we remember that the nerve-fibers of the spinal cord are devoid of neurilemma and that the cord can, to some extent at least, regenerate, we must conclude that regeneration can take place in the cord without the aid of neurilemma cells, and must infer that the same may be true in a nerve.

Repair of the Spinal Cord and Brain.—Can the spinal cord regenerate? Many observers have doubted it. But there is no doubt of the fact that sometimes, after the subsidence of an acute myelitis or after the relief of a pressure

which produced complete and prolonged paralysis, there is a return of functional power. It is usually assumed that restoration is possible in fibers which have not been hopelessly damaged, but is not possible in those which have been destroyed; but, as Gowers says, there are cases in which "we can scarcely believe that the axis-cylinders retain their continuity, although conducting capacity is ultimately restored." Clinical evidence indicates strongly that the pyramidal fibers may regenerate. Mills ("The Nervous System and Its Diseases") says: "Nerve-tracts in the spinal cord and brain have power to regenerate, but this is not so great as in the peripheral nerves, and yet even old cases of compression of the spinal cord may make great improvement after a long time, largely through the regeneration of the columns of the cord." Mills affirms that although nerve-cells sometimes appear to regenerate, the destruction in these cases was not complete. Recently I showed in my clinic a man who had had complete paraplegia with paralysis of the bladder and rectum for nineteen years. The condition was due to a bullet lodged within the spinal canal. Removal of the bullet was followed in a few weeks by restoration of control over the bladder and rectum. In a few months spastic paraplegia was substituted for flaccid paralysis.

When axis-cylinders have been destroyed in the cord and yet some power returns, we ask ourselves: Does this occur because new fibers have grown down from above? Gowers says that such a growth has been proved to occur in the lower animals, but has not as yet been demonstrated in man; although specimens have been described which strongly suggest such an occurrence in the human subject. That the cord can regenerate to some extent seems highly probable from the report of a case operated upon by my colleague, Professor Francis T. Stewart, of Philadelphia. He sutured a completely divided spinal cord and extraordinary restoration of function took place (Francis T. Stewart and Richard H. Harte, in "Phila. Med. Journal," June 7, 1902). This case is commented on at some length in the section of Injuries on the Spinal Cord. Another somewhat similar case was reported by George Ryerson Fowler in the "Annals of Surgery," Oct., 1905.

Many claim that a brain injury cannot be followed by repair with restoration of function; some think that complete regeneration can take place; others, that partial regeneration may occur. Vitzon and Tedeschi even believe that nerve-cells in the brain can regenerate. It seems probable that extensive injuries are not repaired, but slighter ones may be, new ganglion-cells and neuroglia being formed. Tedeschi describes the process of repair after a wound of the brain as follows: Degeneration occurs and a limited focus of necrosis forms and then the adjacent tissue shows evidences of repair. Capillaries form from the endothelial cells, glia tissue from the neuroglia, ganglion-cells present karyokinetic changes, and some nerve-fibers appear in the scar (Senn's "Principles of Surgery").

Repair of Muscles.—It has long been taught that the repair of muscle by muscle is impossible, and, as a matter of fact, it does not take place if the ends of a divided muscle are separated to the extent of an inch or more. When a muscle is divided transversely by a cut of considerable extent, the ends of the divided fibers retract and a wide space is left between them. Blood flows into the space between the ends, and also between individual fibers of the injured muscle and the blood-clots. Exudation of plasma occurs and migration of corpuscles takes place. Fibroblasts are produced by proliferation of connective-tissue cells and a mass of fibroblasts soon replaces the blood-clot. Granulation tissue is formed by vascularization of the mass of fibroblasts, and granulation tissue is converted into scar tissue, but not at all into muscle. After slight injuries a trivial amount of muscular regeneration does occur by the multiplication of living muscle-cells, but not by metamorphosis of fibroblasts.

Fibroblasts are incapable of transformation into muscular tissue. When the ends of a divided muscle are separated only to a very slight degree or when they have been brought together and sutured, some muscular regeneration occurs. After an injury a number of the muscular fibers always wither, perish, and are absorbed. The process of regeneration arises from the remaining fibers. The nuclei of the muscle-fiber proliferate and so do the nuclei of the perimysium. The muscle-cells are called myoblasts, and the nuclei of the perimysium are called sarcoblasts. About the juvenile muscle-cells a deposit of protoplasm takes place (Weber). The embryonal cells gradually become spindle-shaped, and muscular fiber is formed by cellular fusion or by elongation of individual cells.

The above remarks refer to striated muscle. Unstriated muscle-fibers are repaired solely by "indirect multiplication of their nuclei" (Senn).

If a muscle has been divided, it should be sutured. This process insures more rapid repair and secures a better functional result, and is followed by a much greater amount of muscular regeneration.

Repair of Tendon.—When a tendon is divided, the ends retract, and the sheath, as a rule, becomes filled with blood-clot. The blood-clot is rapidly removed, fibroblasts replacing it. This new tissue arises from the sheath, the cut ends of the tendon not participating in its formation. Granulation tissue is formed; this is converted into fibrous tissue, and after a time the fibrous tissue becomes true tendon. If no blood-clot forms in the sheath, the walls of this structure collapse and adhere, and the separated tendon-ends are held together by a flat fibrous band formed from the collapsed sheath (Warren's "Surgical Pathology").

Repair of Bone.—When a bone is broken a blood-clot quickly forms in the medullary cavity, between the broken ends and under and outside the periosteum. Leukocytes invade and destroy the clot. The cells outside the periosteum, the cells of the periosteum and of the medullary tissue, particularly the endothelial cells, proliferate and produce cells which are practically fibroblasts. The osteoblasts in the medullary tissue, and perhaps in the deeper layers of the periosteum, multiply and are distributed through the mass of fibroblasts. The osteoblasts may form bone directly or may form cartilage first. Some teach that fibroblasts can be converted into bone; others positively deny such a conversion. The point is not settled, but it is well to remember that in myositis ossificans a muscle is converted into bone, and hence that it is probable that fibroblasts, which are formed from periosteum and medullary tissue, are more prone to undergo such a development. During regeneration the bone ends soften and are partially absorbed by osteoclasts. Osteoclasts are large osteoblasts which have lost the power of bone production and furnish a secretion which dissolves osseous matter. The excess of callus is finally absorbed by osteoclasts. (For a more extended description see Repair of Fractures.) Sir William Macewan has recently denied that the periosteum plays a leading rôle in bone production ("Brit. Med. Jour.," June 22, 1907). He believes that the periosteum is a membrane to limit and control the osteoblasts and that new bone is formed purely from bone cells. There is much experimental evidence to confirm Sir William's assertion. If he is correct, a considerable osseous defect could not be filled up by new bone even if the periosteum were intact. As a clinical fact, we see this very thing occur. In a more recent article ("Lancet," August 3, 1912) Sir William claims that osteoblasts are the essential elements in repair, that they come from cartilage cells, that when growing bone is stripped of periosteum growth continues, that when bone is removed and periosteum is left no growth occurs, and that transplantation of spicules offers the best chance of repair because each fragment furnishes peripheral growth. During the last few years many surgeons have utilized bone

transplantation, for instance, transplanting a portion of a rib or the crest of the tibia of the same individual to fix an ununited fracture, to fill a bone gap the result of osteomyelitis, or to anchor vertebræ as in Albee's operation for vertebral caries. John B. Murphy in many respects disagrees with Macewan. (See "Practical Med. Series," vol. ii, 1912.) He believes that a bit of periosteum completely detached from the bone of a young individual and placed in the fat or muscle of the same individual may make new permanent bone. If one end of the strip is allowed to retain attachment to the bone, the transplanted end practically always makes new bone. Bone with or without periosteum transplanted in the same individual and placed in contact with growing bone unites to the living bone, acts as a scaffold for blood-vessels and osteogenetic cells, and is eventually absorbed.

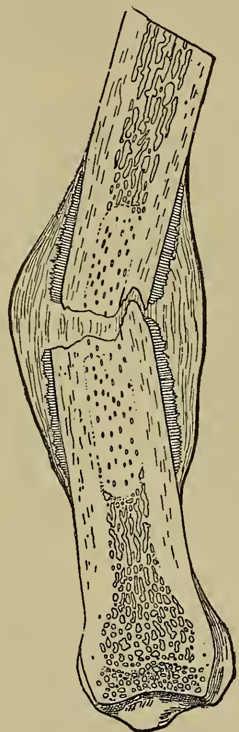

Fig. 69.—Callus of fracture (dog), four weeks: commencing ossification of external callus (Warren).

Fig. 70.—Femur of a child fifth week after fracture (Warren).

Repair of Blood=vessels.—If an artery is cut across and ligated, a clot forms within its lumen and about its divided end, and the circulation in the vessel at this point is permanently arrested. The proximal clot, it used to be thought, always reaches the first collateral branch. This statement was true before the days of asepsis; it is not always true now. Often a clot stops far short of the branch above. Exudation of plasma and migration of corpuscles take place from the vasa vasorum. The clot becomes filled with leukocytes, which gradually destroy it, and it plays no active part in repair. Fibroblasts form by the multiplication of the cells of the vessel wall and the clot is soon replaced by fibroblasts. The fibroblasts are converted into granulation tissue, granulation tissue becomes fibrous tissue, the fibrous tissue contracts, and the

artery is transformed into a fibrous cord. Warren insists that the muscle-cells of the middle coat play an active part in repair. Usually, when a ligature is applied to an artery in continuity, a deliberate attempt is made to rupture the internal and middle coats, in order to permit of contraction and retraction above and below the seat of ligature, and a turning inward of the inner coat. Such a sequence of events happens when an artery is completely divided across and not tied, and favors the rapid formation of a clot.

Ballance and Edmunds ("Ligation in Continuity") maintain that repair is obtained most rapidly when the artery is tied with two ligatures, the vessel at this point being deprived of blood, but the internal and middle coats being kept intact. Cell-proliferation forms a spindle-shaped mass of new cells and the lumen is obliterated at the seat of ligation by fibroblasts obtained from the fixed cells of the wall of the artery. Senn advocates the employment of two ligatures, not placed side by side as in the method of Ballance and Edmunds, but so applied as to include "a bloodless space about ½ inch in length" ("Principles of Surgery").

When a lateral ligature is applied to a vein or when a small wound in a vein or artery is sutured, the circulation in the vessel is not completely cut off, a thrombus of small size is formed on the vessel walls, the fixed cells of the vessel wall proliferate, and a scar of fibrous tissue effects repair. A completely divided vein heals as does a completely divided artery. The clot after the aseptic application of a ligature to a vein may be of slight extent, but in some cases the proximal clot reaches the first collateral branch and in others goes far above it.

Repair of Skin.—The fibrous structure is repaired by fibrous tissue. Hair-follicles, sweat-glands, and sebaceous glands are not re-formed. The epithelial layer is regenerated by the proliferation of adjacent epithelial cells.

Repair of Lymphatic Tissue.—Lymphatic tissue can regenerate either from the fatty tissue, the divided ends of the lymph-ducts, or both structures.

Repair of the Kidney and Testicle.—These organs when damaged can undergo some regeneration.

Repair of the Liver and Spleen.—Each of these organs, after injury, is capable of considerable regeneration.

V. SURGICAL FEVERS

The surgeon encounters fever as a result of an inflammation or an aseptic wound, in consequence of infection, as a result of poisoning by certain drugs, and in several maladies of the nervous system. It is important to remember that, while elevated temperature is generally taken as a gauge of the intensity of fever, it is not a certain index. There may be fever with subnormal temperature (as in the collapse of typhoid or pneumonia), and there may be elevated temperature without true fever (as in certain diseases of the nervous system). It is true, however, that elevation of temperature is almost always noted, and is usually accepted as the measure of the severity of the fever.

Elevated temperature is only a symptom. The elevated temperature of an infection may be regarded as evidence that the body is fighting the infection. An acute infection with a low or subnormal temperature is a far graver condition than an acute infection with a high temperature. The low temperature shows that the body is abandoning the contest; the subnormal temperature shows that it has abandoned it. Exham ("Brit. Med. Jour.," January 27, 1912) points out that the worst cases of pneumonia, peritonitis, and diphtheria are those with subnormal temperature, and that in some of the most malignant cases of scarlet fever the temperature does not rise much above

100° F. As Exham says: elevated temperature is a defence and subnormal temperature means that body resistance is at an end (see page 43). If in doubt as to the cause of fever, count the leukocytes; make a blood-culture, a Widal test, and a Wassermann test.

The *essential phenomena of fever*, according to Maclagan, are—(1) wasting of nitrogenous tissue; (2) increased consumption of water; (3) increased elimination of urea; (4) increased rapidity of circulation; (5) preternatural heat.

Traumatic fevers follow a traumatism and attend the healing or infection of a wound. The forms are—(1) benign traumatic fever; (2) malignant traumatic fever.

Benign traumatic fever is divided into two forms—the *aseptic* and the *septic*. There is but one form of aseptic fever, the postoperation rise. The septic benign fevers are surgical fever and suppurative fever. The malignant traumatic fevers are sapremia, septic infection, and pyemia. In this section we discuss only the benign fevers.

Aseptic traumatic fever, or the *postoperation rise*, often, but not always, appears after a thoroughly aseptic operation and after a simple fracture or a contusion. It is not preceded by a chill, by chilliness, or by a feeling of illness. It may appear during the evening of the day of operation or not until the next day, and reaches its highest point by the evening of the second day (100°–103° F.). This elevation is spoken of as the "postoperation rise" because it is usually encountered after an operation. Besides the elevated temperature there are no obvious symptoms; the patient feels well, sleeps well, and often wants to sit up; there are no rigors and there is no delirium. The wound is free from pain and appears entirely normal. Blood examination may show moderate leukocytosis. This fever is due to absorption of pyrogenous material from the wound area, the material being obtained from clot or inflammatory exudate, or from both. Many observers believe that the pyrogenous element is fibrin ferment, which is absorbed from disintegrating blood-clot and coagulating exudate. Warren thinks the fever is due to fibrin ferment, and "also to other substances slightly altered from their original composition during life." Some have asserted that the fever is due to nervous shock.

Schnitzler and Ewald have studied aseptic fever.[1] These observers maintain that aseptic fever can exist when no fibrin ferment is free in the blood, that fibrin ferment can be free in the blood when there is no fever, and, in consequence, that fibrin ferment is not the cause of the elevation of temperature. They rule out of consideration nervous shock as a cause, and assert that a combination of several factors is responsible, nucleins and albumoses which are set free by traumatism being looked upon as the most active causative agents. The presence of nuclein in the blood in aseptic fever is indicated by leukocytosis and by the increase of the alloxur bodies (including uric acid) in the urine. The capacity of nucleins and albumoses to cause elevated temperature is greater in the tuberculous than in the non-tuberculous, and we know clinically that a tuberculous patient is apt to exhibit a more violent postoperation rise than is a non-tuberculous subject. The diagnosis of aseptic traumatic fever is only to be made after a careful examination has assured the surgeon that there is no obscure or hidden area of infection.

In some cases aseptic fever may appear after an operation, and later be replaced by a septic fever. If the temperature remains elevated more than a day or so, if other symptoms appear, or if after the temperature has become normal it again rises, the wound should be examined at once, as trouble almost certainly exists.

[1] See "Archiv für klinische Medicin," Bd. liii, H. 3, 1896; also statement of their views in "Medical Record," Dec. 19, 1896.

True traumatic, or genuine surgical fever, is seen as a result of infected wounds in which there is decided inflammation, but no pus. The real cause is the presence of fermentative bacteria in the wound and the absorption of a moderate amount of their toxic products. The most active and commonly present organisms are those of putrefaction. Surgical fever ceases as soon as free discharge occurs, and the appearance of such a fever is an indication for instant drainage. The condition is ushered in two or three days after the operation by chilly sensations and general discomfort. The temperature rises pretty sharply, ascends with evening exacerbations and morning remissions, and reaches its height about the third or fourth day, when suppuration sets in; the temperature begins to drop when pus forms, if the pus has free exit, and reaches normal at the end of a week. (See Suppurative Fever.) The temperature may reach 104° F. or more, but rarely rises above 103° F. The patient has the general phenomena of fever, that is to say, thirst, anorexia, nausea, dry and coated tongue, constipation, pain in the back and legs, and headache. The urine is scanty and high colored. Blood examination usually shows decided leukocytosis. The wound is painful, tender, swollen, discolored, and often foul, and stitch-abscesses may form. Some or all of the stitches must be cut, the area should be asepticized, the wound edges separated by iodoform gauze, or the wound drained by a tube. The fact that this fever is apt to cease when discharge of pus begins led the older surgeons to hope for pus and to endeavor to cause it to form. A severe grade of surgical fever, such as arises when there is putrefaction in a large and ill-drained wound, is due to the absorption of a large quantity of the toxic products of putrefactive bacteria, and is known as sapremia (see p. 194).

Suppurative Fever.—This fever, which is due to the absorption of the toxins of pyogenic organisms, occurs after suppuration has begun, is found when the pus has not free exit, and is an intoxication rather than an infection, that is to say, toxins enter the blood, but no bacteria. It can follow or be associated with surgical fever, or may arise in cases in which surgical fever has not existed. Suppuration in a wound is indicated by a rapid rise of temperature—possibly by a chill. The temperature rises to a considerable height, shows morning remissions and evening exacerbations, and as it begins to fall toward morning sweating occurs. The patient is much exhausted and presents the phenomena of fever previously described. The skin about the wound becomes swollen, dusky in color, and edematous, pain becomes pulsatile, and much tenderness develops. Blood examination shows very marked leukocytosis. The wound must at once be drained and asepticized. In a chronic suppuration, such as occurs when there is pyogenic infection of a tuberculous area, there exists a fever with marked morning remissions and vesperal exacerbations, attended with drenching night-sweats, emaciation, diarrhea, and exhaustion. This is known as *hectic fever;* it is really a chronic suppurative fever. The treatment of hectic fever consists in the drainage and disinfection, if possible, the excision of the infected area, the employment of a nutritious diet, stimulants, tonics, remedies for the exhausting sweats, and free access of fresh air.

Some Other Forms of Fever Seen by the Surgeon.—**Fever of Tension.**—When there is great tension upon the stitches, the spots where the stitches perforate ulcerate and some fever arises. To relieve the fever of tension cut one or several stitches. This fever is in some cases surgical, and in some suppurative, according as to whether the infective organisms cause fermentation or suppuration.

Fever of Iodoform Absorption.—(See page 31.)

Fever of Ptyalism, or Mercurial Fever.—(See page 338.)

Fever Due to Awakening of An Area of Pulmonary Tuberculosis.—A quiet, non-progressive area of pulmonary tuberculosis may burst into activity

after an operation, and is particularly apt to if ether was administered. The surgeon must be watchful of this condition. Several times I have seen a person with signs suggesting bronchitis at the base of one lung develop a moderate and prolonged fever. Such a condition is not bronchitis because it is unilateral. The sputum shows pus cocci, but no tubercle bacilli. I formerly regarded it as tuberculosis, but it is always recovered from and is probably bronchopneumonia of one lobe of one lung.

Fever of Morphinism.—Sometimes a morphin habitué suffers from severe chills and intermittent fever of the quotidian or tertian type. The condition is usually thought to be malarial, a view which is strengthened by the common association with neuralgia; but quinin proves futile as a remedy and blood examination gives a negative result. If we have reason to suspect that the patient is using morphin, examine the urine for the drug and wash out the stomach and examine the washing. The latter test is of value even when morphin is used hypodermatically, because some of the drug is excreted into the stomach.

Fever of Cocain-poisoning.—(See Local Anesthesia.)

Hepatic Fever.—(See section on Liver and Gall-bladder.)

Neurotic or Hysterical Fever.—This remarkable condition is occasionally, though seldom, encountered. It is unusual for the temperature to rise above 101° F. Most of the reported cases of great hyperpyrexia are instances of simulation and fraud. That very great elevation can occur is shown by the case seen by Mr. J. W. Teale, which case was also observed by Sir Clifford Allbutt. The temperature rose again and again to 118° F. In such cases the temperature rises very rapidly, remains at its height but a short time, and then falls as rapidly as it arose. It may happen that elevated temperature is the sole evidence of illness, there being no wasting, thirst, or other febrile symptoms. Cold sponging rapidly lowers the temperature. Such elevated temperature may occur irregularly or be attained daily for months. As a rule, hysterical stigmata can be detected. Osler points out that cases of hysterical fever "with spurious local manifestations" are very deceptive. The case may resemble meningitis, peritonitis, or some other acute inflammatory condition; but the course of the supposed malady is found to be atypical and the symptoms are observed to be variable and often anomalous. There is no leukocytosis; frequently there is an apparent increase in red cells, because of vasomotor disturbance, a fall in hemoglobin, and an increased proportion of lymphocytes and eosinophiles ("Clinical Hematology," by J. C. DaCosta, Jr.). It is dangerous to make a diagnosis of neurotic fever; it must not be done unless all other possible causes have been excluded. Some supposed cases depend upon unrecognized tuberculosis, some on visceral syphilis, some on undiscovered malignant disease, some on toxin absorption from the alimentary canal.

An **emotional fever** sometimes occurs after accidents or operations. The patient may have a chill, and then develop violent headache, photophobia, and hysterical excitement, with elevated temperature. Inexplicable elevations of temperature may occur in neurasthenia.

Malaria.—It is wise to examine the blood in supposed septic fevers, for only by this means can malaria be excluded. It is more common to mistake sepsis for malaria than malaria for sepsis. In malaria the spleen is enlarged, the febrile attacks exhibit periodicity, neuralgias are common associates, and quinin cures the condition.

Surgical Scarlet Fever.—It is maintained by some writers (notably Sir Victor Horsley and Sir James Paget) that a child is rendered especially susceptible to scarlet fever by the shock of a surgical operation. Scarlet fever which develops after a wound, a burn, or an operation is spoken of as surgical scarlet fever. Warren quotes Thomas Smith as having had 10 cases of scarlet

fever in 43 operations of lithotomy in children. The puerperal state is supposed also to predispose to scarlet fever. It is not certain whether the poison enters by the wound, or whether shock and exhaustion predispose to ordinary scarlatina, or whether ordinary scarlatina was incubating before the accident or operation. Some surgeons hold that an attack of scarlet fever after an operation is a mere coincidence. Others maintain, and with great show of reason, that a red scarlatiniform eruption appearing after an operation rarely indicates genuine scarlet fever, but usually points to infection, as such eruptions are known occasionally to arise in septicemia. It *rarely* indicates scarlet fever, and yet it sometimes does. There is such a condition as surgical scarlet fever, as is proved by the facts that victims of the disease have been known to communicate it, and that it is often followed by "nephritis and usually by desquamation" (Holt's "Diseases of Infancy and Childhood").

Hoffa has discussed this subject elaborately. He concludes that four types of eruption can follow operation: (1) a vasomotor disturbance due to irritation of sensory nerves, and manifested by a transient urticaria or erythema; (2) a toxic erythema due to absorption of aseptic pyrogenous material from the injured area—the absorption of carbolic acid, iodoform, of corrosive sublimate, or the effect of ether; (3) an infectious rash, which is sometimes found in septicemia or pyemia, and is due to minute emboli composed of bacteria, which emboli lodge in the capillaries; (4) true scarlet fever, with the usual symptoms and complications, the micro-organisms having entered by way of the wound and the eruption often beginning at the wound edges (quoted in Warren's "Surgical Pathology"). Surgical scarlatina is aberrant. It develops rapidly, the period of incubation is extremely brief, and the throat may or may not be involved. Holt tells us that the rash is usually atypical and that "the general symptoms, particularly those relating to the nervous system," are "especially severe" ("Diseases of Infancy and Childhood"). The infection is believed to be due to a specific germ, but it has not been certainly identified. Streptococci have been found in the throat, skin, and the pus from secondary otitis media.

If surgical scarlet fever develops the wound should be drained and asepticized, and, if the situation admits of it, dressed with hot antiseptic fomentations. The general treatment is the same as for ordinary scarlatina.

Fever of Malignant Disease.—Elevation of temperature may occur during the course of sarcoma or carcinoma. It is particularly apt to if growth is very rapid or if ulceration exists. Malignant growths of the liver are especially apt to cause elevation of temperature and leukocytosis.

Fever of malignant disease usually appears as irregular elevations of temperature of short duration. In some cases there is a continuous or remittent fever; in some an intermittent fever. Even the hectic type is met with.

Urinary Fever and Urethral Fever.—(See section on Disease of Genito-urinary Organs.)

Syphilitic Fever.—(See page 322.)

Thyroid Fever.—(See section on Thyroid Gland.)

VI. SUPPURATION AND ABSCESS

Suppuration is a process in which damaged living tissues and inflammatory exudates are liquefied by the action of pyogenic organisms, and it is a common result of microbic inflammation. The organisms which are responsible are referred to on page 48. Staphylococci tend to produce local suppuration; streptococci tend to cause spreading suppuration. It is generally taught that pyogenic bacteria liquefy damaged tissues and exudates by peptonizing them,

the active agent in effecting the chemical change being poison furnished by the bacteria. There is some evidence that white corpuscles by disintegration set free enzymes, which dissolve or aid in dissolving albumin. Streptococci and staphylococci vary greatly in virulence, and the intensity and diffusion of a pyogenic infection depends upon the virulence and number of the bacteria and the level of vital resistance. Streptococci and staphylococci may both be present in one focus, and there may be secondary infection with bacteria of putrefaction or other bacteria. The pyogenic infection may be primary or it may be secondarily implanted in a disease area containing other micro-organisms. The pyogenic organisms are very irritant, and when deposited cause inflammation; inflammation leads to exudation, but the exudate cannot coagulate or coagulates but imperfectly, because it is peptonized by the ferment of the micro-organisms and also perhaps because albumin is dissolved by leukolysin from the white corpuscles. If an area of embryonic tissue is invaded by many pyogenic micro-organisms, it is promptly peptonized. The peptonizing action is upon the fibrinous elements of an exudate and upon the intercellular substance of embryonic or granulation tissue. Cells are separated from intercellular substance, and in consequence degenerate and die. Peptonized exudate or peptonized embryonic tissue is called pus. In suppurations induced by staphylococci a barrier of leukocytes is first formed around the region of irritation; this barrier is reinforced by fibroblasts, the pus is imprisoned, and rapid spreading and wide diffusion are prevented. In inflammations induced by streptococci the peptonizing action of the organisms is so great that no barrier of white blood-cells or of proliferating connective-tissue cells forms in time to imprison the micro-organisms, hence the suppuration spreads rapidly and widely. During the existence of a streptococcic infection some bacteria always enter the blood. Suppuration can be induced by the injection of pyogenic bacteria, by their entry through a wound, and by rubbing them into the skin. In some rare instances, especially when the diet has been putrid, they may enter through the blood and lodge at a point of least resistance. When a medullary canal suppurates after a chill to the surface or after a blow that does not cause a wound, we know that the bacteria must have arrived by means of the blood. Bacteria which reach a point of least resistance through the blood come from some atrium of infection which may be discoverable or which may not be found. The entry of pyogenic bacteria does not necessarily cause suppuration, as the healthy human body can destroy a considerable number, even if given in one "dose"; but a large number in a healthy, or even a small number in an unhealthy, body almost certainly leads to pus formation. The pus of all acute abscesses contains bacteria of suppuration, but the pus of tuberculous abscesses does not, unless there be a mixed infection; in other words, pure tuberculous pus is not pus at all.

Can suppuration be induced without the actual presence of bacteria? It is true that the injection of irritants can cause the formation of a thin fluid which contains no bacteria, but this non-bacterial fluid is not pus. A purulent fluid is formed by injecting cultures of pus cocci which have been rendered sterile by heat, the bacteria having been killed, a ferment contained in the bacterial cells being the active agent. Purulent material also results from the injection simply of the sterile products of the growth of pyogenic cocci. This purulent or sterile fluid is known as *spurious* or *aseptic pus*. An area of such aseptic suppuration does not tend to spread and the process concerns us but little as surgeons, except in cases of pyemia, in which thrombi containing toxins alone may occasionally induce limited secondary abscesses.

Impaired health or an area of lowered vitality predisposes to suppuration. Diabetes and albuminuria are common and influential predisposing causes, because in these diseases tissue resistance is always at a low ebb. In

amyloid disease resistance to pus cocci is greatly impaired. It is lessened in lithemia and in any condition of ill health. The lymphatic glands, medulla of bones, serous membranes, and connective tissue are especially prone to suppurate.

Pus may form within twenty-four hours after bacteria have been deposited, or it may not be formed for days. The older surgeons claimed that pus could do good by protecting granulations and separating disorganized tissue. It is now held that it is absolutely harmful by melting down sound tissue and poisoning the entire organism. Modern surgery has to a great degree abolished pus.

If pus stands for a time, it separates into two portions—(1) a watery portion, the liquor puris or pus-serum, containing peptone, fat, microbic products, osmazone, and salts, and not tending to coagulate; (2) a solid portion, or sediment composed of dead and living micro-organisms of suppuration, connective-tissue cells, often epithelial cells, perhaps red blood-cells, lymphocytes, pus-corpuscles (Fig. 71), débris of tissue, and shreds of dead tissue. The

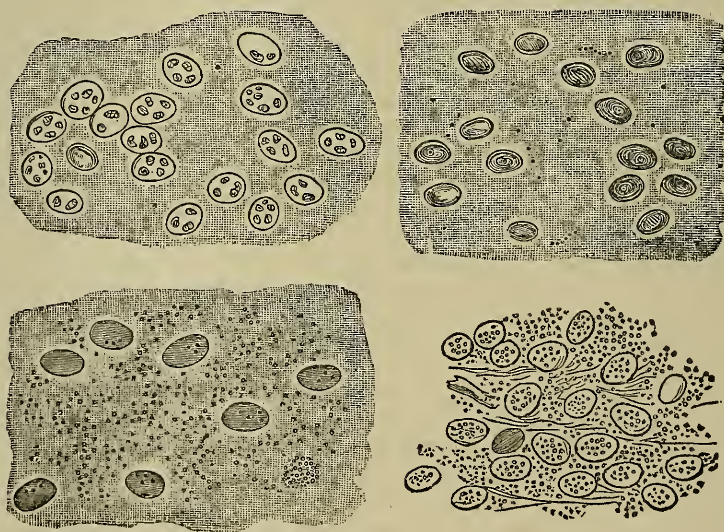

Fig. 71.—Fragmentation of nucleus in leukocytes undergoing transformation into pus-corpuscles (Senn).

pus-corpuscles are either polynuclear white blood-cells or altered connective-tissue cells containing many nuclei. Some of them are dead, some have ameboid movements, some are fatty, others are granular and contain more than one nucleus, and all are degenerating. A pus-cell is waste matter, and it cannot aid in repair. Very exceptionally pus disappears by absorption, by caseation, or by calcification.

Pus in General.—The color of pus is variable and depends upon the nature of the bacteria; the presence or absence of blood, fibrin, body secretions or body excretions (bile, urine, mucus, feces, etc.); and the existence or non-existence of putrefaction.

Its consistence varies. In some cases it is scarcely thicker than water, in others it is like cream, and in still others it is cheesy. Thick pus is opaque and of a greenish-yellow color, and thin pus has a distinct reddish or yellowish tinge. When freshly evacuated many varieties are almost or quite odorless, and are alkaline or slightly acid in reaction.

Some varieties possess a very offensive odor. Pus contaminated by the

bacteria of putrefaction is certain to have a foul odor. Pus which forms in the tonsil, in the brain, about the vermiform appendix, or around the rectum usually possesses an offensive odor.

Forms of Pus.—*Laudable*, or *healthy pus*, a name long in vogue, is a contradiction, no pus being healthy. In former days free suppuration after an operation was regarded as a favorable indication, and when it occurred the surgeon congratulated himself that surgical fever was at an end. At the present day suppuration after an operation is an evidence of previous infection, of lack of care, failure in our precautions, or of infection by the blood. The so-called *laudable pus* is seen coming from a healing ulcer, and is an opaque, yellowish-white, or a greenish fluid of the consistence of cream, without odor or with a very slight odor if it is not putrid, and having a specific gravity of about 1030.

Malignant, *watery*, or *ichorous pus* is a thin, watery, putrid fluid. It is pus filled with the organisms of putrefaction.

Stinking pus may be ichorous. Its odor may be due to the Bacterium coli commune. If this bacterium is the cause the pus is very foul, but not thin. Pus of this nature is met with in ischiorectal abscess and appendiceal abscess. The odor of stinking pus may be due to ordinary bacteria of putrefaction, in which case the pus is usually thin.

Sanious pus is a form of ichorous pus containing blood coloring-matter or blood. It is thin, of a reddish color, and very acrid, corroding the parts with which it comes in contact. It is found notably in caries and carcinoma.

Concrete or *fibrinous pus*, which contains flakes of fibrin or coagulated fibropurulent masses, is met with in serous cavities (joints, pleura, etc.). These masses also form in infective endocarditis.

Red pus signifies the presence of the Bacillus prodigiosus.

Blue Pus.—The color of blue pus is due to the Bacillus pyocyaneus.

Orange Pus.—The color of orange pus is due either to the action of Sarcina aurantiaca, or to the formation of crystals of hematoidin from the coloring-matter of red blood-cells which have been mingled with the pus. Pus of this color appears only in violent inflammations.

Serous pus is a thin, serous fluid, containing few flakes.

So-called *tuberculous*, *scrofulous*, or *curdy pus* is not pus at all, unless the tuberculous area has undergone pyogenic infection.

So-called *gummy pus* arises from the breaking down of a gumma which has outgrown its own blood-supply. It is not pus.

Mucopus is found in purulent catarrh—that is, in suppurative inflammation of an epithelial structure. It contains pus elements and epithelial cells.

Caseous pus comes from the fatty degeneration of pus-corpuscles or inflammatory exudations. It occurs especially in tuberculous processes. A caseous mass may calcify.

Signs and Symptoms of Suppuration.—Suppuration is announced by the intensification of all local inflammatory signs. The heat becomes more marked, the discoloration dusky, the swelling augments, the pain becomes throbbing or pulsatile, and the sense of tension is greatly increased. The skin at the focus of the inflammation after a time becomes adherent to the parts beneath, and fluctuation soon appears. This adhesion of the skin is a preparation for a natural opening, and is known as *pointing*. An important sign of pus beneath is edema of the skin. This is always observed in a superficial abscess, and is sometimes noticeable in empyema or pyothorax, in appendiceal abscess, and in perirenal suppuration. The above symptoms can be reinforced and their significance proved by the introduction of an aseptic tubular exploring needle and the discovery of pus. Irregular chills, high fever, drenching sweats, weakness, and a feeling of serious sickness are very significant of suppuration in an

important structure or of a large area. It must always be remembered that in some virulent pyogenic infections the human organism is so overwhelmed with toxins that, though the patient is desperately ill, the temperature is normal or even subnormal. This means that body resistance has abandoned the conflict. In abscess of the brain the temperature, after an initial rise, often becomes normal or subnormal.

Diffuse Cellulitis or Phlegmonous Suppuration (Purulent Infiltration).— This process may involve a small area or an entire limb, and is due to infection by the Streptococcus pyogenes (streptococcus of erysipelas), usually associated with mixed infection with other bacteria, particularly the bacteria of putrefaction. The streptococci are intensely virulent. Barriers of white corpuscles do not form early enough to restrain them, and tissues break down before cellular multiplication is able to encompass the bacteria. The bacteria disseminate through the lymph-spaces and lymph-vessels. The disease in severe cases produces enormous swelling, areas which feel boggy, a dusky red discoloration, and great burning pain. Gangrene of superficial areas is not unusual, due to thrombosis of vessels or coagulation necrosis from toxins. The discharges of the wound, if a wound exists, are apt to dry up, and the wound becomes foul, dry, and brown. The adjacent lymphatic glands are much enlarged. The disease is ushered in by a chill, which is followed by high oscillating temperature, due to suppurative fever, sapremia, or even septic infection or pyemia. Sweats are noted during periods of falling temperature. Diffuse suppuration tends to arise in an infected compound fracture after extravasation of urine and after the infliction of a wound upon a person broken down in health. It is not unusual after typhoid or scarlet fever, and is typical of phlegmonous erysipelas. The pus is sanious and offensive, and burrows widely in the subcutaneous tissue and intermuscular planes. This diffuse suppuration may widely separate muscles and even lay bare the bones. It is a very grave condition, and may cause death by exhaustion, septic intoxication, septic infection, pyemia, or hemorrhage from a large vessel which has been corroded. *Cellulitis* of a mild degree is due to attenuated streptococci or to staphylococci. An area of cellulitis may surround an infected wound or a stitch-abscess. Its spread is manifested by red lines of lymphangitis running up to the adjacent lymphatic glands. Light cases may not suppurate, the lymphatics carrying off the poison. Any case of cellulitis is, however, a menace, and any severe case is highly dangerous. (See Erysipelas.)

Wooden, Woody, or Ligneous Phlegmon.—This condition was fully described by Réclus in 1893. It is chronic inflammation of the cellular tissue and fascia, and is characterized by the production of quantities of fibrous tissue. It occurs in those over fifty years of age. The neck is the region usually involved. It begins with hard swelling of one side or of the front of the neck and for weeks is unaccompanied by any other sign. The swelling may be at first localized, but it spreads slowly and widely and finally comes to involve an extensive area, even perhaps the front of the neck and both sides from the jaw to the collar-bone. It may involve the cervical muscles and thus create rigidity, and it may compress the larynx and trachea and thus interfere with breathing. In most cases there is difficulty in swallowing. After weeks, or perhaps a month or two, the skin becomes edematous and red or rather of a violet hue. There is no fever and rarely pain. The significant facts are the gradually advancing hard swelling long unaccompanied by fever, pain, discoloration, or cutaneous edema. The condition is due to the deposition and multiplication of bacteria, which reach the tissues from the lymph-glands and reach the glands from an area of infection in the pharynx, a salivary gland, or the mouth. Pus does not form at all or only minute encapsulated foci form, probably because the bacteria are of greatly attenuated virulence or because

the local vital resistance is at a high level to these bacteria. Inflammation occurs, there is copious exudation, and enormous amounts of fibrous tissue form. If pus forms, it may discharge spontaneously in six or seven weeks. The causative bacteria are often attenuated pyogenic microbes. In one of Réclus's cases diphtheria bacilli were found, and this case got better after being given antitoxin. Cases have been reported which were caused by pneumococci.

Wooden phlegmon is occasionally found in syphilitics, but it is not a syphilitic condition. Neither Bright's disease nor diabetes has anything to do with its origin. It may be mistaken for actinomycosis or tuberculosis. It is frequently mistaken for sarcoma or carcinoma, in fact, Lange believes it to be cancer. It arises in those who are in ill health rather than in the vigorous or robust. Wooden phlegmon is always dangerous and is sometimes fatal. One of Réclus's cases died of edema of the glottis. We have spoken of woody phlegmon as though it only could involve the neck; as a matter of fact it can involve other parts. Réclus maintains that it can occur in the right iliac fossa, and that perinephric sclerosis is in reality due to it (Powers, in "Jour. Amer. Med. Assoc.," July 20, 1911). A case has been reported by Todd in which the abdominal wall was involved ("Jour. Missouri State Med. Assoc.," February 8, 1912). Duse also reported such a case ("Gazz. d. Osped.," 1910, xxxi). W. W. Grant, of Denver, has reported ligneous phlegmon of the abdominal wall ("Jour. Amer. Med. Assoc.," April 5, 1913). A similar condition may arise in the perineum, after urinary extravasation or fistula formation. Charles A. Powers, of Denver, has reviewed this subject and presented the report of an admirably studied case (Ibid., July 20, 1911).

Treatment.—Extirpation, if feasible, is the best plan. It is seldom feasible, and the surgeon instead makes numerous incisions and usually dresses with antiseptic poultices. In these cases free suppuration occasionally occurs after a long delay, and when it does occur a cure may promptly follow evacuation. An autogenous vaccine should be made and injected into the indurated area. The surgeon must be prepared to do tracheotomy should an emergency arise.

Furuncle, or **boil,** is an acute and circumscribed inflammation of the deep layer of the true skin and the subcutaneous cellular tissue following bacterial infection of a hair-follicle or a sebaceous gland and resulting in local necrosis of the dermis. A boil is caused by infection of a hair-follicle through a slight wound (by scratching, shaving, etc.) with the Staphylococcus pyogenes aureus. Boils are very common in individuals with Bright's disease, diabetes, gout, lithemia, tuberculosis, and disorders of menstruation and digestion; and crops of boils are apt to appear during convalescence from typhoid fever. Boils are commonest in the spring, and sometimes an epidemic of furunculosis appears in a hospital, a jail, or an asylum.

The **symptoms** of a boil are as follows: a red elevation appears, which stings and itches; this elevation enlarges and becomes dusky in color; a pustule forms that ruptures and gives exit to a very little discharge which forms a crust. Inflammatory infiltration of adjacent connective tissue advances rapidly, and the boil in about three days consists of a large, red, tender, and painful base capped by a pustule and a little crusted discharge. In rare instances, at this stage, absorption occurs, but in most cases the swelling increases, the discoloration becomes darker, the skin becomes edematous, the pain becomes severe and pulsatile, and the center of the boil becomes raised. About the seventh day rupture occurs, pus flows out, and a "*core*" of necrosed tissue is found in the center of a ragged opening. This core consists of the sebaceous gland and hair-follicle, which have undergone coagulation necrosis (Warren). In a day or two more the core will be discharged, and healing by granulation will begin. A *blind boil* lasts only three or four days and has no core. The

constitution often shows reaction during the progress of a boil. Boils may be either single or multiple. The development of one boil after another, or the formation of several boils at once, is known as "*furunculosis*." Boils are commonest upon the neck and the back.

The **treatment** consists in excision or in crucial incision, removal of necrotic tissue, irrigation with peroxid of hydrogen, touching with pure carbolic acid, and the application of hot antiseptic fomentations.

Aleppo Boil (*Endemic Boil of the Tropics; Delhi Boil; Oriental Sore, etc.*).—It is not a pyogenic process. Papules appear upon the exposed parts of the body. These papules, which ulcerate, do not cicatrize for at least a year, and leave ineradicable scars. This condition is due to a protozoön. Man is infected by means of flies, lice, or other insects. The Aleppo boil was once apparently confined to India, Arabia, Persia, Egypt, Algeria, etc. Of late it is said to have appeared in Panama, Philippine Islands, and Hawaii.

Carbuncle (*benign anthrax*) is a circumscribed infectious inflammation of the deeper layer of the true skin and of the subcutaneous tissue, with fibrinous exudation, multiple foci of necrosis arising, and the tissue adjacent to each necrotic plug becoming gangrenous. The infection takes place through a hair-follicle. It is really a boil with extensive infiltration of adjacent tissues. A boil may become a carbuncle, and pus from a carbuncle inoculated into a healthy person may cause either a boil or a carbuncle. The causative organism seems to be the Staphylococcus pyogenes aureus. Carbuncle is most common in the upper part of the back and on the back of the neck. In this region the skin is very thick; each hair-follicle holds only a downy hair, is shallow, and projects but a short distance into the cutis vera. Columns of fatty tissue run from the subcutaneous tissue in an oblique direction to join the point and sides of the hair-follicle. These columns are known as *columnæ adiposæ*, and each one contains a sweat-gland (Fig. 72). When pus runs down one of these columns, it seeks an outlet; it cannot spread easily to the sides, so it slowly works its way to deeper tissue and from one to another interspace and finds its way to the surface through other fatty columns (Warren's "Surgical Pathology") (Fig. 73). When pus finds its way to the surface, an opening forms, hence the numerous foci of pointing; finally a large opening forms (Fig. 74). Carbuncles are most common in the spring of the year. In persons with diabetes and Bright's disease carbuncles not unusually occur.

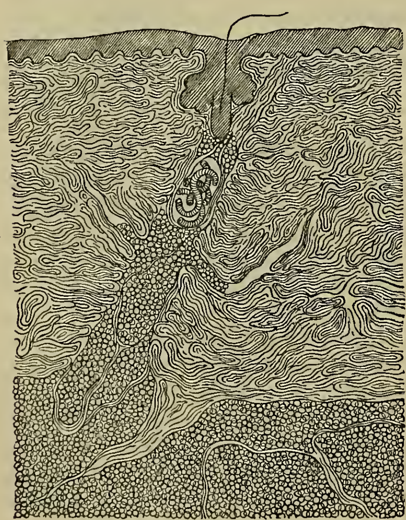

Fig. 72.—Columna adiposa (Warren).

The local **symptoms** in the beginning resemble those of a boil, but the constitution sympathizes from the very start (perhaps a chill and always a septic fever) and the pain is usually severe. The inflammatory area begins as a papule with an indurated base, it enlarges enormously, is boggy to the touch, is dusky in color, is edematous, and the skin is not freely movable over the deeper parts. In a few days many pustules appear, each pustule marking the site of a focus of necrosis. Large vesicles filled with bloody

serum very frequently form. In some cases about the tenth day the pustules rupture, the necrotic plugs are discharged, and the case slowly progresses toward cure; but in many cases the carbuncle spreads at the periphery while pustules are rupturing near the center of inflammation, and pus forms in the deeper tissues, reaching the surface through many small openings, each of which is partly blocked by a plug of dead tissue. A carbuncle in this stage

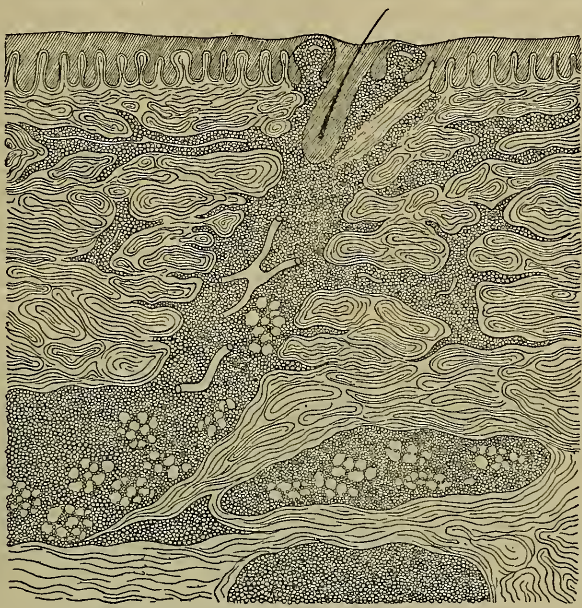

Fig. 73.—Infiltration of columna adiposa and subcutaneous tissue with pus in carbuncle (Warren).

resembles a honeycomb (Fig. 74), discharges bloody pus, and large masses of skin and subcutaneous tissue are destroyed. The entire carbuncular mass may become gangrenous, and a sudden and almost complete cessation of pain points to this complication. An ordinary carbuncle remains acute for about three weeks, but healing requires a month or more. The most dangerous situations in which to have a carbuncle are the face and neck (tends to produce septic

Fig. 74.—Diagram of a carbuncle (Warren).

phlebitis, septic clots in the facial, jugular, or ophthalmic veins, or in the cerebral sinuses, or infective emboli). The mortality of facial carbuncle is at least 50 per cent. The most usual positions for carbuncle are the neck, the back, and the buttocks. The diagnosis of carbuncle is made by noting the multiple foci of necrosis and the profound constitutional involvement. A carbuncle may produce death by causing septicemia, pyemia, or profuse hemorrhage.

Treatment.—Some have suggested the treatment of a carbuncle in an early stage by injecting 5 to 30 drops of carbolic acid (80 per cent.) into and around the inflammatory mass. Such a method does not promise success and necessitates dangerous delay. The best treatment if the case is seen sufficiently early is thorough extirpation while the patient is anesthetized. The entire area of the infection is thus removed, and the large wound heals by granulation and is subsequently skin-grafted. When the condition is too far advanced to admit of complete extirpation, the following useful plan should be employed:

Give ether, make free crucial incisions, remove dead and necrosing tissue and also the points of the skin-flaps with the scissors and forceps, curet pockets, arrest hemorrhage by pressure and hot water, cauterize with *pure* carbolic acid, dust with iodoform, pack with iodoform gauze, and dress with hot antiseptic fomentations. Cover the gauze with a piece of some impermeable material and lay a hot-water bag upon the dressing. Every day, or several times a day, remove the dressings, wash with peroxid of hydrogen, irrigate with corrosive sublimate solution, dust with iodoform, and reapply the iodoform gauze and antiseptic fomentation. Keep up this treatment until sloughs are separated,

Fig. 75.—Infiltration of connective tissue of cutis (× 500) with beginning suppuration in the center (Senn).

then dress with dry antiseptic gauze. Secure sleep by morphin, give quinin, milk-punch, and nourishing diet, and maintain the action of the bowels and kidneys.

Acute Abscesses.—An acute abscess is a circumscribed cavity of new formation containing pus. We emphasize the fact that it is a *circumscribed cavity* —circumscribed by a mass of leukocytes and proliferating fibroblasts. A *purulent infiltration* is not circumscribed, hence it does not constitute an abscess. An essential part of the definition is the assertion that the pus is in a cavity of *new* formation, in an abnormal cavity; hence pus in a natural cavity (pleural, pericardial, synovial, or peritoneal) constitutes a *purulent effusion*, and not an abscess, unless it is encysted in these localities by walls formed of inflammatory tissue.

An acute abscess is due to the deposition and multiplication of pyogenic bacteria in the tissues or in inflammatory exudates. These bacteria attack exudates or tissues, form irritants which cause inflammation or intensify existing inflammation, and by exerting a peptonizing action on intercellular substance and the fibrin of the exudate, liquefy tissue and the products of inflammation, and form pus. As a rule, within twenty-four hours after lodg-

ment of the bacteria the exudation increases in amount, the migrated leukocytes gather in enormous numbers, the fibers of tissues swell, and the connective-tissue spaces distend with cells and fluid. The connective-tissue cells, acted on by pus cocci, multiply by karyokinesis, develop many nuclei, lose their stellate projections, degenerate, and constitute one form of pus-corpuscle, leukocytes forming the other. All the small vessels are choked with leukocytes, this blocking serving to cut off nourishment and tending to produce anemic necrosis. Liquefaction occurs at many foci of the inflammation, drops of pus being formed, the amount of each being progressively added to and many foci coalescing (Fig. 75). The pus-cavity is circumscribed, not by a secreting pyogenic membrane, but by a mass of fibroblasts, whose cells and intercellular material have not as yet broken down; such a mass of fibroblasts is often called embryonic tissue, and it is circumscribed by a zone of inflammation in which there are hordes of migrated leukocytes (Fig. 76). As an abscess increases in size, the embryonic tissue from within outward liquefies into pus, and the zone of inflammation beyond continually enlarges and forms more embryonic tissue. After a time the inflammation reaches the surface, the embryonic tissue glues the superficial to the deeper parts, the superficial parts inflame and become embryonic tissue, and the intercellular substance is liquefied. When pus has all but reached the surface, a thin layer of tissue only being undestroyed, an elevation or tit of thin tissue is formed, due to the fluid pressure. This process is known as *pointing*. The elevation or point thins from tension and liquefaction, and finally gives way and *spontaneous evacuation* occurs. When an abscess forms in an internal organ or in some structure which is not loose, like connective tissue—for instance, in a lymphatic gland—a mass of pyogenic bacteria, floating in the blood or lymph, lodges, and these bacteria by means of irritant products cause coagulation necrosis of the adjacent tissue and inflammatory exudation around it. The area of coagulation necrosis becomes filled with white blood-cells, and the dry necrosed part is liquefied by the cocci. Suppuration in dense structures causes considerable masses of tissue to die and to be cast off, and these masses float in the pus. Death of a mass with dissolution of its elements is necrosis, or inflammatory gangrene. Pus travels in the line of least resistance. It may reach a free surface, or may break into a cavity or joint, may invade bone or destroy a vessel. When an abscess ceases to spread or is evacuated, the fibroblastic layer forming the walls becomes vascularized and is converted into *granulation tissue*. An abscess heals by the collapse of its walls and fusion of the granulations (union by third intention), or by granulation (union by second intention). In either case granulation tissue is ultimately converted into fibrous or scar tissue.

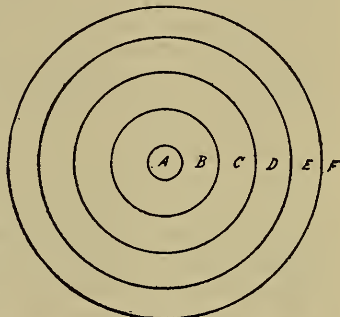

Fig. 76.—Diagram of an abscess: *A*, Pus; *B*, layer of fibroblasts; *C*, tissue infiltrated with leukocytes; *D*, zone of stasis; *E*, zone of active hyperemia; *F*, healthy tissue.

Forms of Abscesses.—The following are the various forms of abscesses: *Acute*, which follows an acute inflammation. *Strumous, cold, lymphatic, tuberculous*, or *chronic* abscess is due to the bacilli of tuberculosis, and does not contain true pus unless there is secondary pyogenic infection. It presents no signs of inflammation. Such abscess occasionally forms in a week or two, and hence is not necessarily chronic. *Caseous* or *cheesy* abscess, a cavity containing thick cheesy masses, is due perhaps to the fatty degeneration of inflammatory exudate and pus-corpuscles, but most commonly results from the caseation of a tuber-

culous focus. *Circumscribed* abscess is one limited by a layer of fibroblasts. *Diffused* abscess is an unlimited collection of pus, in reality not an abscess, but either a purulent effusion or a purulent infiltration. *Congestive, gravitative, wandering,* or *hypostatic* abscess is a collection of pus or tuberculous matter which travels from its formation point and appears at some distant spot (as a psoas abscess). *Critical* or *consecutive* abscess is one which arises during an acute disease. *Diathetic* abscess finds its predisposing cause in a diathesis. *Embolic* abscess is due to an infected embolus. *Tympanitic* or *emphysematous* abscess is one which contains air or the gases of putrefaction. *Encysted* abscess, in which pus is circumscribed in a serous cavity. *Fecal* or *stercoraceous* abscess is one containing feces in consequence of a communication with the bowel. *Follicular* abscess is one arising in a follicle; *hematic* abscess, one arising around a blood-clot, as a suppurating hematoma; *marginal* abscess, which appears upon the margin of the anus. *Pyemic* or *metastatic* abscess is the embolic abscess of pyemia. *Milk* abscess is an abscess in the breast in a nursing woman. *Ossifluent* abscess arises from diseased bone. *Psoas* abscess is a tuberculous abscess arising from vertebral caries, the matter following the psoas muscle, and usually pointing in the groin (see page 241). A *sympathetic* abscess, arising some distance from the exciting cause, such as a suppurating bubo from chancroid, is not in reality sympathetic, because infective material has been carried from the primary focus. *Thecal* abscess is a purulent effusion in a tendon-sheath. *Tropical* abscess is an abscess of the liver, so named because it occurs chiefly in those dwelling in tropical countries: it usually follows dysentery. *Urinary* abscess, caused by extravasated urine. A *verminous* abscess is one which contains intestinal worms and communicates with the bowel. A *syphilitic* abscess occurs in the bones during tertiary syphilis, and is gummatous and not primarily pyogenic. *Brodie's* abscess is a chronic abscess of the head of a long bone, most common in the head of the tibia (see page 497). A *superficial* abscess occurs above the deep fascia; a *deep* abscess occurs below the deep fascia. A *residual* or *Paget's* abscess is a recurrence of active changes; it may be after years around the residue of a former tuberculous abscess (see page 237).

Symptoms of Acute Abscesses.—In an acute abscess, as before stated, a part becomes inflamed and a quantity of fibroblasts are formed; fibroblastic tissue is liquefied (as above noted) and pus is produced. An acute abscess can occur in a person of any constitution.

Local Symptoms.—Locally, there is intensification of inflammatory signs and enormous increase of the swelling. At first the area is hard, but afterward becomes soft, and it finally fluctuates. The discoloration becomes dusky. The pain becomes throbbing and the sense of tension increases. The pain is greater the denser the implicated tissue and the greater the number of nerves it contains. At every pulse-beat the tension in the abscess increases temporarily, and hence the pain momentarily increases. Pain is increased by a dependent position of the part. There is great tenderness. The pain may be felt at the seat of suppuration or may be referred to some distant point. Tenderness is located at the focus of disease. The cutaneous surface, if the abscess is adjacent, is seen to be polished and edematous, and after a time pointing is observed and fluctuation can be detected. If pus is deeply situated the skin may not be reddened, and perhaps the area of induration cannot be palpated. In such a case there is often rigidity of the muscles overlying the abscess (as in abdominal suppurations), the skin may be edematous (as in deep abscess of the neck), and besides local pain there may be pain due to pressure upon a nerve-trunk, the pain perhaps being referred to a distant point.

Constitutional Symptoms.—If there is a small collection of pus in an unimportant structure, there may be no obvious constitutional disturbance.

If the abscess contains much pus or affects an important part, disturbances generally appear, from slight rigors or moderate fever to chills, high temperature, and drenching sweats. The constitutional condition typical of an abscess is due to the absorption of retained toxins, and is known as "suppurative fever." When an abscess is open but ill-drained, or when it is unopened and deep-seated, long-continued suppuration causes a fever which is markedly periodic: the temperature rises in the evening, attaining its highest point usually between 4 and 8 P. M., and sinks to normal or nearly normal in the early morning (from 4 to 8 A. M.). When the temperature begins to fall, profuse sweating takes place. This fever is known as *hectic*. As previously stated, the temperature may be normal or subnormal in abscess of the brain. Prolonged suppuration causes albuminoid changes in various organs, notably in the liver, spleen, and kidneys. Albuminoid changes are especially common when there has been mixed infection of a tuberculous area and long-continued suppuration. It also occurs as a result of syphilis.

J. C. DaCosta, Jr. ("Clinical Hematology") tells us that "in both trivial and extensive pus foci the number of leukocytes may be normal or even subnormal; in the former instance because systemic reaction is not provoked, and in the latter because it is overpowered. Leukocytosis may also be absent in case toxic absorption is impossible, owing to the complete walling off of the abscess. In all other instances save these a definite and usually well-marked leukocytosis occurs, amounting on the average to a count of about twice the mean normal standard, but frequently greatly exceeding this figure in the individual case."

The signs and symptoms of an abscess are somewhat modified by location, and it is wise to discuss acute abscesses in different situations.

Acute Abscesses in Various Regions.—*Abscess of the brain* may follow cerebral concussion or fracture of the skull, may arise during a general infection, but in about 50 per cent. of cases results from chronic suppurative disease of the middle ear. In *abscess* of a silent region of the *brain* symptoms may long be entirely absent. The usual symptoms are a temporary initial rise of temperature, which soon gives place to a normal and in one-half of the cases to a subnormal temperature, headache, vomiting, delirium, drowsiness, and choked disk. Localizing symptoms, spasmodic or paralytic, may be present. There is usually but not always leukocytosis. In but few uncomplicated cases are there elevated temperature and sweats. Toward the end of the case there may be elevated temperature and delirium. In extradural abscess there is fever from beginning to end (see page 805).

Appendiceal or *appendicular abscess* results from inflammation, usually but not always with perforation of the vermiform appendix, plastic peritonitis leading to agglutination of the mesentery and omentum, adhesion of the bowels and mesentery, and the formation of a barrier of leukocytes and a mass of fibroblasts. This process circumscribes the pus. If the pus in suppurative appendicitis has been formed by colon bacilli or staphylococci, it will probably be circumscribed and limited. If the pus has been formed by streptococci, it will probably not be limited, and the peritoneum will be attacked by diffuse septic peritonitis. The signs of appendicular abscess are pain, tenderness, muscular rigidity, and the existence of a mass in the right iliac fossa. The mass may be palpated through the abdominal wall or perhaps the rectum and is dull on percussion. There may be vomiting, and sometimes constipation and sometimes diarrhea. Very seldom is there skin edema and fluctuation. The patient lies upon his back, usually with one or both thighs flexed. In appendicular abscess there is fever, usually higher at night than in the morning, profuse sweating occurring during the fall. In some cases the temperature is persistently high; in some the elevation is trivial; in some chills occur. A sud-

den fall of temperature with shock is produced by rupture of the abscess wall. If this accident happens, general peritonitis quickly arises. In appendicular abscess there is marked leukocytosis, unless the walls are very thick or unless the process has diffused and general peritonitis has taken place, in which conditions it may be absent. Appendiceal abscess may be assumed to exist when the symptoms of appendicitis persist after the fifth or sixth day, or when, after the symptoms have subsided, they reappear a day or two later (see page 1006).

Abscess of the liver may not be announced by symptoms until rupture. It may follow dysentery, may be a result of the lodgment of infected clots from the hemorrhoid veins, may follow upon the infective phlebitis of appendicitis, may result from septic cholangitis or suppuration of a hydatid cyst. Abscess from dysentery is apt to be solitary. Portal infection induces multiple abscesses. We speak now of solitary abscess. The bacterial origin of this is in doubt. Ameba are usually present. We usually find fever of an intermittent type, profuse sweats, pain in the back, the right shoulder, or the right hypochondriac region, enlargement of the area of liver-dulness, and hepatic tenderness. Sometimes there are fluctuation and skin edema over the liver, and the general cutaneous surface may be a little jaundiced. The symptoms vary as the pus invades adjacent organs. When there are pain on respiration and evidences of diaphragmatic pleuritis, the pus is probably breaking into the pleural sac. There may or may not be leukocytosis (see page 1035).

Deep Abscess of the Neck.—The majority of these abscesses are due to suppuration of lymph-glands, bacteria having reached the glands from an adjacent area of infection, cutaneous, mucous, or osseous. Suppuration beneath the deep fascia induces dusky discoloration of the surface, great pain, extensive edematous swelling, and often interference with respiration. The constitutional evidences of suppuration are noted. Acute suppuration under the deep fascia of the submaxillary region causes extensive inflammatory edema, interference with respiration and deglutition, violent constitutional symptoms, and often sloughing of tissues (see Ludwig's Angina). A deep abscess over the carotid artery is lifted by each arterial beat and may be mistaken for aneurysm, but the pulsation is not expansile. The pus of a deep cervical abscess may track its way into the mediastinum or axilla, or the abscess may break into a large blood-vessel, the pharynx, the wind-pipe, or the gullet.

Axillary Abscess.—Superficial abscesses are usually multiple, are in reality furuncles, and result from infection of the sweat-glands and hair-follicles.

Deep abscesses are in most instances due to suppuration of the axillary lymph-glands. The most common cause is an infected wound or a focus of suppuration about the hand, forearm, arm, or chest, but it may result from caries of a rib or may follow a deep cervical abscess. An axillary abscess may be lifted at each beat of the artery and to this extent it resembles an aneurysm, but the pulsation is not expansile.

Acute retropharyngeal abscess is due to pyogenic infection of the retropharyngeal tissues. The abscess usually forms upon one of the lateral halves of the pharynx. It may be due to traumatism, to acute infectious diseases, to infective processes of the mucous membrane of the mouth, ear, and nasopharynx, or to pyogenic infection of a tuberculous abscess. In the great majority of cases the disease is due to suppuration of the deep cervical glands. There is pain, difficulty in swallowing, dyspnea, nasal voice, bulging into the pharynx, which is detected by inspection and palpation, enlargement of the deep cervical glands, fever, sweats, and great weakness. Tuberculous Retropharyngeal Abscess is considered on page 241.

Subphrenic or *subdiaphragmatic abscess* is apt to begin beneath the diaphragm, though in some few instances the pus forms above this muscle, and sub-

sequently gains access to the region beneath. Such an abscess may contain not only pus, but gas, and in some cases also fluid from the stomach or intestine. The gas of a subphrenic abscess may have entered from a perforation of a hollow viscus or may have been made by gas-forming bacteria. Subphrenic abscess may arise after perforation of the bowel or stomach, or it may result from Pott's disease, perinephric abscess, traumatism, abscess of liver, kidney, spleen or pancreas, empyema, or pneumonia (Greig Smith). Inflammation of the gall-bladder or appendicitis may cause it. The symptoms are pain, fever, sweats, dyspnea, cough, and the physical signs of a collection of fluid beneath the diaphragm and often of gas in the cavity of the abscess. There is usually leukocytosis (see page 143).

Abscess of the lung gives the physical signs of a cavity; the expectoration is offensive and contains fragments of lung-tissue. An abscess may often be located by the use of the *x*-rays. Pyemic abscesses may exist and yet escape discovery. (See Surgery of Respiratory Organs.)

Abscess of the mediastinum may arise secondarily to deep abscess of the neck or vertebral suppuration; suppuration of the mediastinal glands, lung, or pleura; caries of a rib or of the sternum, ulceration of the esophagus or pericarditis. It causes throbbing retrosternal pain, pain in the back, chills, fever, sweats, irregular pulse, and often dyspnea. A lump may appear which pulsates and fluctuates, but the pulsation is not expansile.

Perinephric abscess usually causes tenderness and pain in the lumbar region or about the hip-joint, which pain runs down the thigh and is accompanied by retraction of the testicle. Induration, fluctuation, or edema of the skin may be observed in the lumbar region. The constitutional symptoms of suppuration usually exist (see page 143). There is a high leukocytosis.

Abscess or *empyema of the antrum of Highmore* is a collection of pus within the maxillary antrum. It results from inflammation of the jaw, the teeth, or the mucous membrane of the nose. It causes pain, edematous swelling of the overlying soft parts, and crepitation on pressure upon the superior maxillary bone. Pus may escape from the nostril of the diseased side when the head is bent in the direction of the healthy side. A rhinoscopic examination discloses the fluid passing into the nares. The antrum on the side of the abscess cannot be transilluminated by an electric light in the mouth (Garel's sign). The constitutional symptoms of suppuration usually arise.

Alveolar abscess is suppurative dental periostitis due to diseased teeth. The simplest form is a *gum-boil*, a collection of pus between the gum and the bone external to the inflamed root of a tooth. In more severe cases the suppuration begins within the tooth socket and the pus escapes around the neck of the tooth; a distinct and local abscess may be situated at the end of the root, absorption of bone having occurred, or a considerable cavity may form in the bone, the external maxillary plate being perforated. In the very severe cases the cheek is involved. An alveolar abscess may break through the gum into the mouth or it may break externally through the cheek. Alveolar abscess causes intense pulsatile pain, marked swelling of the gum and cheek, and sometimes very great edematous and dusky swelling of the face. A sinus may follow its evacuation. Dead bone may form.

Abscess of the larynx invariably causes laryngeal edema, which obstructs respiration and puts life in jeopardy. Such an abscess is most apt to appear upon the oral surface of the epiglottis, but may arise within the larynx. It induces violent cough, pain, interference with the voice, swallowing, and breathing, and the swelling can often be felt with a finger and can always be seen by the aid of a laryngoscope.

An *ischiorectal abscess* is situated in the areolar tissue of the ischiorectal fossa. The pyogenic organisms usually gain entrance to the lymphatics by

way of an abrasion, fissure, or ulceration of the rectum or anus. A perforation made by a foreign body may inaugurate the condition. In rare cases bacteria reach the fossa in the blood-stream. The pain is severe and throbbing; there are great tenderness, redness and edema of skin, induration, and usually the constitutional symptoms of pus formation. Fluctuation is a very late sign because of the density of the fascia.

Prostatic abscess may result from catheter infection, from infection of the bladder or urethra, or from traumatism, but the commonest cause is gonorrhea. There may be one abscess, several abscesses, or many abscesses. Pus may break into the rectum, the bladder, or the urethra, or may break externally. A prostatic abscess is manifested by chills, fever, sweats, frequency of micturition, tenderness of the perineum and rectum, and agonizing pain, developing during an attack of acute prostitis. A finger in the rectum can palpate the swollen gland.

Abscess of the breast follows absorption of pyogenic bacteria from a fissure or abrasion of the nipple. Some surgeons maintain that the bacteria enter along the milk-ducts, while others assert that they gain entrance by the lymphatics. It is most common in nursing women. Its symptoms are swelling, tenderness, pulsatile pain, dusky discoloration, skin edema, fluctuation, and usually constitutional disorder. (See Mastitis.)

Orbital abscess is a diffuse suppuration, due to cellulitis or a collection of pus due to caries or necrosis of the orbital wall, suppuration of the accessory nasal sinus, facial erysipelas, or dental caries. In severe orbital cellulitis the movements of the eye are limited, the lids are very red and edematous, the conjunctiva is red and swollen (chemosis), and, if the case is not promptly relieved, optic neuritis may arise and sloughing of the cornea occur.

Von Bezold's Abscess.—In this condition the pus of a suppurating mastoid process breaks through the mastoid near the tip and enters into the sheath of the digastric muscle or the sheath of the sternocleidomastoid. There exist extensive inflammatory swelling of the neck, a history of mastoid trouble, usually a lessened amount of pus from the ear, pain in the neck, and constitutional symptoms. The condition suggests thrombosis of the lateral sinus, but the symptoms are not so violent and are not pyemic as they are in that disease.

Abscess of the Groin or Pyogenic Bubo.—Such an abscess may have mounted up from the pelvis, tracked forward from the sacro-iliac joint, or descended in the psoas sheath from the vertebræ, but in a very great majority of cases it is due to suppuration of the lymphatic glands. A bubo may be tuberculous, venereal, or pyogenic. A pyogenic bubo results from an area of infection in the trajectory drained by the lymph-vessels of the inguinal or femoral glands. The glands involved may be superficial or deep. The symptoms are those ordinarily linked with suppuration. Occasionally, the pulsations of the great vessels may lift the mass.

Abscess of the Popliteal Space.—This results from traumatism, mixed infection of a tuberculous or syphilitic area, suppuration of the contained lymph-glands, of one of the adjacent bursæ, or of the neighboring bone. In rare cases it arises as a result of suppuration of the sac of an aneurysm. The symptoms are severe pain, swelling, flexion of the knee, and edema of the leg. The pulsations of the popliteal artery may be transmitted to the abscess. These pulsations are not expansile, as in aneurysm. Pus may pass under the deep fascia, up or down the extremity, or may break into the knee-joint.

Suppurative thecitis or *felon* is a form of diffuse suppuration. (See Felon.)

Palmar abscess is a purulent effusion (see page 721).

Furuncle and *carbuncle* are discussed on pages 137 and 138.

Empyema is a purulent effusion into the pleural sac (see page 891). It is technically an abscess if it becomes encapsuled.

Diagnosis.—The diagnosis of an abscess rests upon—(1) its history; (2) fluctuation; (3) pointing; (4) surface edema; (5) the use of the tubular exploring needle; (6) leukocytosis.

Fluctuation is the sensation imparted to a finger held against a sac containing fluid when a wave is started in the fluid by striking the mass with a finger of the other hand. Fluctuation cannot be obtained if the amount of fluid is small. It should never be sought for across a limb, but rather along it, because a false sense of fluctuation can always be obtained across the muscles of the limb. *Pointing* and *surface edema* have been discussed.

A suspected abscess in a part containing large blood-vessels under no circumstance should be opened by a bistoury without knowing that the diagnosis is certainly correct. This knowledge is obtained in some cases by inserting a small aspirating needle and observing the nature of the fluid which exudes. This operation must be performed with aseptic care; otherwise, if there is no abscess, infection may be inaugurated; if there is an abscess, mixed infection may occur. The older operators used a grooved exploring needle, but many able surgeons object to its use, on the ground that when plunged into an infected area pus bathes the track of puncture and may cause infection of

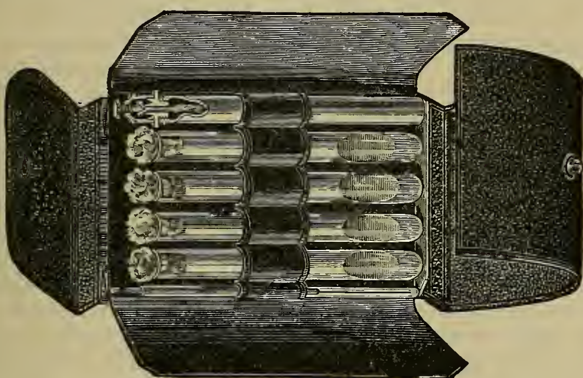

Fig. 77.—Vischer's case for carrying culture-tubes for inoculation.

other tissues and diffusion of the pyogenic process. The tubular exploring needle is the proper instrument.

An abscess which moves with the pulse because it rests upon an artery may be confounded with an aneurysm. The pulse movements of such an abscess are in one direction only; the abscess is lifted with each pulse-beat, but does not enlarge, and if a finger is laid upon either side of it the fingers will be lifted, but not separated. The pulse movements of an aneurysm are in all directions; they are expansile, the sac grows larger, and the fingers will not only be lifted, but will also be separated. The small tubular exploring needle may be used in doubtful cases; if aseptic, it will do no harm even to an aneurysm. A rapidly growing, small-cell sarcoma feels not unlike an abscess, but the exploring needle discovers blood and not pus. A cystic tumor is separated from an abscess by the absence of inflammation, or, if it inflames, by the nature of the contained fluid. Ordinary caution will prevent one confounding an abscess with strangulated hernia. A tuberculous abscess is separated from an acute abscess by the absence of inflammatory signs in the former. The contents of the acute abscess differ from those of the tuberculous abscess. When an abscess exists in an important region (brain, appendix, liver, etc.) cultures of the pus should be taken after incision. Such studies often give valuable information as to the probable course of the condition,

and an accumulation of many accurate observations will add greatly to scientific information. Figure 77 shows a convenient case for carrying culture-tubes.

Prognosis.—The prognosis varies according to the number of abscesses, their location and size, the strength of the patient, and the virulence of the causative bacteria.

Treatment.—In the treatment of an abscess there is one absolute rule which knows no exception, namely, that whenever and wherever pus is found the abscess should be evacuated at once, and, after evacuating it, thorough drainage must be provided for. It should be opened early, if possible, even before fluctuation and positively before pointing, to prevent tissue destruction, subfascial burrowing, and general contamination. Drainage is continued until the discharge becomes scanty, thin, and seropurulent.

Alveolar abscess requires prompt incision through the gum, extraction of the diseased tooth in most cases, and the rinsing of the mouth at frequent intervals with hot fluid. Heat should not be applied to the cheek or jaw externally, as it would favor external rupture. If spontaneous rupture externally is inevitable, then an incision must be made at the point where the abscess is nearest the surface. The cut will leave less scar than will spontaneous evacuation. It is sometimes necessary to gouge through the external table of the bone, pus being lodged within the two osseous plates.

Abscess of the liver, if the liver is adherent to the parietal peritoneum, is opened at one operation; if the liver is not adherent, some surgeons operate in two stages. In the two-stage operation an incision is made along the edge of the ribs down to the liver, which organ is then stitched to the edges of the wound. In a day or two after the first operation the two layers of peritoneum are firmly adherent, and the abscess can be opened without danger of the passage of pus into the peritoneal cavity. The abscess, located by an aspirating needle, is opened by the Paquelin cautery, is washed out with salt solution, and a tube is inserted. If care is taken, the operation can be safely completed in one séance even if the liver is not adherent to the parietal peritoneum. If this course is determined on, after the liver is exposed by incision, the exposed surface of the organ is surrounded with iodoform gauze, the abscess is located by an aspirating needle, is opened by the cautery, is irrigated and drained as directed above. Some physicians try to locate an abscess by plunging an aspirating needle into the liver before making an abdominal incision. This procedure seems to me uncertain and dangerous.

Abscess of the dome of the liver may be reached by resecting a rib, incising the pleura, and opening through the diaphragm (transthoracic hepatotomy).

Abscess of the mediastinum, like all other abscesses, requires incision and drainage. This is effected, if the abscess can be reached from in front, by cutting between the rib cartilages or by trephining the sternum. Abscess of the posterior mediastinum can be reached only by resecting portions of several ribs near their vertebral ends.

In *abscess of the lung* an incision is made and the pleura is exposed. The incision is usually through an intercostal space; but if the spaces are narrow, it will be necessary to resect a rib. If the two layers of pleura are found adherent, the operation is proceeded with. If they are not adherent, they are stitched together with catgut sutures, and the surgeon waits forty-eight hours before continuing. This precaution is taken in order to prevent collapse of the lung from acute traumatic pneumothorax, and to save the pleura from receiving pus during operation. The operation is completed by locating the pus by means of an aspirating needle, evacuating it by the cautery at a dull-red heat, and inserting a drainage-tube into the abscess-cavity.

A *subphrenic abscess* requires operation at once. Immediately before operating, if in doubt, it may be justifiable to endeavor to locate pus with an aspirating needle. Incise the abscess and open any secondary abscesses. Many abscesses point below the diaphragm, and are easily reached by an incision in the loin or in the epigastric region. Lannelonge resects the eleventh and twelfth ribs and raises the pleura out of the way. Some surgeons prefer to practice rib resection and incise the adherent pleural layers and the diaphragm. After drainage has been continued for a time it may be necessary to do a secondary operation in order to cure the lesion causative of the abscess, for instance, it may be necessary to close a chronic gastric perforation.

In *abscess of the antrum of Highmore* bore a gimlet-hole through the superior maxillary bone, above the canine tooth, or perforate the bone by means of a trocar. Irrigate daily with boiled water or normal salt solution. Keep the opening from contracting by inserting a small tent of iodoform gauze. In persistent cases it may be necessary to draw a tooth, break through the socket of the first or second bicuspid into the antrum, and insert a silver or hard-rubber tube, and also to perforate the antrum from the inferior meatus and keep the opening patent. In very persistent cases osteoplastic resection of a portion of the upper jaw will be demanded.

In *appendicular abscess* incise, support the abscess walls with gauze, remove the appendix in most cases, but not in all, and insert a drainage-tube and strands of gauze (see page 1018).

An *ischiorectal abscess* must be opened early. The surgeon never waits for fluctuation. Fluctuation is a very late symptom. To wait for it entails great destruction of tissue and serves no useful purpose. Place the patient on his side, with the legs drawn up. Insert a finger in the rectum, lift the abscess toward the surface, and incise it from the surface. The incision runs from the anal margin like a spoke from the hub of a wheel. Irrigate with salt solution, inject iodoform emulsion, insert a drainage-tube, dress, and let the patient know he is in danger of developing a fistula.

A *retropharyngeal abscess* must be opened early, because delay may lead to fatal obstruction and because if spontaneous evacuation occurs the patient may be suffocated. Some surgeons open it from within the mouth, but this exposes the patient to the danger of septic bronchopneumonia from inhalation of purulent elements and to serious gastro-intestinal disorder from swallowing quantities of pus. Again, if opened through the mouth, the abscess is liable to become putrid. It is better to open it from the neck by Hilton's method, the incision being carried through the sternocleidomastoid muscle or posterior to it. Drainage is inserted and the abscess treated in the usual way.

In *abscess of the breast* make an incision radiating from the nipple, or, what is better, incise under the breast by means of a cut at the inferior thoracic mammary junction and enter the abscess from beneath.

In *abscess of the brain* the skull should be trephined, the membranes incised, and the abscess sought for, opened, and drained (see page 804).

In suppuration within the *orbit* due to cellulitis, incise from the conjunctiva and drain. In suppuration due to caries or necrosis of the upper orbital wall make a transverse incision through the upper lid, reach the pus by Hilton's method (see page 150), remove carious or loose necrotic bone, and drain.

A *perinephric abscess* requires an incision in the lumbar region and free drainage.

An *abscess of the larynx* requires immediate scarification and inhalation of steam to abate swelling. In a severe case the surgeon should at once perform tracheotomy.

Bezold's abscess requires one or more incisions in the neck for drainage.

Then the mastoid is exposed, its tip, including the osseous fistula, is removed, and its interior is cleared out by a complete operation.

A *prostatic abscess* should be opened promptly by a perineal incision.

In an ordinary *superficial abscess*, after cleansing the parts, make the skin tense, locate the superficial vessels and nerves, and plan the incision to avoid them. Incise with a sharp-pointed curved bistoury at the most dependent part of the abscess or through the region of pointing. If the abscess is upon the face or neck, make the incision in the line of the skin creases so as to limit the scar. The incision must not be made suddenly and fiercely, neither should it be made with hesitation and uncertainty. Thomas Bryant says: "It should be done, as ought every other act of surgery, with confidence and decision, boldness and rapidity of action being governed by caution and made subservient to safety" ("Practice of Surgery"). Permit the pus to run out spontaneously; pressure, as a rule, is undesirable because it may damage the abscess wall and cause diffusion of the infection. If tissue shreds block the opening, they must be picked out with forceps. If the atmospheric pressure will not cause the pus to flow out, make light pressure with warm, moist, aseptic gauze pads. After the pus has come away gently wash the cavity with normal salt solution or boiled water, and drain with a tube for two or three days when the discharge becomes serous. It is not desirable to overdistend the abscess-cavity with fluid, because the hydrostatic pressure might break down the wall of young cells and infection be diffused. Do not irrigate with powerful disinfectants. They cannot be used strong enough to really disinfect, but may easily be used strong enough to cause necrosis of an abscess wall. Peroxid of hydrogen is not to be used unless the incision is large, because the gas it generates may tear the abscess wall and diffuse the infection. Peroxid of hydrogen is a dangerous agent to inject into the cavity of a deep abscess of the neck, as the liberated gas may not escape from the opening, but may pass widely into the tissues and cause great distention. The author saw a child who narrowly escaped death after such an injection. In this patient the gas passed beneath the pharyngeal mucous membrane and the swelling almost occluded the air-passages. If an abscess contains putrid pus the incision should be free, and after evacuation it should be irrigated with hot salt solution or peroxid of hydrogen and injected with iodoform emulsion. Pursue rigid antisepsis in dealing with purulent areas. It is true we already have infection with pyogenic bacteria, but infection can also take place with organisms of putrefaction, causing pus to become putrid, or with other bacteria, for instance, those of tetanus. If a tube is not used and the cavity is packed with iodoform gauze, remember that gauze will not drain pus and requires to be changed once a day or oftener. An abscess should be dressed with hot, moist, antiseptic dressings (antiseptic fomentation) and the part must be put at rest. When the discharge becomes thin and scanty, dry aseptic or antiseptic dressings are used.

In a *deep abscess* or an abscess situated near important vessels do not boldly plunge in a knife. Hilton says to "plunge in a knife is not courageous, as it is without danger to the surgeon, but may be fatal to the patient." Remember also that a large amount of pus displaces normal anatomical relations. *Hilton's method* of opening a deep abscess (as in the axilla or neck) is to cut to the deep fascia, nick the fascia with a knife, and then push into the abscess a grooved director until pus shows in the groove; along the groove push a pair of closed dressing forceps; after they reach the depths take out the director, open the forceps, and withdraw them while open, and so dilate the opening; then insert a tube and gently irrigate with warm salt solution.

Always endeavor to open an abscess at its most dependent part, remembering that the situation of this part may depend upon whether the patient is to

be erect or recumbent. If we do not make the opening at the lowest point, all the pus will not run out and the walls will not completely collapse. A deep abscess must be drained thoroughly until the discharge becomes seropurulent. When the tube is removed it is wise to insert a tent of iodoform gauze just through the outlet of the abscess. This tent prevents the skin from closing over the channel. It is removed and a new one inserted every day until it is clear that there is no longer danger of fluid becoming blocked and retained. When an abscess contains diverticula or pouches they should be slit up or a counteropening ought to be made. A counteropening is made by entering the dressing forceps at the first incision, pushing them through the abscess to the point where we wish to make our counteropening, opening the blades, and cutting between them from without inward. The blades are then closed and projected through the incision; they are opened in order to dilate the new door, and are closed again upon a drainage-tube, which is pulled through from opening to opening as the instrument is withdrawn. When pus burrows, insert a grooved director in each channel and slit the sinus with a knife. An abscess may make an opening through dense fascia, the opening being small like the neck of an hour-glass (*shirt-stud abscess*). Always examine to see if such a condition exists, and if it is found, incise the fascia.

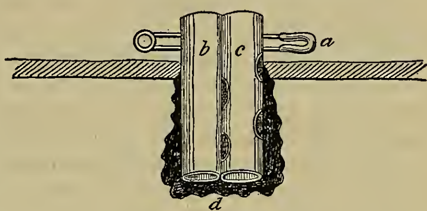

Fig. 78.—Drainage-tubes for abscess requiring irrigation.

In a deep abscess containing putrid pus frequent irrigation is desirable. In such a case two tubes may be employed (Fig. 78). The tubes are prevented from slipping in by the use of a safety-pin (*a*). The irrigating fluid is passed into the cavity (*d*) through the tube *b*, which is without fenestra, and most of it runs out through the tube *c*, which possesses fenestra.

Rest is of the first importance in the healing of an abscess, and we try to obtain it by bandages, splints, and pressure, which will immobilize adjacent muscles and approximate the abscess walls. If an abscess is slow to heal, use as a daily injection a solution of corrosive sublimate of the strength of 1:1000, or 3 drops of nitric acid to 1 oz. of water, or 3 gr. of zinc sulphate to 1 oz. of water, or a 5 per cent. solution of carbolic acid, or a 2 per cent. aqueous solution of pyoktanin, or 20 drops of tincture of iodin to 1 oz. of water, or a 2 per cent. solution of acetate of aluminum. The constitutional treatment of an abscess depends upon the severity of the morbid process and the importance of the structures involved. In a serious case the patient should be put to bed, opiates should be given with a free hand, the bowels be kept active by calomel and salines, skin activity be maintained, the taking of nutritious food insisted on, and stimulants liberally employed.

Purulent Effusions.—(See Suppurative Thecitis, Palmar Abscess, Suppurative Synovitis, Purulent Peritonitis, Empyema, etc.)

VII. ULCERATION AND FISTULA

An **ulcer** is a loss of substance due to molecular death of a superficial structure. The molecular death is brought about by bacteria. Ordinary ulcers are caused by pus organisms. The action of the pus organisms is the same as in an abscess. A broken abscess becomes an ulcer, and an ulcer is in structure a half-section of an abscess. The floor of an ulcer consists of

granulation tissue and corresponds to the abscess wall. An abscess arises from molecular death within the tissues; an ulcer, from molecular death of a free surface. An ulcer may increase in size by molecular death of adjacent structures or by sloughing, that is to say, by death of visible masses of tissue. A wound healing by granulation is often wrongly called an ulcer. An ulcer must not be confounded with an excoriation. In an ulcer the corium is always, and the subcutaneous tissue is generally, destroyed, and a scar is left after healing. In an excoriation the mucous layer of epithelium is exposed, or this is destroyed and the corium is exposed. In an excoriation the corium is never destroyed, and no scar remains after healing. An ulcer heals by granulation (see page 117). Embryonic tissue by vascularization becomes granulation tissue, granulation tissue is converted into fibrous tissue, the fibrous tissue contracts, and by pulling the edges of the ulcer toward each other lessens the size of the cavity. When the granulations reach the level of the skin the epithelium at the edges of the ulcer proliferates and the sore is soon covered over with new epithelium.

Necrosis of a superficial part may arise from—(1) Inflammation. The pressure of the exudate can cut off the circulation, or bacteria may directly destroy tissue. Suppuration occurs. (2) The action of pus bacteria, causing primary cell-necrosis. (3) Bacteria of putrefaction and organisms of suppuration acting upon a wound. (4) Traumatism or irritants, producing at once stasis, which is added to by secondary inflammation, the exudate undergoing purulent liquefaction. (5) Prolonged pressure. (6) Deficient blood-supply. (7) Faulty venous return. (8) Degeneration of a neoplastic infiltration (gummatous, malignant, or tuberculous). (9) Trophic disturbance. (10) Nutritional disturbances (as scurvy). Most ulcers are due directly to pus organisms, and areas of necrosis of superficial parts that arise from something else (as gummatous degeneration) suppurate.

Classification.—Ulcers are classified into groups according to the condition of the ulcer and the associated constitutional state. In the first group we find the varicose, hemorrhagic, acute, chronic, irritable, neuralgic, etc. In the second group are placed the tuberculous, syphilitic, senile, scorbutic, etc. All ulcers, whatever their origin, are either *acute* or *chronic*, and such conditions as great pain, hemorrhage, edema, exuberant granulations, phagedena, sloughing, eczema, gout, syphilis, scurvy, etc., are to be looked upon as complications. The leg is so common a site for ulcers as to warrant a special description of ulcers of this part. In describing an ulcer state the patient's previous history; the supposed cause; the situation; the outline; the duration, and the mode of onset of the ulcer. State if the ulcer is single or if multiple sores exist, and if there is or is not pain; whether or not any healing has ever occurred, and the patient's constitutional condition. Set forth the complications; the state of anatomically related glands; the condition of the edge, the floor, and the parts about the ulcer, and the nature and quantity of the discharge.

Acute or **inflamed ulcer of the leg** may follow an acute inflammation and may be acute from the start, or may be first chronic and then become acute. It is especially common in drunkards, and among those of dilapidated constitutions. It is characterized by rapid progress and intense inflammation. There is rarely more than one ulcer. In outline these ulcers are usually oval, but may be irregular. The floor of an acute ulcer contains no granulations, but is composed of the raw and inflamed tissues, or is covered by a mass of gray aplastic lymph, or it may have upon it large greenish sloughs. The edges are thin and undermined. The discharge is very profuse and ichorous, excoriating the surrounding parts. The adjacent cutaneous surface is inflamed and edematous, and there is much burning pain. In some cases the

glands in the groin enlarge. Constitutionally, there is gastro-intestinal derangement, but rarely fever. When the ulcer spreads with great rapidity and becomes deeper as well as larger in surface area, it is called "phagedenic." The formation of sloughs indicates that tissue death is going on so rapidly that the dead portions have not time to break down and be cast off. Limited stasis produces molecular death; more extensive stasis, a slough. If a chronic ulcer becomes acute, existing granulations are destroyed.

Treatment.—In treating an acute ulcer of the leg, give a dose of blue mass or calomel, followed in eight or ten hours by a saline (2 dr. each of Rochelle and Epsom salts), and order light diet. Deny stimulants except in a case of diphtheritic ulcer. Administer opium if pain is severe. Spray the ulcer with hydrogen peroxid, use the scissors and forceps to get rid of sloughs, and after sloughs are removed wash the ulcer with corrosive sublimate solution (1:1000) or paint it with pure carbolic acid. Paint the skin adjacent to the ulcer with equal parts of tincture of iodin and alcohol. Dress with hot antiseptic fomentations. Apply a bandage from the toes to well above the ulcer. Insist on the patient remaining in bed with the leg slightly elevated. Change the dressings before they become cool and always as soon as they are saturated with discharge. Every day or two paint the parts about the ulcer with equal parts of iodin and alcohol.

Many cases do very well after antiseptization and dusting the ulcer with iodoform, lead-water and laudanum being applied to the inflamed parts around the ulcer; but in a bad case hot antiseptic fomentations, compression, and elevation are more useful until sloughs separate. If the discharge is offensive, apply acetanilid, aristol, or iodoform, or use 3 gr. of chloral to 1 oz. of water before applying hot fomentations or ordinary antiseptic dressings. A 25 per cent. ointment of ichthyol is very useful when applied to parts around the ulcer. If sloughs continue to form, touch the sloughing area with a 1:8 solution of acid nitrate of mercury or with a solution of pure carbolic acid, and reapply antiseptic fomentations. If an ulcer continues to spread, cleanse with peroxid of hydrogen, dry with absorbent cotton, touch with nitrate of mercury solution (1:8), and apply antiseptic fomentations. Repeat the application of nitrate of mercury every day until the ulcer ceases to extend and granulations begin to form. When granulations begin to form freely moist hot dressings are no longer desirable, and dry aseptic or antiseptic dressings can be used.

If an ulcer is covered with a great mass of aplastic lymph, touch daily with a solution of silver nitrate (40 gr. to 1 oz.) or with acid nitrate of mercury (1:15), and dress with iodoform and antiseptic fomentations. Give internally tonics, stimulants, and nutritious liquid food. In any case, when granulations form, dress antiseptically with dry dressings, or employ a non-irritant ointment, such as cosmolin. If granulations form slowly touch them every day with a solution of silver nitrate (10 gr. to the oz.) and dress antiseptically, or apply a stimulating ointment (resin cerate or 1 dr. of ung. hydrarg. nitratis to 7 dr. of ung. petrolii, or an ointment of copper sulphate, 3 gr. to the oz.), or dress with gauze soaked in a solution of 3 drops of nitric acid to 1 oz. of gum arabic. When the granulations are healthy cicatrization can be greatly hastened by an application of scarlet red ointment (8 per cent.). This is kept in place for twenty-four hours at a time. It is used intermittently.

Chronic ulcer of the leg is characterized by low action and slow progress. It may be chronic from the start, or it may result from acute ulcer. Usually it is found as a solitary ulcer 2 inches above the internal malleolus. *Syphilitic ulcers* often occur in a group, are usually crescentic, and are frequent upon the front of knee. A *tuberculous ulcer* may have no granulations, but is usually covered with pale edematous granulations, which signify

the existence of a tendency to venous stasis. The edges of the tuberculous ulcer are undermined and irregular, the parts about it are livid and tender, and the discharge is thin and scanty (see page 246). An *ordinary chronic ulcer* is circular or oval, and is surrounded by congested, discolored, and indurated skin, this induration being due to fibrous tissue, and there is often eczema or a brown pigmentation of the neighboring skin. The floor of the ulcer is uneven, and usually is covered with granulations, each of which is red and the size of a pin-point, but which may be exuberant or edematous. If granulations are absent, the ulcer has the appearance of a piece of liver, or is smooth and glazed. The edges are thick, turned out, and not sensitive to the touch. Occasionally, but rarely, they are thin and undermined. Some ulcers are indurated and adherent; this adhesion to the deeper structures prevents healing by antagonizing contraction. An ulcer may fail to heal because of severe infection; because of want of rest; because of absence of granulations resulting from deficient blood-supply; because of edematous granulations; because of exuberant granulations; because of adhesion to deep structures, or because of some constitutional disease.

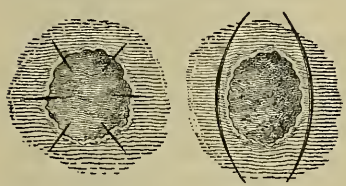

Fig. 79. Fig. 80.

Figs. 79 and 80.—Incisions for adherent ulcer.

Treatment.—In treating a chronic ulcer, give a saline cathartic every day or so. Treat any existing diathesis. Insist on rest and, if possible, elevation. Asepticize the ulcer. Draw blood by shallow scarifications of the bottom and edges of the ulcer and the skin about it. If the ulcer is adherent to deeper structures, make incisions like those shown in Figs. 79 and 80, each cut going through the deep fascia. These incisions, besides permitting contraction, allow granulations to sprout in the cuts and absorb exudate. Nussbaum advocated encircling the ulcer with an incision about $\frac{1}{2}$ or $\frac{3}{4}$ inch away from the edge of the ulcer, the incision passing through the skin. After incision keep the part elevated and dressed antiseptically for two days. In two days after scarification or incision scrape the ulcer with a curet until sound tissue is reached. Use hot antiseptic fomentations for two days more, then paint the parts adjacent to the ulcer with tincture of iodin and alcohol (1:3), dress the parts about the ulcer with ichthyol ointment, and dress the ulcer antiseptically or with sterile gauze. In a day or so the use of ichthyol should be discontinued and the ulcer be dressed with sterile gauze, normal salt solution, boric acid, solution of acetate of aluminum, chlorin-water, a solution of permanganate of potassium, sulphur, glutol, protonuclein, or bovinin. Glutol (formalin-gelatin) is very useful in some cases and so is protonuclein. When healing begins, treat as outlined for healing acute ulcer (see page 153). Many cases can be cured by baking in the hot-air apparatus from half an hour to an hour daily. A moderate heat is indicated, and in the intervals of treatment an elastic bandage should be used and, if possible, the patient should be kept in bed.

Unna's dressing is satisfactory in many cases. It is applied as a fluid, painted on when hot. It solidifies on cooling and resembles rubber. The paint is made as follows: Dissolve 4 parts of the best gelatin in 10 parts of water by means of a hot-water bath. While the fluid is hot add 10 parts of glycerin, and then 4 parts of powdered white oxid of zinc and stir energetically until the mixture is cold. Melt the paint before using by placing the receptacle in a hot-water bath. The extremity must be clean and thoroughly dry. Apply the paint from just above the roots of the toes to just below the knee. Cover the layer of paint with a gauze bandage; put over this another layer of paint,

then another bandage, and so on until three, four, or five bandages have been applied. To prevent wrinkling apply the gauze in short pieces. The outer layer of the dressing is a coat of the paint. This dressing is worn from four to eight weeks unless it loosens sooner. When it loosens, it is changed. If the ulcer discharges freely and stains the dressing, cut a trap-door in the dressing and through this cleanse the ulcer and apply dressings and a bandage as often as necessary (Michel, in "Chicago Clinic," No. 8, 1900).

An excellent treatment if the patient must walk about is *camphor*, first recommended by Schulze ("Münchener medicinische Wochenschrift," March 19, 1901). It is most conveniently used, as Walbaum shows, in the form of spirits of camphor (Ibid., June 25, 1901). He applies the dressing in the following manner: Clean the ulcer with green soap and dress it daily with dressings wet with a 2 per cent. solution of the acetate of aluminum. In about three days the discharge will become scanty and free from odor. It is at this period that camphor should be used. A small piece of gauze wet with spirits of camphor is applied directly and only to the ulcer. Over this is applied a large piece of dry sterile gauze, a rubber-dam, a large piece of absorbent cotton, and a bandage from the toes up. Every other day the dressings are removed, the ulcer is washed with a 2 per cent. solution of carbolic acid, and the dressings are reapplied. Usually the ulcer is healed in three weeks.

Complications.—Remove by scissors and forceps any badly damaged tissue. Take out dead bone; slit sinuses; trim overhanging edges. Treat **eczema** locally by washing with ethereal soap and applying powdered oxid of zinc or borated talcum, the leg then being wrapped in cotton. Unna's paint is very useful in chronic eczema. If the part is crusted, the crusts should be removed by applying some oily materials and washing with ethereal soap and water. Ordinary soap should not be used. In an acute case soap and water always do harm and the part is to be cleaned by "gently wiping with cold cream or petrolatum" (Stelwagon, on "Diseases of the Skin"). If crusting is very marked it may be necessary to remove it by means of an ordinary poultice or, better, a starch poultice made with a 2 per cent. solution of boric acid. When scales or crusts are slight or absent or when they have been removed, the remedial agent should be applied. The remedies for eczema are legion. Among them are a solution of lead acetate; lead-water and laudanum; a powder composed of 30 gr. of powdered boric acid and ½ oz. each of talc and zinc oxid; ung. picis liquidæ, 1 dr., with sufficient ung. zinci oxidi to make 1 oz.; ½ oz. of liquor carbonis detergens to 1 pint of water. In every case of eczema place the patient upon a plain and nutritious diet; order him to avoid wines and liquors; give an occasional saline laxative; keep the skin and kidneys active, and if the patient is gouty or rheumatic, give appropriate remedies. The value of arsenic in eczema has been much overrated.

Varicose veins may demand either ligation at several points, excision, Trendelenburg's operation (see page 462), or the continued use of a flannel roller or a Martin rubber bandage. Never operate on varicose veins if phlebitis exists unless a clot has formed, in which case apply a ligature above the clot. Never operate on the veins for varicose ulcer unless the ulcer is in an aseptic state. *Inflammation* of the ulcer is met by rest, elevation, painting the neighboring parts with dilute tincture of iodin, and applying about the ulcer ichthyol ointment. For *calloused edges*, blister, employ radiating incisions, or cut the edges away. Ordinary *thick edges* should be strapped. In strapping use zinc oxid adhesive plaster and do not completely encircle the limb (Fig. 81). When the parts are *adherent* the ulcer is immovable, being firmly anchored to structures beneath it. In such a condition completely or partly surround the sore with a cut through the deep fascia (see Figs. 79, 80). This cut sets the ulcer free

from its anchorage and permits it to contract. *Edematous granulations* require dry dressings and pressure by a flannel bandage, a rubber bandage, or adhesive plaster. If the bottom of the ulcer is *foul,* dry it and touch with a solution of acid nitrate of mercury (1:8) or with crystals of pure carbolic acid. Repeat this every third day and dress with hot antiseptic fomentations until granulations appear. *Superfluous granulations* (proud flesh) should be cut away with scissors, scraped away, or burned down with a strong solution of silver nitrate, with the solid stick of lunar caustic or, better, with pure carbolic acid, which causes much less pain than does silver. *Absence of granulations* or scantiness of granulations means deficiency of blood-supply. The surgeon endeavors to bring more blood to the part, and to do this induces inflammation. The usual method of procedure is to apply daily to the sore a solution of nitrate of silver (10 or 15 gr. to the ounce). Argyrol of a strength of 25 per cent. is not painful and is as efficient. In obstinate cases blister the ulcer or scrape it, or paint it with tincture of iodin, or apply pure carbolic acid, or touch it with the actual cautery. In many cases granulation is greatly stimulated by a twenty-four-hour application of an 8 per cent. ointment of scarlet red. If it causes irritation its use is suspended for a day or two, and then the ointment is reapplied. If an ulcer of the leg becomes painful at one point (see page 157), touch with pure carbolic acid after curetting, or find the painful spot with a probe and divide the exposed nerve filament with a tenotome.

Fig. 81.—Strapping an ulcer of leg ("Keen's Surgery").

If healing entirely fails, *skin-graft.* Among the methods of skin-grafting are—(1) Reverdin's, (2) Thiersch's, and (3) Wolfe's. (See Plastic Surgery.)

When a man having an ulcer must go out and about, the camphor treatment can be employed (see page 155), Unna's dressing may be applied (see page 154), the patient can use a firmly applied roller or, better still, a Martin bandage. Martin's bandage, which is made of red rubber, limits the amount of arterial blood going to the ulcer and favors venous flow from the sore and its neighborhood. The bandage should be used as follows: Before getting out of bed spray the sore with hydrogen peroxid by means of an atomizer, remove the froth with absorbent cotton, wash the leg with soap and water, dry it with a towel, dust the skin with borated talcum powder, and apply the bandage from the toes up. All of these things should be done before putting the foot to the floor. At night, after getting on the bed, remove the bandage, wash it with soap and water, dry it with a towel, hang it unrolled over the back of a chair to air, and again cleanse the leg and ulcer. If these rules are not strictly observed, the Martin bandage will produce pain, suppuration, and eczema of the leg.

Tuberculous Ulcers.—(See pages 246, 247.)

Syphilitic Ulcers.—(See page 328.)

A **healthy ulcer** is covered with small, bright-red granulations which do not bleed on touching, are painless, and grow rapidly. The edges of the sore are soft and show the opalescent blue line of proliferating epithelium. The sore is movable, the discharge is purulent and yellow, and the parts about are not inflamed.

Various Ulcers.—The **fungous** or **exuberant ulcer of the leg** is produced by interference with the return of venous blood from the part, and it is specially common after burns and other injuries when cicatricial contraction causes venous obstruction. The granulations are large, deep red in color, bleed when touched, form rapidly, and mount above the level of the skin. The discharge from a fungous ulcer is profuse, thin, and bloody. In the treatment of such an ulcer venous return must be favored by bandaging and by elevation of the part. If the edges are very thick, divide them in a number of places. The superfluous granulations should be burnt down with lunar caustic or pure carbolic acid or should be cut off. Strapping with adhesive plaster or the use of a rubber bandage does good. The sore can be dressed with europhen, aristol, or dry aseptic gauze.

A **varicose ulcer of the leg** is an ulcer complicated by varicose veins. It is usually single, is oval, round, or irregular in outline, and is most often seen above the inner malleolus. Its edges are thick, everted, and swollen. The swelling is largely due to edema, and is found to pit on pressure. The edges are not undermined, but slope gently to the floor of the ulcer. The floor is usually covered with rather large granulations which bleed freely on touching. In a varicose ulcer the destruction of tissue often begins at the margin of a congested area and advances toward the center. Such an ulcer is usually surrounded by eczema. To aid the healing of a varicose ulcer it is first of all necessary to favor the return of venous blood from the part by position and bandaging. Martin's bandage is very useful and the daily use of the hot-air apparatus is of value. It may be necessary to operate on the veins.

Erethistic, irritable, or **painful ulcers** are very sensitive, a condition due to the exposure of nerve-filaments and destruction of nerve-sheaths. Irritable ulcers are especially found near the ankle, over the tibia, in the anus (fissure), or in the matrix of the nail (ingrowing nail). Fissure of the anus is considered on page 1177. An *ingrowing nail* is sometimes encountered on the finger, but far more commonly affects the toe. The great toe is especially apt to suffer. We call it ingrowing nail, but the condition is really overgrowing skin. As a result of wearing ill-fitting boots or stockings, especially shoes which are too short or are pointed, the toes are forced together and the skin at the edge of the nail is squeezed. After a time an ulcer forms.

When a nail begins to ingrow the condition can usually be arrested by wearing well-fitting shoes and stockings, allowing the nail to grow somewhat long and cutting it square across instead of cutting away the troublesome corner. Daily a little absorbent cotton should be packed under the ingrowing corner. In more severe cases, under local anesthesia cut away the overlapping skin and a portion of the flesh on the side of the toe, split the nail longitudinally, remove the ingrown portion of nail and a corresponding part of the matrix.

An erethistic ulcer of the cutaneous surface is treated as follows: Curet and touch with pure carbolic acid or with the solid stick of silver nitrate. Chloral, 20 gr. to the ounce, allays the pain; so do cocain and eucain for a time. In some cases the painful area can be located by a probe and the nerve-filament divided by a tenotome.

The **indolent ulcer of the leg** shows no tendency to heal. In such an ulcer there is usually venous congestion from varicose veins or from cardiac weakness. A great mass of scar-tissue forms at the base and edges, which fastens the ulcer to bone or fascia, so that the edges cannot contract. Healthy granula-

tions cease to form. The edges of such an ulcer are thick, smooth, immovable, and free from tenderness. Granulations are entirely absent or there are seen here and there a few unhealthy granulations. The discharge is thin, sero-

Fig. 82.—Marjolin's ulcer (epithelioma) in a man twenty years of age, arising in the cicatrix of a burn.

purulent, and offensive. The parts about the ulcer are congested and pigmented. The pigmentation is due to the fact that in the area of chronic con-

Fig. 83.—Same case as Fig. 82, after excision and skin-grafting by the Thiersch method.

gestion numbers of red blood-cells have been disintegrated. Such an ulcer is treated by making incisions to loosen the base and edges, so that contraction can take place. Venous congestion is corrected by means of position, the

use of compression, and in some cases the administration of cardiac stimulants. In all cases the surgeon employs stimulating applications to the ulcer in order to increase the supply of arterial blood. Scarlet red ointment (8 per cent.) strongly stimulates granulation.

The **callous ulcer of the leg** is the most chronic form of indolent ulcer and is sunken deeply below the level of the skin. Its border is hard and knobby. Its floor shows no granulations, and is either smooth and glistening or foul and liver colored. The discharge is thin and scanty, and the ulcer varies little in appearance from week to week or even from month to month. The treatment consists in scraping and cauterizing the ulcer; making radiating incisions through the margins and floor or elliptical incisions about the ulcer; applying antiseptic dressings and firm bandages. In some cases the ulcer should be strapped. The daily baking in the hot-air oven is often of great benefit. In severe cases it is necessary to extirpate the ulcer and apply skin-grafts.

Hemorrhagic ulcers bleed easily and profusely. Pressure must be applied; it is sometimes necessary to cut or burn away the granulations.

Phagedenic Ulcers.—The phagedenic ulcer results from the profound microbic infection of tissues debilitated by local or constitutional disease, and is commonly venereal. This ulcer has no granulations and is covered with sloughs; its edges are thin and undermined, and it spreads rapidly in all directions. Such an ulcer should be touched with strong caustics or Paquelin's cautery, and dressed with iodoform gauze and antiseptic fomentations. Tonics and stimulants should always be administered.

Fig. 84.—Marjolin's ulcer (epithelioma) from the scar of a burn.

The **edematous ulcer** may result from inpediment to the venous return or, as De Nancrede points out, may be produced by the persistent use of poultices or wet dressings upon any ulcer.[1] It is most often met with in tuberculous processes and is occasionally seen in the leg when varicose veins exist. The granulations are large and pale, and are apt to bend over like unsupported vines. The discharge is profuse and seropurulent. The edges are softened and desquamating. An edematous ulcer requires dry dressings, stimulation, and compression.

A **rodent** or **Jacob's ulcer, noli me tangere,** or **cancroid ulcer,** is a superficial epithelioma developing usually from sebaceous glands, sweat-glands, or hair-follicles. It requires scraping and cauterization, the application of the x-rays, or, what is better, excision (see page 394).

Marjolin's ulcer (Figs. 82–86) is an epithelioma arising from a chronic ulcer or an old cicatrix. The malignant change begins at some point of the edge of the ulcer, and its first evidence is induration. The induration spreads slowly and comes to involve a considerable part of or even the entire ulcer. Marjolin's ulcer is the seat of scalding, darting pain; the discharge is profuse, ichorous, and foul, and the floor of the ulcer is uneven, warty, or cauliflower-

[1] "Principles of Surgery."

like. The anatomically related lymph-glands eventually become involved. This involvement is seldom early because induration has blocked lymph-channels. In order to confirm the diagnosis a bit of tissue should be removed, and the removed piece must include a portion of the edge of the ulcer and of some apparently sound tissue beyond it. If a microscopic examination

Fig. 85.—Epithelioma arising in the scar of a burn (Marjolin's ulcer).

shows epithelial infiltration of the apparently sound tissue, a diagnosis of malignant disease must be made. In an early stage of such an ulcer free extirpation and removal of the anatomically related glands may cure the patient. In a more advanced case, if an extremity is involved, amputate and clear out the related lymphatic area. In a very advanced case use the x-rays.

Fig. 86.—Marjolin's ulcer arising from a chronic ulcer of the leg.

Fig. 82 shows a Marjolin ulcer in a man twenty years of age. It arose in the cicatrix of a burn. I removed it and applied Thiersch grafts to the raw surface. Figs. 84, 85, and 86 show Marjolin's ulcers.

Decubitus, or **bed-sore**, is due to pressure upon an area of feeble circulation (see page 180). It is in most instances a condition of gangrene.

Neuroparalytic or **trophic ulcer** is due to impairment of the trophic nerve-fibers or of the trophic centers in the cord.

The **perforating ulcer**, as it was named by Vesigne, is believed to result from peripheral neuritis. It is certain, however, that in some of these cases there is arteriosclerosis, and it has been held that the vascular sclerosis is the real cause and that the nerve changes are secondary to the vascular changes. My own belief is that perforating ulcer is a condition dependent upon both arteriosclerosis and peripheral neuritis, traumatism usually being the exciting cause of the ulcer. It is met with most frequently in diabetics, but may be encountered in the victims of chronic alcoholism, injuries and diseases of the spinal cord, injuries and diseases of nerves, Bright's disease, and syphilis. I have seen this ulcer in an individual with a fractured spine, in several tabetics, and in not a few diabetics. The perforating ulcer commonly affects the plantar surface of the metatarsophalangeal joint or the pulp of the great toe or little toe about a callosity or corn. It may arise on the heel or the sole or the side of the foot. It is usually unilateral, but sometimes both feet are affected. In very rare cases more than one ulcer is present on the foot. Very rarely it affects the palm of the hand. The parts about the corn inflame, and pus forms and reaches into the bone. A sinus evacuates the pus by the side of the corn or callosity or the center of the callosity exhibits a blister containing seropus. A portion of the callous mass is cast off and a shallow ulcer is often exposed. This ulcer is small, has a punched-out appearance, and is surrounded by calloused margins. The ulcer penetrates deeply and after a time the bone is laid bare or the joint opened. The margins of the ulcer or sinus exhibit sprouting granulations and these are encircled by an area of markedly thickened epidermis. The discharge from a perforating ulcer is thin and scanty, and the ulcer, which slowly advances, is very chronic. It is not painful and is slightly, if at all, tender. The foot is cold and often edematous and the parts about the ulcer may be anesthetic. The ulcer may heal when the patient is kept in bed and open again when he gets out. The disease is far more common among males than among females and is most often met with in the fifth or sixth decades of life. As this ulcer may be present in anesthetic leprosy, in diabetes, peripheral neuritis, syphilis, in a paralyzed limb, and tabes dorsalis, and as the part on which it occurs is apt to be sweaty, cold, and more or less anesthetic, and as the sore may be hereditary, it is usually set down as trophic in origin. In treatment of a perforating ulcer I follow the plan suggested by Treves. This consists in putting the patient to bed and applying poultices to the sore. Every time a poultice is removed the raised epithelium around the ulcer is cut away and then the poultice is reapplied. In about two weeks an ulcer remains surrounded by healthy tissue. Treves treats this sore with glycerin made to a creamy consistency with salicylic acid, to each ounce of which mixture 10 min. of carbolic acid have been added. He directs the patient to wear during the rest of his life some form of bunion-plaster to keep off pressure. If in a perforating ulcer the bone is diseased, it must be removed. If the patient is diabetic he must be placed on antidiabetic diet and drugs. Nerve-stretching has been recommended as the proper treatment for perforating ulcer, but I have never tried it. No matter what treatment is employed, the sore is apt to reappear in the old situation or an adjacent region when the part is subjected to pressure. In order to prevent pressure upon the region of ulceration some advise the use of an artificial leg, the knee being kept bent. It may be necessary to amputate the toe or the foot.

The **scorbutic ulcer** is covered with a dark-brown crust, beneath which are pale and bleeding granulations. The parts adjacent are of a violet color.

Epitheliomatous, sarcomatous, tuberculous, and syphilitic ulcers and ulcers of the stomach and duodenum are considered under these respective diseases.

Curling's Ulcer.—This is an ulcer of the first portion of the duodenum which in very rare cases follows an extensive burn or scald of the cutaneous surface. Curling described this condition in 1841, but Sir Berkeley Moynihan points out in his book upon "Duodenal Ulcer" that Long, of Liverpool, described it in 1840. It is small, clean cut, and deep. It may be due to toxic material in the bile, the toxic material being due to the burn, but against this is the occurrence of the ulcer well above the opening of the bile-duct. Sir Berkeley Moynihan regards it as a toxic ulcer and points out that the ulcer practically never occurs unless there were septic changes in the burnt area. Septic emboli may be the cause. So far no case of Curling's ulcer seems to have been treated surgically. As Sir Berkeley Moynihan says, "there is no reason why it should not prove successful if the condition of the patient were not too exhausted by the extent or severity of the original injury." If perforation occurs the treatment is as for any other perforating duodenal ulcer.

A **fistula** is an abnormal communication between the surface and an internal part of the body, or between two natural cavities or canals. The first form is seen in a rectal fistula, a urethral fistula, or a biliary fistula; and the second form is seen in a vesicovaginal fistula. Fistulæ may result from congenital defect, as when there is failure in the closure of the branchial clefts, and can arise from sloughing, traumatism, and suppuration. Fistulæ are named from their situation and communications. For instance, a pleural fistula, an intestinal or fecal fistula, a rectal fistula, an anal fistula, a gastric fistula, a bronchial fistula, a vesical fistula, a biliary fistula, etc. Many fistulæ are tuberculous and lead to some deeply placed tuberculous focus. A fistula in communication with a viscus (for instance, the gall-bladder) may be maintained by an obstruction of the duct of that viscus; the removal of such an obstruction cures the fistula.

A **sinus** is a tortuous track opening usually upon a free surface and leading down into the cavity of an imperfectly healed abscess. A sinus may be an unhealed portion of a wound. Many sinuses are due to pus burrowing subcutaneously. A sinus fails to heal because of the presence of some irritant fluid, as saliva, urine, or bile; because of the existence of a foreign body, as dead bone, a bit of wood, a bullet, a septic ligature, etc.; or because of rigidity of the sinus walls, which rigidity will not permit collapse. Sinuses may be maintained by want of rest (muscular movements) and general ill health. The walls of a tuberculous sinus are lined with a material identical with the Volkmann's membrane of a cold abscess.

Treatment.—In treating a fistula or a sinus, remove any causative obstruction and any foreign body, lay the channel open, curet, brush with pure carbolic acid, and pack with iodoform gauze. Sometimes cure of a tuberculous sinus may be secured by repeated injections of iodoform emulsion or by injecting a paste of subnitrate of bismuth and vaselin (see page 894). The mixture remains in the sinus and serves as a framework for granulations. When a sinus closes after injections of bismuth paste, bismuth concretions sometimes form and lead to reopening after weeks or months. In obstinate cases of fistula or sinus entirely extirpate the fibrous walls, sew the deeper parts of the wound with buried catgut sutures, and approximate the skin surfaces with interrupted sutures of silkworm-gut. To stimulate a sinus to granulation it is sometimes necessary to touch it throughout with the actual cautery, nitric acid, pure carbolic acid, nitrate of silver fused on a metallic probe, or in a solution of a strength of 40 gr. to the ounce, or argyrol of a strength of 50 per cent. Fresh air is a necessity to the patient, and nutritious food and tonics must be ordered. There is some testimony, although scarcely as yet evidence, that the use of bacterial vaccines may at times be of value in the treatment of certain sinuses (see page 47).

VIII. MORTIFICATION, GANGRENE, OR SPHACELUS

Mortification, or gangrene, is death in mass of a portion of the living body—the dead portions being large enough to be visible—in contrast to ulceration, or molecular death, in which the dead particles have been liquefied, cannot be seen, and are cast away. When all the tissues of a part are dead, the process is spoken of as *sphacelus*. Gangrene is, in reality, a form of necrosis, but clinically the term "necrosis" is restricted to molar death of bone or to death of parts below the surface *en masse*. In gangrene a portion of tissue dies because of anemia, and the dead portions may either desiccate or putrefy. Gangrene may be due to tissue injury, either chemical or mechanical, to heat or cold, to failure of the general health, to circulatory obstruction, to nerve disorder, the nerves involved being the vasomotor or possibly the trophic, or to microbic infection. A microbic poison can directly destroy tissues. It can indirectly destroy them by causing such inflammation that the products obstruct the circulation, but gangrene can occur when no bacteria are present. The essential cause of gangrene is that the tissues are cut off from a due supply of nourishment, and cell-nutrition is no longer possible. In other words, the essential cause of gangrene is the cutting off of arterial blood. De Nancrede says: "Indeed, except when the traumatism physically disintegrates tissues, as a stone is reduced to powder, heat or strong acids physically destroy structure, or cold suspends cellular nutrition so long that when this nutrition becomes a physical possibility vital metabolism cannot be resumed, gangrene always results from total deprivation of pabulum (" Principles of Surgery ").

Classification.—Gangrene is divided into the following three great groups:

(1) **Dry gangrene,** which is due to circulatory interference, the arterial supply bing decreased or cut off. The tissues dry and mummify.

(2) **Moist gangrene,** which is due to interference not only with arterial ingress, but also with venous return or capillary circulation, the dead parts remaining moist.

(3) **Microbic gangrene,** arising from virulent bacteria. In this form the bacterial process *causes* the gangrene, and is not merely associated with it.

The above classification, if unqualified, suggests erroneous ideas. It indicates that there is an essential difference between dry gangrene and moist gangrene, which is not the case. If, when gangrene begins, the tissues are free from fluid, the patient develops dry gangrene; if they are full of fluid, he develops moist gangrene. If the arterial supply is gradually cut off, the tissues are sure to be free from fluid, and the gangrene will certainly be of the dry form. If arterial blood is suddenly cut off, the gangrene may be dry or moist, according as to whether the tissues are or are not drained of fluid. When gangrene results from inflammation, strangulation, and infection it is certain to be of the moist variety, because the tissues are sure to be filled with fluid.

De Nancrede says, in his very valuable work on the "Principles of Surgery": "Yet, let accidental inflammation have preceded the final blocking of an artery, or let ligation of the main artery cause gangrene because the collateral circulation cannot become developed, and if an aneurysmal sac is so situated as to interfere with a free return of venous blood and lymph, this anemic gangrene will in both instances prove moist and not dry."

There are many gangrenous processes which belong under one or other of the above heads, namely: *congenital* gangrene, a rare form existing at birth; *constitutional* gangrene, arising from a constitutional cause, as diabetes; *cutaneous* gangrene, which is limited to skin and subcutaneous tissue, as in phlegmonous erysipelas; *gaseous* or *emphysematous* gangrene, in which the

subcutaneous tissues are filled with putrefactive gases and crackle on pressure; *hospital* gangrene, which is defined by Foster as specific serpiginous necrosis, the tissues being pulpefied: some consider it a traumatic diphtheria; *cold* gangrene, a form in which the parts are entirely dead (sphacelus); *hot* gangrene, which is associated with inflammation, as shown by heat; *dermatitis gangrænosa infantum*, or the multiple cachectic gangrene of Simon; *idiopathic* gangrene, which has no ascertainable cause; *mixed*, which is partly dry and partly moist; *primary*, in which the death of the part is direct, as from a burn; *secondary*, which follows an acute inflammation; *multiple*, as gangrenous herpes zoster; *diabetic* or *glycemic gangrene*, which arises during the existence of diabetes; *gangrenous ecthyma*, a gangrenous condition of ecthyma ulcers; *pressure*, which is due to long compression; *purpuric* or *scorbutic*, which is due to scurvy; *Raynaud's* or *idiopathic symmetrical*, which is due to vascular blocking, perhaps from nerve disorder; *senile*, the dry gangrene of the aged; *venous* or *static*, which is due to obstruction of circulation as in a strangulated hernia; *trophic*, which is due to nutritive failure by reason of disorder of the trophic nerves or centers; *thrombotic*, which is due to thrombus; *embolic*, which is due to embolus; and *decubitus*, *decubital* gangrene, or bed-sores due to pressure.

Dry gangrene arises from deficiency of arterial blood. For this reason De Nancrede calls it anemic gangrene.

This form of gangrene is far more apt to result from the gradual than from the sudden cutting off of the supply of arterial blood, and is more common if the blood-vessels are atheromatous than if they are healthy; but even in a person with healthy arteries gangrene will ensue upon blocking of the main artery, if the collaterals fail to supply the part with blood. This form of gangrene can occur after laceration, ligation, or the lodgment of an embolus in the main artery of a limb; but in such accidents considerable fluid usually remains in the tissues and the gangrene is apt to be moist rather than dry.

Gangrene Due to Embolism or Thrombosis.—An embolus may cause gangrene in rare instances, hence the cause of embolism is responsible for the gangrene. There may be vascular disease. There may be or have been an infectious process (typhoid fever, pneumonia, influenza, diphtheria, etc.). If an embolus causes gangrene, it is probable that the blocking was not at once complete. Why an embolus in a young person causes gangrene is perplexing, because in such a person we can tie a large artery with comparatively little fear of gangrene. It must be that a clot forms proximally to the embolism, fills a considerable extent of the vessel, and cuts off the collaterals. When an embolus lodges in an artery and causes dry gangrene, the case runs the following course: sudden severe pain at the seat of impaction, and also tenderness; pulsation above, but not below, this point, after obstruction has become complete; the limb below the obstruction is blanched, cold, and anesthetic; within forty-eight hours, as a rule, the area of gangrene is widespread and clearly evident; the limb becomes reddish, greenish, blue, and then black; the skin becomes shriveled and its outer layer stony or like horn because of evaporation. The entire part may become dry; but usually there are spots where some fluid remains, and these spots are soft and moist, and the dead tissue, where it joins the living, is sure to be moist. The moist areas become foul and putrid, but the dry spots do not. In dry gangrene, at the point of contact of the dead and living tissues, inflammation arises in the latter structures, a bright-red line forms, exudation occurs, and ulceration takes place. This line of ulceration in the sound tissues is called the *line of demarcation*. It is Nature's effort at amputation, and in time may get rid of a large portion of a limb, and then heal as any other ulcer. A line of demarcation rarely causes hemorrhage, because it enters a vessel only after inflammation has caused occlusion by throm-

bosis. In dry gangrene from arterial obstruction there is gastro-intestinal derangement and also some fever. The gangrene does not extend up to the point of obstruction, but only to a region in which the anastomotic circulation is sufficiently active to permit of the formation of a line of demarcation. Below this point inflammatory stasis arises, but before this can go on to ulceration the parts die. In cases in which the arterial obstruction is sudden and complete the limb swells decidedly. This is due to the sudden loss of *vis a tergo* in the arterial system, venous reflux occurring and fluids transuding. In such a case the tissues contain fluid and putrefy, and the process, though due to the cutting off of the arterial circulation, is moist gangrene. Embolic gangrene attacks the leg more often than the arm. A thrombus in an artery rarely causes gangrene except in the aged, as the collateral circulation has time to adjust itself; but gangrene may follow thrombus formation, and when it does it comes on more slowly than does gangrene from embolus, and is certain to be of the dry form.

Treatment of Thrombotic and Embolic Gangrene.—When injury or blocking of a healthy artery causes us to fear the onset of gangrene, the patient should be placed in bed, the extremity should be elevated a little, kept wrapped in cotton-wool, and surrounded with bottles filled with warm water. It is useless when an artery is extensively diseased to incise it and remove a clot, because another clot will form at once. If a clot forms in a limited area of disease, it may be possible to excise a small section of the artery and do end-to-end anastomosis, and insert by implantation a section taken from a distant vein. In cases of thrombosis, however, the best operation is probably arteriovenous anastomosis (see page 463). In embolism it is a logical procedure to make a longitudinal incision in the artery, remove the embolus, and suture the wound in the vessel. So far arteriotomy for embolism has not been as successful as Carrel's experiments lead us to infer it should be; the probable reason is that most reported operations were upon elderly people, in whom, because of diseased arteries, extensive clots existed. Lejars believes that in the young results are sure to be better. Mosny and Dumont report a successful arteriotomy for embolism of the femoral artery in a case of mitral stenosis (quoted in "Lancet," March 9, 1912). If in spite of our efforts gangrene begins and progresses, wait for a line of demarcation, and while waiting dress the dying and dead parts antiseptically, wrap the extremity in cotton and keep it warm, and see to it that the patient gets plenty of sleep and nourishment. It is also advisable to give tonics and stimulants. When a line of demarcation forms, amputate well above it.

Fig. 87.—Gangrene from thrombo-angiitis obliterans.

Presenile Spontaneous Gangrene.—I have adopted Buerger's suggested name for this condition. The vascular disease responsible for the gangrene is in dispute. Winiwarter and others believe it is obliterative endarteritis of all the arteries of a leg. Buerger regards the condition as thrombo-angiitis obliterans, appearing in the larger arteries and also in the veins of the leg ("Amer. Jour. Med. Sciences," Oct., 1908).

It occurs among young adults (from twenty to forty) and is especially noticed among the Polish Jews in our large cities. It usually, but not always, begins in the left leg. It may start almost simultaneously in both legs. If it begins in one leg, the other tends to become affected sooner or later. It comes on with attacks of severe pain in the toes, foot, or leg, the extremity feels cold and looks bloodless, and no pulse can be detected in the dorsalis pedis and posterior tibial arteries. Such attacks are at first brought on by cold, later they appear to arise spontaneously.

When the foot is warmed some color returns and feeble pulse may be appreciated. Many of these patients get so that any attempt at walking causes violent pains in the calf muscles, pain so violent as to make the victim limp in torture or at once stop walking (*intermittent claudication*).

After a case has lasted a number of months *erythromelagia* may develop. In this condition when the foot is hung down the toes and dorsum of foot rather rapidly grow bright red.

After a case has lasted for many months it will be impossible at any time to detect a pulse in the dorsalis pedis or posterior tibial. The patient is wearing out with violent pain and cannot walk. Whenever the foot hangs down it becomes red or cyanotic. A bleb or ulcer may form upon the foot or great toe; it is sure to be intensely painful, and finally dry gangrene occurs.

I have seen 5 such cases of gangrene and in 3 of them I performed amputation. The examination of the vessels in the amputated legs accorded with Buerger's view that the condition is one of thrombo-angiitis obliterans, the veins often suffering as well as the arteries. Perivascular inflammation exists and in cases which have lasted for years there is arterial sclerosis, but cases seldom last for years without gangrene. The clot often fills the vessels of the toes, the dorsalis pedis, the plantar, and may extend well up both tibials toward the popliteal. Before gangrene arises various diagnoses are apt to be made (Raynaud's disease, intermittent claudication, erythromelagia).

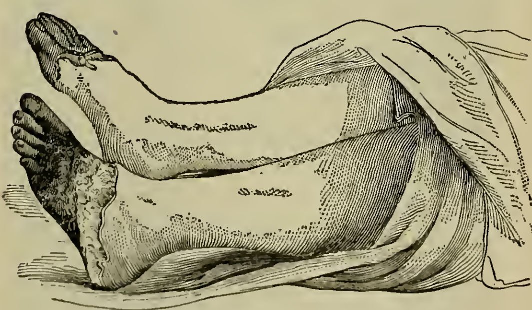

Fig. 88.—Senile gangrene of the feet (Gross).

The characteristic combination is violent pain, with absent pulse in the dorsalis pedis and posterior tibial arteries.

Treatment. — I have never seen the slightest lasting benefit result from medication. Sooner or later these cases come to amputation. In some cases violent pain compels amputation even before gangrene begins. Gangrene imperatively calls for it. Not unusually, weeks or months after amputation of one leg, the other leg has to be sacrificed.

The amputation should always be above the knee in order to be well above the thrombi in the vessels. Surgeons have used Moskowicz's test to determine where to amputate. (See Senile Gangrene, page 169.) Since Carrel's studies on reversal of circulation surgeons have attempted to prevent this and other forms of gangrene by arteriovenous anastomosis.

Early in a case, when we may assume that the veins are free from clot, the operation is clearly justifiable and may perhaps prove successful. Bloodgood has had success in a case which seems to have been of this type (Bernheim, in "Amer. Jour. Med. Sciences," Feb., 1912).

Senile gangrene, chronic gangrene, Pott's gangrene (Fig. 88), is a form

of gangrene due to feeble action of the heart plus obliterating endarteritis or atheroma of *peripheral* vessels. The vessels do not carry a normal amount of blood, and may at any time be occluded by thrombosis. In a drunkard or in a victim of syphilis or tubercle the changes supposed to characterize old age may appear while a man is young in years. It was long ago said, with truth, "a man is as old as his arteries." Senile gangrene most often occurs in a toe or the foot.

Symptoms.—A man whose vessels are in the state above indicated is generally in feeble health and has a fatty heart and an arcus senilis (a red or white line of fatty degeneration around the cornea). His toes and feet are cold and feel numb, and they "go to sleep" very easily, and he suffers from cramp of the legs and feet. He is dyspeptic and short of breath, and his urine is frequently albuminous. The arteries are felt as rigid tubes, like pipe-stems. He is in danger of edema of the lungs and of dry gangrene of the toes. A slight injury of a toe—for instance, cutting a corn too close—will produce extensive inflammatory stasis followed by thrombosis, which completely cuts off the blood-supply and causes gangrene of the part. Gangrene is usually announced by the appearance of a purple and anesthetic spot followed by a vesicle which ruptures and liberates a small amount of bloody serum and exposes a dry floor. In the parts about the gangrenous area there is often burning pain. The circulation in the tissues immediately adjacent to the dead spot is retarded or stagnated, the parts being purple and the color not disappearing or disappearing *slowly* under pressure. If the color fades under pressure it returns *slowly* when pressure is removed. The parts a little further removed are hyperemic, the color disappearing rapidly on pressure, and returning rapidly when pressure is removed. The dead parts do not putrefy at all or do so but slightly, hence the odor is never very offensive and is usually trivial. They are anesthetic, hard, leathery and wrinkled, and resemble a varnished anatomical specimen or the extremity of a mummy (hence the term *mummification*). Before the line of demarcation forms there is burning pain; after it forms pain is rarely present. If an embolus or thrombus in a diseased vessel of some size causes gangrene, the pain is severe at the point of impaction. In senile gangrene the distal portion of the dead area is always dry, the part nearer the body being generally somewhat moist. The process may be very limited or it may spread up along the dorsum of the foot and the leg, even to the knee. As it spreads the area of hyperemia advances at the margin, the area of stasis follows, and the zone of gangrene becomes more extensive. When tissues are reached, the blood-supply of which is sufficiently good to permit of inflammation going beyond the stage of stasis and to allow of stasis without extensive thrombosis, Nature tries to limit the gangrene by the formation of a *line of demarcation*. A line of demarcation may begin, but prove abortive, the tissue mortifying above it. This proves that tissue near the line is in a state of low vitality. The line of demarcation may

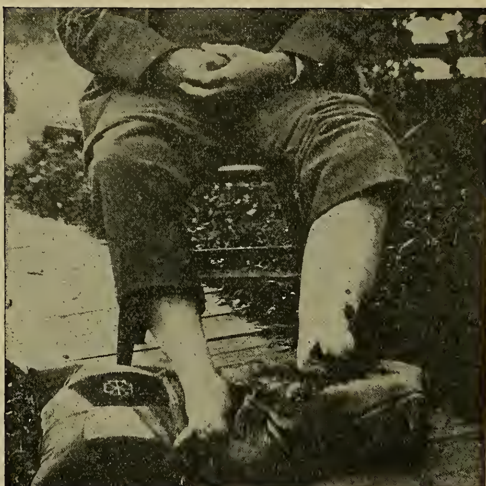

Fig. 89.—Dr. Keller's case of spontaneous amputation of a foot and part of a leg in a condition of senile gangrene.

prove durable and in some few cases spontaneous amputation takes place (Fig. 89). When a limited area is gangrenous, constitutional symptoms are trivial or absent; but when a large area is involved, the fever of septic absorption exists. Death may ensue from exhaustion caused by sleeplessness and pain, from septic absorption, from embolism of internal organs, or from some complication (renal, pulmonary, or cardiac). In many cases of senile gangrene clots are formed in the superficial femoral artery or its branches, an observation it is important to bear in mind when amputating.

Prevention of Senile Gangrene in the Predisposed.—Such a patient must avoid injuring the toes and feet. Cutting corns carelessly is highly dangerous, and any wound, however slight, requires rest and antiseptic dressing. The victim of general atheroma must wear woolen stockings, put a rubber bag containing warm water to his feet on cold nights, and attend to his general health. He must avoid overeating and is to be particularly moderate in the use of meats, should have a daily bowel movement, and should drink water in plenty between meals. He should avoid as far as may be work and worry, and enough sleep is imperative. A little whisky after each meal is indicated, and occasional courses of nitroglycerin are desirable. Courses of iodid of potassium, given in small doses, may retard the progress of the sclerosis.

Treatment of Senile Gangrene.—When gangrene occurs, if it is limited to one toe or a portion of several toes, if it is a first attack, if there is no fever or exhausting diarrhea, if there is no tendency to pulmonary congestion, if the appetite is fair and sleep refreshing, it is best to avoid radical interference and to await the formation of a line of demarcation. While awaiting the line of demarcation dress the part antiseptically, raise the foot several inches from the bed, and surround the part with bottles of moderately warm water. Very warm water may do harm. Give the patient nourishing diet, stimulants, and tonics; see to it that he sleeps, and during the spread of the gangrene watch for fever, diarrhea, pulmonary congestion, and kidney failure. When a line of demarcation forms, dress with warm antiseptic fomentations and iodoform, and every day pick away dead bits with the scissors and forceps. A tendon or ligament should be cut through and a protruding phalanx should be divided with a Gigli saw. If, after separation, an ulcer forms, skin-grafts may be applied. In many cases healing will occur; but even when the parts heal the patient will always be in deadly peril of another attack. If the gangrene shows a tendency to spread, if it involves more than a portion of several toes, if it is not a first attack, if there is sleeplessness, fever, exhausting diarrhea, anorexia, or a strong tendency to pulmonary congestion, do not delay, but at once amputate high up. If the gangrene shows no tendency to limit itself, or if the patient develops sepsis or exhaustion, at once amputate high up. The best point at which to amputate is above the knee, so that the deep femoral artery, which rarely becomes atheromatous, can nourish the flap and gangrene will not occur. It has been pointed out that the superficial femoral artery and its branches often contain a clot. Never amputate below the tubercle of the tibia. Some operators disarticulate at the knee-joint. Heidenhain affirms that so long as the gangrene is limited to one or two toes we should merely treat it antiseptically, elevate the limb, and wait for the dead part to be cast off spontaneously; if, however, it extends to the dorsum or sole of the foot, we should amputate at once above the knee. He further states that gangrene of the flaps almost always occurs in amputations below the knee, and high amputation is indicated in advancing gangrene with or without fever.[1] Personally, I still follow Heidenhain's rule. Many surgeons dissent from it and believe that in certain cases we can amputate lower down. Moskowicz suggested a method of determining the viable area. He applies an elastic bandage from

[1] "Deutsche medicinische Wochenschrift," 1891, p. 1087.

the toes to high up the thigh, puts in place the tourniquet band, and removes the bandage. In five or ten minutes he removes the band and notes the color of the limb as it is invaded by reactionary hyperemia. This wave of color travels toward the periphery. High up the extremity the reactionary blush appears quickly. The nearer the area of vascular obstruction, the slower the manifestation of color. In doubtful areas the blush comes slowly and imperfectly, and patches of white show here and there in the color. In a region of total ischemia no reactionary blush occurs.

Operation must be performed in the region where there was a complete red reaction, and never through an area where anemic patches were noted. This very ingenious test of Moskowicz has not seemed to me conclusive, and I have fancied in cases of threatened gangrene that it helped to bring about the very condition we feared. It is only just to say that in other hands the test seems to have proved successful. When amputation has been performed and the Esmarch band has been removed and no arterial bleeding takes place from the superficial femoral artery, a clot is lodged in that vessel. If such a condition exists, insert into the artery a fine rubber catheter or a filiform bougie and break up the clot. When blood flows we are sure that the clot has been washed out.[1]

Some surgeons have practised arteriovenous anastomosis between the femoral vein and common femoral artery in hope of establishing sufficient circulation to prevent impending or to cure existing gangrene. The results are as yet inconclusive, but some successes have been reported (see page 183).

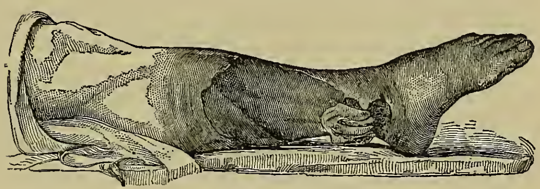

Fig. 90.—Acute gangrene (Gross).

In **moist or acute gangrene** (Fig. 90) the dead part remains moist and putrefies. As De Nancrede points out, there are two forms of moist gangrene: "that limited to the areas actually killed by a traumatism, with some surrounding tissue which dies," and "that which tends to spread widely, this latter being usually caused by specific micro-organisms, an intense, widespread, pyogenic inflammation resulting, involving the subcutaneous and intermuscular cellular planes, by strangulation of the vessels by which all blood-supply to the remaining soft parts is destroyed."[2] In a case of moist gangrene the parts remain moist, either because the main artery has become suddenly blocked, and the tissue fluids are not urged by sufficient *vis a tergo* to cause them to flow out of the limb, or because the main vein is blocked. It may arise in a limb after ligation, obstruction, or destruction of its main artery, main vein, or both; after long constriction, as by a tight bandage; after crushes and lacerated wounds, and after thrombosis of the vein. Moist gangrene may follow severe pyogenic infection or may be due to local constriction (strangulated hernia), crushing, chemical irritants, heat, and cold.

Moist gangrene of a limb may be seen typically in certain cases in which the main vein or artery or both vein and artery are constricted, damaged, or destroyed. The leg swells greatly and is pulseless below the obstruction; the skin, at first pale, cold, and anesthetic, becomes livid, mottled, purple, or greenish. A greenish color signifies putrefaction. Blebs are formed which contain a reddish or brown fluid. "These blebs, being caused by the accumulation of serum beneath epithelium which has lost its vital connection with the

[1] Severeano. See Mancozet's report before the Second Pan-American Medical Congress.
[2] De Nancrede's "Principles of Surgery."

derm, can be slipped around upon the surrounding true skin, the epithelium readily separating for long distances around, as in a cadaver" (De Nancrede). The extremity swells enormously, there may be pain at the seat of obstruction, but there is no pain in the gangrenous area, and sapremic symptoms quickly develop. The bullæ break and disclose the brown derm and sometimes the deeper structures, which are swollen and edematous. The fetor is horrible. Slight or moderate fever usually exists. In mild cases a line of demarcation soon forms. In severe cases in which virulent saprophytes are present the process spreads with great rapidity, neighboring glands enlarge, the temperature is much elevated, no line of demarcation forms, there is profound exhaustion, and gases of decomposition accumulate in and distend the tissues and cause crackling when the parts are pressed upon. Such severe cases are, in reality, examples of foudroyant or emphysematous gangrene.

Moist gangrene from inflammation is due to pressure of the exudate, cutting of the blood-supply, or to loss of blood-circulation because of microbic involvement of vessels and clotting of blood. It occurs typically in phlegmonous erysipelas. When an inflammation is about to terminate in gangrene all the signs of inflammation, local and constitutional, increase; swelling becomes very great and may be due partly to fluid and partly to gas. If gas is present pressure will cause crackling. The color becomes livid or purple. The anatomically related glands are enlarged and the symptoms of sapremia or suppurative fever exist. When gangrene is actually present the signs of inflammation have passed away, bullæ and emphysema are noted, with great swelling and all the other symptoms of molar death. The sudden cessation of pain is very suggestive of gangrene. The constitutional symptoms are those of suppurative fever and sapremia, or possibly of septic infection.

When a wound becomes gangrenous the surface looks like yellow or gray tow, the discharge becomes profuse and very fetid, and the parts about swell enormously and gradually become gangrenous.

Treatment of Moist Gangrene.—In extensive moist gangrene of a limb, if the condition is of the form described as mild, in which there are not severe symptoms of sepsis and in which the gangrene is not rapidly progressive, wait for a line of demarcation, and amputate clear of and above it. While waiting for the line to form, dress the dead parts antiseptically, wrap the extremity in cotton, apply warmth, and slightly elevate the limb. Give opium, tonics, nourishing food, and stimulants. In the severe form of moist gangrene (really foudroyant gangrene) amputate at once high above the gangrenous process. In inflammatory gangrene, such as is sometimes associated with phlegmonous erysipelas, relieve tension by incisions, cut away the dead parts, brush the raw surface with pure carbolic acid, dust with iodoform, and dress with hot antiseptic fomentations. Stimulate freely, administer nourishment at frequent intervals, and treat the patient in general as we would a case of sapremia or suppurative fever. A gangrenous wound is treated as pointed out in the section on Sloughing.

Acute microbic gangrene, fulminating gangrene, emphysematous gangrene, gaseous phlegmon, gangrenous emphysema, gangrène foudroyante, or traumatic spreading gangrene, results from a virulent infection of a wound. It was first described in 1853 by Masionneuve under the name of gangrène foudroyante. In 1864 Pirogoff called it *acute gangrenous edema.* The condition may be due to a mixed infection with virulent streptococci and organisms of putrefaction; or to infection with the bacilli of malignant edema, and putrefactive organisms. Some cases are due to the *bacillus of malignant edema* alone; some are due to the *Bacillus aërogenes capsulatus* of Welch and Flexner. These gas bacilli are found in soil, in animal and human feces, in street dirt, and the dust of floors. The injury is usually severe—often a crush which destroys

the main artery and renders an anastomotic circulation impossible, sometimes a compound fracture or a gunshot-wound. In such severe accidents the limb is much swollen and the pulse below the seat of injury is imperceptible, and the surgeon is often at this time uncertain whether to amputate at once or to wait. Emphysematous gangrene is commonest after compound fractures, and begins within forty-eight hours of the accident. The extremity becomes enormously swollen from edema and gas. The gangrene does not begin at the periphery, as does ordinary moist gangrene, but at the wound edges, which turn red, green, and finally black; the extremity soon undergoes a like change and becomes mortified. The skin peels off, emphysematous crackling, due to gas formed and retained in the tissues, can be detected over large areas, and the extremity becomes anesthetic and pulpy. The gases formed in the tissues are sulphid of hydrogen, sulphid of ammonium, volatile fatty acids, and ammonia. Great fetor is soon noted. The gangrene spreads up and down from the wound, and red lines, due to lymphangitis, run from above the wound. The adjacent lymph-glands swell. I have seen the gangrene involve an entire limb in thirty-six hours. No line of demarcation forms. The system is soon overwhelmed with ptomains, and the patient suffers from putrid intoxication, with delirium, and often passes into profound collapse with coma and subnormal temperature. Traumatic spreading gangrene must not be confused with erysipelas. In erysipelas the color is red, pressure instantly drives it out, and on the release of pressure it at once returns. In early gangrene the color is purple, pressure fails to drive it out at all or only does so very slowly, and if the surface is blanched by pressure, on the release of pressure the color crawls slowly back. Sometimes emphysematous gangrene, in the form of gangrenous cellulitis, follows a trivial injury such as a puncture, the entrance of a splinter, an abrasion, or a slight cut. The region about the injury becomes red, then livid, and finally green or black. Enormous swelling takes place, partly due to edema, partly to gas, and the swelling and discoloration spread rapidly. Red lines, subsequently becoming greenish, run toward enlarged lymphatic glands above the gangrenous part. The tissues are rapidly separated and destroyed and the bone is often quickly exposed and infected. The symptoms point to overwhelming sepsis. There is high fever and delirium, and coma and death are apt to ensue. The patient may die in from twenty-four to forty-eight hours. Welch estimates the mortality from gaseous phlegmon at almost 60 per cent.

Treatment.—In acute spreading gangrene of an extremity following a severe injury no delay is admissible. To wait for a line of demarcation is to expect the impossible, and a delay dooms the patient inevitably to death. Amputation must be performed at once high up, the flaps should be brushed with pure carbolic acid, and then every effort is to be made to sustain the patient's strength by the administration of food and stimulants. Antistreptococcic serum may possibly be useful. In cases of acute spreading gangrene following trivial injuries it may be possible to arrest the process by free incisions, thorough drainage, hot antiseptic fomentations, the continuous hot bath or continuous antiseptic irrigations, stimulants, etc., but in some cases amputation is necessary. Some surgeons, notably Doerfler ("Münchener medicinische Wochenschrift," April 23 and 30, 1901), oppose amputation in cases of spreading gangrene following trivial or moderately severe injury. Doerfler maintains that cases which recover after amputation would have recovered if amputation had not been performed. From this positive statement I am obliged to dissent. (See article on this form of gangrene by Blake and Labey, "Jour. Amer. Med. Assoc.," May 21, 1910.)

Hospital gangrene or **sloughing phagedena** is a disease that has practically disappeared from civilized communities. It formerly occurred in

crowded, ill-ventilated hospitals. Some consider it traumatic diphtheria. Koch thinks it is due to streptococci. Jonathan Hutchinson says: "Hospital gangrene is set up by admitting to the wards a case of syphilitic phagedena." It may show itself as a diphtheritic condition of a wound, as a process in which sloughs which look like masses of tow form, or as a phagedenic ulceration. The surrounding parts are inflamed and painful, and buboes form in adjacent lymphatic glands. The system passes into a low septic state.

Treatment.—In treating hospital gangrene ether should be given, the large sloughs removed with scissors and forceps, the parts dried with gauze and cauterized with bromin. The surgeon should take a tumblerful of water and into it pour the bromin, which will fall to the bottom of the glass. The drug can be drawn up with a syringe and injected into the depths of the wound. The wound should be plentifully sprinkled with iodoform and dressed with hot antiseptic fomentations. When the sloughs separate the sore can be treated as an ordinary ulcer. The constitutional treatment is that employed for sepsis.

Special Forms of Gangrene.—**Raynaud's disease** may be responsible for **symmetrical gangrene.** Raynaud's disease (Fig. 91) was first described

Fig. 91.—Raynaud's disease (Horwitz).

as a distinct malady by Maurice Raynaud in 1862. It is usually regarded as a vasomotor neurosis, is seen particularly in children and young female adults, but is sometimes met with in men. Chlorotic and hysterical women seem more apt than others to suffer from it. The condition is much commoner in winter than in summer, and cold seems to be an exciting cause. The well-known chilblain is an area of local asphyxia. The essential cause of Raynaud's disease is uncertain. In some acute cases associated with fever, albuminuria, and splenic enlargement it seems to be a part of an acute infectious disease. It can occur in a variety of toxic conditions and in a number of infectious diseases (typhoid fever, for instance). It may develop in the course of gout and also of diabetes. In many cases neuritis exists; in some there is either obliterative endarteritis or angiothrombosis of the larger peripheral vessels. Some cases seem to be purely hysterical. The fact that attacks of Raynaud's disease are sometimes accompanied by hemoglobinuria has suggested malaria as a possible cause. Raynaud's disease is characterized by attacks of cold, dead bloodlessness in the fingers or toes as a result of exposure to cold or of emotional excitement (*local syncope*). In the more severe cases

there are capillary congestion and mottled, livid swelling (*local asphyxia*). A case may begin with attacks of local syncope, and after a longer or shorter time get instead attacks of local asphyxia. Attacks may be occasional and far apart, may be frequent, or the condition of "dead" bloodlessness or asphyxia may be almost continuous. In some cases they only occur in winter; in others the slightest chill develops them. The patient complains of pain, tingling, numbness, coldness, and stiffness in the affected parts. In some few cases the skin of the face or trunk is attacked. Local syncope is thought to be due to vascular spasm, and local asphyxia to some contraction of the arterioles, with dilatation of the capillaries and venules. It is after local asphyxia that gangrene may appear. Attacks of Raynaud's disease occur again and again, and may never eventuate in gangrene.

Raynaud's disease is seldom fatal and is often recovered from.

Ever since Raynaud's day it has been generally maintained that the attacks are always symmetrical and that the blood-vessels are not diseased. We now know that many cases are successive but not symmetrical in the beginning, and that some never become symmetrical. This is especially true in the lower extremities. It has been shown of recent years that cases of thrombotic blocking of the larger arteries of the legs exhibit symptoms of Raynaud's disease before gangrene occurs, and that cases of Raynaud's disease of the feet and of erythromelalgia are apt to suffer from vascular thrombosis and gangrene from this cause.

Fig. 92.—Raynaud's gangrene. Patient has lost most of the terminal phalanges of the fingers and also the left leg. Right leg was amputated soon after this picture was taken. (Patient of Dr. T. E. Wannamaker, Jr., of Cheraw, S. C.)

Raynaud's gangrene (Fig. 92) is a dry gangrene and is most commonly met with upon the ends of the fingers or the toes, but it may attack the lobes of the ears, the tip of the nose, or the skin of the arms or the legs. Sometimes the disease is seen upon the trunk. The gangrene may be symmetrical from the beginning, may be successive, or may remain asymmetrical. Certain it is that many cases which we formerly regarded as clear cases of Raynaud's disease of the lower extremities develop gangrene, due either to obliterative endarteritis or angiothrombosis (see page 165). In such cases there is usually violent pain for weeks or months before gangrene begins. When gangrene is about to occur in Raynaud's disease the local asphyxia at that point deepens, anesthesia becomes complete, and the part blackens and feels cold to the touch. The epidermis may be raised into blebs at the margin of the gangrene, which blebs rupture and expose dry surfaces. A line of demarcation forms, and the necrosed area is removed as a slough. Widespread gangrene from pure Raynaud's disease is rare; there is not often an extensive area involved—rather a small superficial spot. Small areas are usually recovered from if not upon the lower extremity.

Treatment of Raynaud's Disease and of Raynaud's Gangrene.—If an individual suffers from attacks of Raynaud's disease, every effort should be made to improve the general health and to avoid chilling the surface of the body. During the attack employ gentle massage, place the extremity in warm water, and, if pain is severe, give morphin hypodermatically. Amyl nitrite is without value in this condition. When attacks of Raynaud's disease are so severe as to threaten gangrene, put the patient to bed; if the feet are attacked, elevate the legs slightly, wrap the affected extremities in cotton-wool, and apply warmth. If the hands are affected, wrap them in cotton-wool, elevate them slightly, and apply warmth. Massage is useful. Arteriovenous anastomosis has been employed for threatened gangrene, and several apparent successes have been reported (see page 166). When gangrene occurs, dress the part antiseptically until a line of demarcation forms, and then remove the dead parts by scissors, forceps, and antiseptic fomentations. If amputation becomes necessary, wait for a line of demarcation. In gangrene of a toe, toes, or foot due to angiothrombosis or obliterative endarteritis, amputation is always necessary. The terrible pain calls for it, and even if the gangrenous area is very small it is certain to spread or new areas are sure to arise. This form of gangrene has been treated by several surgeons by anastomosing the femoral vein to the femoral artery. Several times this operation seems to have proved successful. In an advanced case with thrombosed veins it cannot succeed (see page 166).

Diabetic gangrene often resembles strongly senile gangrene, but in many cases the dead portions remain somewhat moist and putrefy. Some surgeons attribute it directly to the sugar in the blood. Some think diabetes causes gangrene indirectly by rendering the tissues less resistant to infection and less capable than normally of repair. We know that sugar in blood removes fluid of the tissues and causes wound fluids to contain sugar. Hence wound fluids become excellent culture-media and body cells lose resisting power (see Morris, page 116). There is a great deficiency of oxygen in the tissues, which probably predisposes to infection (Lockwood, in "Lancet," February 10, 1912). The frequency in diabetes of boils, carbuncles, and spreading suppuration indicates lessened resistance to infection, and any infected area may become gangrenous. If phthisis exists or arises in a diabetic it develops with fearful speed toward a fatal issue. J. C. DaCosta, Jr., and Beardsley demonstrated that diabetic blood-serum shows a lowered opsonic index for tubercle bacilli, staphylococci, and streptococci. It is an interesting fact in this connection that the blood-serum of a pancreatectomized dog has a very low bactericidal power. Some hold that diabetic gangrene is of neurotic origin, being the result of nerve degeneration. Heidenhain believes that it is due to arterial sclerosis. That most of the victims of diabetic gangrene suffer from arteriosclerosis is certain. It seems probable that the gangrene is due to infection of tissue predisposed to infection by the presence of sugar and lessened amount of oxygen, and weakened by changes in the nerves and blood-vessels. Diabetic gangrene is most usually met with upon the feet and legs of elderly people, but it may arise at any age and may attack the genital organs, thigh, lung, buttock, eye, back, finger, or neck. It may affect only a single area, may attack several areas, or may be symmetrical. It may arise in any stage of diabetes, from the earliest to the latest. It may begin as a perforating ulcer. It is much more common in men than in women. There are clearly two forms of this condition. In one there is a slowly progressive, fairly dry gangrene, probably due chiefly to arterial sclerosis. In such a case a small, dry, dead patch sometimes lasts months before spreading begins. As in senile gangrene, a trivial injury is apt to be the exciting cause. In such a case the urine contains sugar and perhaps albumin, but seldom either acetone or diacetic acid. In the other form an injury, perhaps a trivial one, is

followed by a rapidly spreading cellulitis, which seldom forms pus and which eventuates in moist gangrene. In such a case the urine is apt to contain acetone and diacetic acid and there is grave danger of coma. When the gangrene follows a traumatism there are no prodromic symptoms. When it arises spontaneously in the skin, it is often preceded by pain of a neuralgic nature and attacks of "livid or violaceous discoloration of the skin, with lowered surface temperature and sometimes loss of sensation" (Elliot). In diabetic gangrene of an extremity the pain is often most violent, due probably to neuritis. In fact, neuritis may precede the gangrene. Diabetic gangrene is often superficial, but may become deep if it follows an injury or ulceration. Many of these patients are cyanosed (Lockwood, in "Lancet," February 10, 1912). A sufferer from diabetic gangrene is liable to cardiac failure, collapse, and coma.

Diabetic coma is an acid intoxication due to accumulation in the blood of acids which do not belong there, the chief of which is beta-oxybutyric acid. Acid gathers in the blood because of lack of proper oxidation. Diacetic acid is formed from beta-oxybutyric acid, and the breaking up of diacetic acid in the urine forms acetone. Hence, *acetonuria* means *acidosis*. Acetone is found in the urine when carbohydrates are not taken in sufficient quantity or are not assimilated by the tissues. Coma in acidosis commonly comes on rapidly, with vomiting, abdominal pain, weakness, restlessness, and drowsiness, which soon passes into coma. Sometimes it is ushered in by collapse, at other times by confusion of thought and speech. In coma the respiration is usually slow and deep, but may be sighing. The pulse is small, of low tension, and usually rather frequent. The temperature becomes subnormal, although during the onset it may be elevated. Cyanosis arises, the breath smells of acetone, the patient lies quietly in bed, and the pupils are dilated. In from twenty-four to forty-eight hours, as a rule, the patient dies.

Never fail to carefully examine the urine in every surgical case and especially in every case of gangrene, because diabetes may exist when least suspected. If albumin is present in the urine of a diabetic it means increased peril; if casts are found the prognosis is still worse. In such a case uremic coma may occur and be mistaken for diabetic coma.

Treatment of Diabetic Gangrene of Foot.—Most surgeons had grown very shy of amputating for diabetic gangrene until Küster, of Berlin, warmly advocated amputating above the knee without waiting for a line of demarcation. He showed that if amputation is performed below, the flaps will become gangrenous, and that after high amputation sugar may disappear from the urine. Of 11 amputations by Küster, 6 recovered and 5 died; and of these 5, 3 had albumin in the urine as well as sugar.

Heidenhain warmly advocated early high amputation, with the making of short flaps, and, in the United States, Powers, of Denver, defended the views of Küster ("Amer. Jour. of Med. Sciences," Nov. 11, 1892). I always amputate through the lower third of the thigh. Most writers now advocate high operation without waiting for line of demarcation if the gangrene is moist and due to bacteria attacking tissue weakened by diabetes. The same practitioners, if dry gangrene due to arterial changes exists, advocate awaiting the formation of a line of demarcation before amputating. I agree with Klemperer ("Therapie der Gegenwart," Jan., 1907) that we should reach a conclusion as to the proper course to pursue more from the character of the diabetes than from the nature of the gangrene. If neither diacetic acid nor acetone is in the urine, the glycosuria can be much improved and the general health vastly benefited by restricting the carbohydrates and administering codein or opium. In many cases sugar rapidly disappears. In such a case during the improvement of the glycosuria we await the formation of a line of demarcation, and while waiting

the gangrenous area and the parts immediately above are dressed with warm antiseptic fomentations. When a line of demarcation forms, spontaneous healing will probably occur. If it does not occur, amputate high up.

If acetone and diacetic acid persist in the urine, and if that excretion contains not only sugar, but also quantities of albumin, we cannot dare to wait for a line of demarcation because of the high probability that during the wait the patient will perish of septicemia (Klemperer, "Therapie der Gegenwart," Jan., 1907). In such a case perform an immediate high operation.

If the urine contains acetone and diacetic acid a line of demarcation will almost never form, and high amputation must be performed at once.

To put such a patient on a pure meat diet increases the risk of diabetic coma. In order to lessen the risk of coma give bicarbonate of sodium before and after operation. Twenty grains of this drug dissolved in Vichy water are given every two or three hours. If coma arises give intravenously 40 gr. of carbonate of sodium in 1 quart of water.

The worst cases are those in which the urine contains sugar, albumin, casts, acetone, and diacetic acid. In any case if over 1 gr. of ammonia is excreted in twenty-four hours, postpone operation until ammonia is reduced by diet.

In operating, ether and chloroform (especially chloroform) are to be avoided, because either is liable to induce acid intoxication. The operation may be performed under spinal anesthesia, although 1 case in which I amputated under spinal anesthesia died of coma. In a recent successful case I infiltrated all the nerves with cocain and amputated. There was no pain and apparently no shock.

My experience in diabetic gangrene of the leg comprises 6 cases. In 4 cases the urine contained sugar, acetone, and diacetic acid, and in 2 of these cases albumin was also present. In 2 cases sugar was in the urine, but no albumin, acetone, or diacetic acid. In each case a high amputation was performed—1 case (one of those with albumin) died of shock; 2 cases died in coma; 1 case died of sepsis; 2 cases recovered.

Treatment of Diabetic Gangrene in General.—In gangrene of some region other than an extremity, place the patient on antidiabetic treatment, treat locally with hot antiseptic fomentations, remove tissue which is completely dead with scissors and forceps, and sustain the strength.

Gangrene from Ergotism.—Ergotism is a diseased condition resulting from eating bread made from rye which has been attacked by a fungus (*Claviceps purpura*). In former days it was not unusual to have epidemics of ergotism from time to time, but at present the disease is found in individuals or, at most, in a few of a community. Ergotism is very rare in the United States, but it is not uncommon in southern Russia. It has occurred during the administration of ergot as a drug. Billroth reported such a case. It is never seen in unweaned children. The eating of bread made of diseased rye provokes gastro-enteritis, the evidences of which are abdominal pain of a crampy character, vomiting, diarrhea, and exhaustion. The patient complains of formication and itching of the skin of the extremities; severe, cramp-like, and tingling pains in the limbs, and disorders of vision. The pulse becomes small and slow. In some cases very painful spasms attack the muscles of the extremities and, finally, tonic spasm is noted, and the patient probably perishes from exhaustion after developing general convulsions and passing into coma. In other cases certain areas exhibit "gradual blood-stasis" (Osler), anesthesia, and, finally, gangrene. The gangrene is dry and peripheral. It usually affects the fingers or toes, but may involve an entire limb and may be symmetrical. Chronic ergotism is usually recovered from, but acute cases die in from seven to ten days.[1] The ingestion of ergot in quantity sufficient to produce chronic

[1] Pick, in Heath's "Surgical Dictionary."

poisoning causes tonic contraction of the peripheral blood-vessels, degeneration of the inner coats, and thrombosis of some arterioles. It is also maintained that degeneration of the posterior columns of the spinal cord takes place.

Treatment.—Ergotism is treated by forbidding the eating of the poisonous bread, allaying gastro-enteric inflammation, favoring elimination, and administering nourishment and stimulants. If gangrene is threatened, endeavor to prevent it by gentle massage and the application of warmth. If superficial gangrene occurs, dress with warm antiseptic fomentations and elevate the part, and every day take scissors and forceps and remove the loose crusts. If deeper and more extensive gangrene arises in an extremity wait for a line of demarcation and amputate above it.

Gangrene from Frost-bite.—Frost-bite is most common in the fingers, toes, nose, and ears, but the genital organs, the cheeks, the chin, the feet and legs, and the hands and arms may be attacked. Cold causes a primary contraction of the vessels and pallor and numbness of the part. After reaction the vessels dilate, the part reddens and swells, and a burning sensation or actual pain is experienced. In a trivial frost-bite the swelling and redness usually disappear after a few days, but in some cases the redness is permanent, and in many cases the redness, in the form of local asphyxia, returns under the influence of slight cold. (See Chilblains.)

In a more severe frost-bite the affected part becomes purple and covered with vesicles, and gangrene may or may not follow. When a part has been badly frozen it is whiter than normal, painless, anesthetic, and the peripheral portion dries. The part is deprived of all blood because of contraction of the vessels and because plasma coagulates at a few degrees above freezing. Cold disorganizes the blood, breaking up white corpuscles with the liberation of fibrin ferment. Coagulation of plasma and destruction of red corpuscles with the liberation of hemoglobin subsequently takes place. The thrombosis which is established prevents circulation, and the tissue-cells are damaged beyond repair. The part is bloodless and anesthetic, and a line of demarcation forms; hence we note that severe frost-bite causes dry gangrene. Areas of superficial gangrene are not uncommon. If a part which is not so badly frozen is brought suddenly into a warm atmosphere, hyperemia takes place when the blood runs into the frosted tissues, blebs form, and moist gangrene may result. Baron Larrey ("Surgical Memoirs"), in speaking of the retreat from Russia, tells a dreadful story of the suffering from cold. He says: "Persons were seen to fall dead at the fires of the bivouacs. Those who approached them sufficiently near to warm their frozen feet and hands were attacked by gangrene."

Treatment of Frost-bite and of Gangrene from Frost-bite.—A frost-bite in which the skin is livid and not as yet gangrenous should be treated by frictions with snow or rubbing with towels soaked in iced water. Larrey says that if frictions with snow or ice fail the part should "be plunged in cold water, in which it should be bathed until bubbles of air are seen to disengage themselves from the congealed part. This is the process adopted by the Russians for thawing a fish" ("Surgical Memoirs"). Whatever method is used, as the skin becomes warmer and congestion disappears the part should be subjected to dry friction and wrapped in cotton-wool. As previously stated, a sufferer from frost-bite should not suddenly be brought into a warm room. When gangrene follows frost-bite, if only small areas are involved, allow the dead parts to come away spontaneously, applying in the meanwhile hot antiseptic fomentations. If separation be delayed by cartilage, ligament, or bone, cut through the restraining structure. If amputation becomes necessary, await a line of demarcation, as it is not possible otherwise to be certain how high tissue damage extends, and to amputate through devitalized parts would mean renewed gangrene.

Noma is a rapidly spreading gangrenous process which is most apt to begin upon the mucous membrane of the gums or cheeks. Noma of this region is known as *cancrum oris*. Occasionally it begins in the ears, the genitals, or the rectum. When it attacks the vulva it is called *noma pudendi*. It may originate in the mouth and subsequently attack other regions. Noma is a very rare disease, is chiefly met with in children between the ages of three and ten, but it may attack older persons. O. Zusch[1] reports a case in a man sixty-six years of age. King reports a case in a woman of fifty-nine.[2] It occurs in girls oftener than in boys. The disease is most frequently encountered in children recovering from an acute disease. It is seen after scarlatina, typhoid, pneumonia, erysipelas, nephritis, dysentery, and especially after measles; in fact, Osler says that over one-half the cases follow measles. Children of tuberculous tendencies seem more liable than others. Young children who live amidst filth and squalor, in damp and ill-lighted apartments are most prone to

Fig. 93.—Noma. Seven days after first appearance of measles child showed gangrenous condition of mouth. Now, three days later, it involves both cheeks and under surface of upper and lower lips. Left cheek perforated. Two days before death a septic diarrhea developed which was uncontrollable (Crandon, Place, and Brown).

suffer, but that such conditions are not essential to the genesis of the disease is shown by the report of an epidemic of noma in the Albany Orphan Asylum. In this excellently situated, well-lighted, and well-ventilated building the children are carefully fed and cared for, and yet 16 cases of noma occurred after an epidemic of measles. (See "An Epidemic of Noma," by Geo. Blumer and Andrew MacFarlane, in "Amer. Jour. of Med. Sciences," Nov., 1901.) The disease is thought by many to be due to pus organisms. Lingard describes a bacillus which he considers causative. Blumer and MacFarlane conclude that the disease begins as a simple infection and a mixed infection takes place later. The mixed infection is not always due to the same organism, but is usually due to a long organism of a leptothrix type (Ibid.). Some

[1] "Münchener medicinische Wochenschrift," May 14, 1901.
[2] "Jour. Amer. Med. Assoc.," 1911, vol. lvi.

think that cases of noma are due to a variety of spirochetes, and it is an interesting observation that in noma the Wassermann serum reaction can be obtained.

In 1908 Crandon, Place, and Brown studied an outbreak of noma. Measles had been through the ward, 46 children had had gangrenous stomatitis, and 6 of them developed gangrene of the lip and cheek. A seventh case of gangrene appeared from another source ("Boston Med. and Surg. Jour.," April 15, 1909). They decided that the lesion was necrosis due to fusiform bacilli which invade living tissue, but rapidly die in necrotic tissue. Of these 7 cases, 2 recovered. The writers state that the duration of the disease is from four to ten days. They do not regard it as proved that noma is contagious and do not advise isolation.

Symptoms.—The disease begins as a sloughing ulcer; thrombosis and gangrene are soon observed. The edges of the ulcer are dark red and indurated. The gangrene usually spreads with very great rapidity, but in some cases it remains apparently stationary for days at a time. There is little or no pain. The odor is horrible. The disease is frightfully destructive, and if the mouth is involved is apt to destroy the cheeks, lips, eyelids, and large portions of the jaws. There is usually fever, but the temperature may be normal or even subnormal. The pulse is rapid, and exhaustion appears early and deepens rapidly. The mortality is large: Bruns says 70 per cent.; Rilliet and Barthez say 95 per cent. ("Amer. Jour. of Med. Sciences," Nov., 1901). Out of Nicoll's 11 cases, 9 died ("Progressive Med.," March, 1912). The cause of death is exhaustion, pyemia, or septic bronchopneumonia.

Treatment.—Administer an anesthetic and destroy the gangrenous area with the Paquelin cautery. In noma of the mouth chloroform is used instead of ether because the hot iron is to be applied in a region surrounded with anesthetic vapor, and ether vapor is inflammable. In noma in some other regions ether can be given. After cauterization directions are given to wash the part every few hours with peroxid of hydrogen, irrigate it with hot salt solution or boric acid solution, and dress it with compresses soaked in Labarraque's solution (Blumer and MacFarlane, in "Amer. Jour. of Med. Sciences," Nov., 1901). Nourishing food is given at frequent intervals, alcohol is administered, and strychnin is used to combat weakness. Rumple and Nicoll have each employed salvarsan and they believe with benefit. In one of Nicoll's successful cases two doses of 3 gr. each were given intravenously at an interval of three days. Each injection produced a great local reaction in the cheeks. If the surgeon succeeds in arresting the gangrene it will probably be necessary later to perform a plastic operation in order to replace loss of substance.

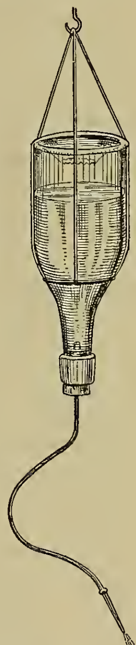

Fig. 94.—Improvised apparatus for the irrigation of a wound.

Sloughing is a septic process by which visible portions of dead tissue are separated. These visible portions are called "sloughs"; if they were large they would be called "gangrenous masses." A large septic slough is a gangrenous mass; a small gangrenous mass is a slough; there is no difference in the process, which corresponds to the formation of a line of demarcation.

Treatment.—Sloughing requires thorough and frequent irrigation by an antiseptic fluid, removal of the sloughs, and antiseptic treatment. An irrigator can be improvised from an ordinary bottle (Fig. 94). Warm antiseptic fomentations are applied until granulation is well advanced. In some cases

continuous irrigation with a hot antiseptic fluid is useful; in other cases continued immersion in a hot antiseptic solution is employed.

Phagedena is a process of ulceration and gangrene (most common in venereal sores) in which the surrounding tissues are rapidly eaten up, the sore becoming jagged and irregular, with a sloughy floor and thin edges. The discharge is thin and reddish, and the encircling tissues are deeply congested. This ulcer has no tendency to heal. Phagedena may attack wounds, but in this age is almost never seen except in venereal sores. When it does so the wound discharge is arrested, the parts about the wound become dark red and swollen, a black slough forms upon the wound, and the process spreads rapidly in all directions. The process when it attacks a wound is similar to or identical with a mild case of hospital gangrene, differing from the gangrene in the fact that in most cases a line of demarcation forms and the depression is not so great. Phagedena is probably due to mixed infection with pus organisms.

The **treatment of phagedena** consists in repeated touching with tincture of chlorid of iron and the local use of iodoform, the employment of continued irrigation or immersion in hot antiseptic fluids, or the application of the cautery, chemical or actual. After using the cautery the part is dressed with hot antiseptic fomentations. Whatever else is done, tonics, stimulants, and nutritious diet must be given and opium is often required.

Decubitus, Decubital Gangrene, or Bed-sore.—A bed-sore is the result of local failure of nutrition in a person whose tissues are in a state of low vitality from age, disease, or injury. The arterial condition of the aged favors the development of bed-sores. Such sores are due to pressure, aided it may be by some slight injury or by the irritation produced by urine, feces, sweat, crumbs or other foreign bodies in the bed, or by wrinkling of the sheets. The pressure destroys vascular tone, stasis results, thrombosis occurs, and gangrene follows. Sores occur over the heels, elbows, scapulæ, trochanters, sacrum, and nucha. In some cases after pressure is removed there are stasis, vesication, suppuration, and the formation of an ugly ulcer, surrounded by a zone of swelling and hyperemia. These ordinary pressure-sores arise like a *splint-sore* due to the pressure of a splint upon the tissues over a bony prominence. The pressure interferes with the blood-supply, the weakened tissues inflame, vesication occurs, sloughs form, and an ugly ulcer is exposed. When a bed-sore is about to form the skin becomes red and edematous. Pressure with the finger drives the color out rather slowly. The color becomes purple or black, a slough forms and separates, and a large, irregular, foul cavity is exposed. The discharge is profuse and offensive. The parts about are swollen and red. If the sore is not upon an anesthetic part, much suffering is produced by it. Bed-sores are most common in paralyzed parts; such parts are anesthetic, and injurious pressure is not painful and does not attract attention, and in such parts there is vasomotor paresis.

The **acute bed-sores of Charcot** are seen during certain diseases and after some injuries of the nervous system. These sores are usual over the sacrum in acute myelitis, and may appear in four or five days after the beginning of that disease or the infliction of an injury upon the spinal cord. The surgeon sees acute bed-sores upon the buttock of the paralyzed side after brain-injuries, and over the sacrum and other bony points after spinal injuries. Some believe these sores are due to vasomotor disorder; but others, notably Charcot, attribute them to disturbance of the trophic nerves or centers.

Treatment of Bed-sores.—The "ounce of prevention" is here invaluable. From time to time, if possible, alter the position of the patient, keep him clean, maintain the blood-distribution to the skin by frequent rubbing with alcohol and a towel, keep the sheet clean and smooth, and in some situations use a ring-shaped air-cushion to keep pressure from the part. When conges-

tion appears (*paratrimma*, or beginning sore), at once use an air-cushion or a water-bed and redouble the care to frequently change the position of the patient. Not only protect, but also harden, the skin. Wash the part twice daily and apply spirits of camphor or glycerol of tannin; or rub with salt and whisky (2 dr. to 1 pint); or apply a mixture of ½ oz. of powdered alum, 2 fl.oz. of tincture of camphor, and the whites of four eggs; or paint with corrosive sublimate and alcohol (2 gr. to 1 oz.); or apply tannate of lead or equal parts of oil of copaiba and castor oil; or paint upon the part a protective coat of flexible collodion.

When the skin seems on the verge of breaking, paint it with a solution of nitrate of silver (20 gr. to 1 oz.). When the skin breaks, a good plan of treatment is to touch once a day with a solution of silver nitrate (10 gr. to 1 oz.) and cover with zinc-ichthyol gelatin. We can wash the sores daily with 1:2000 corrosive sublimate solution, dust with iodoform, and cover with soap plaster, with lint spread with zinc ointment, or with dry aseptic gauze. When sloughs form, cut most of them off with scissors after cleansing the parts, slit up sinuses, and use antiseptic fomentations. In sloughing Dupuytren employed pieces of lint wet with lime-juice and dusted the sore with cinchona and charcoal. In obstinate cases use the continuous hot bath. When the sloughs separate, dress antiseptically or with equal parts of resin cerate and balsam of Peru. If healing is slow, touch occasionally with a solution of silver nitrate (10 gr. to 1 oz.). Bed-sores, being expressive of lowered vitality, demand that the patient shall be stimulated, shall be well nourished, and shall obtain sound sleep.

Ludwig's Angina (*Angina Ludovici*).—This disease, which was first described by Ludwig, of Stuttgart, in 1836, is an acute septic infection about the submaxillary salivary gland and in the cellular tissue beneath the mucous membrane of the floor of the mouth and of the upper portion of the neck. Ludwig called it "gangrenous induration of the neck" (D. Ludwig, "Med. Correspondez Blatt," p. 21, Feb., 1836, Stuttgart). The disease may arise in an apparently healthy man or during or after an infectious fever. It can arise at any age. The bacteria enter from the mouth by way of abrasions, wounds, ulcerations, or dental caries. It may be caused by delayed development of the third molar, necrosis of the tooth and alveolar process taking place and an abscess forming (G. G. Ross, "Annals of Surgery," June, 1901). In most cases the condition is a pure streptococcic infection or a streptococcic infection associated with infection by some other organism, for instance, staphylococci, pneumococci, or bacilli. In one of Davis's cases it was due to pneumococci alone; in another, to staphylococci alone (Gwillym W. Davis, "Annals of Surgery," August, 1906). In a case reported by Lockwood the bacillus of malignant edema was found. The condition is essentially an acute spreading cellulitis about the submaxillary gland. It usually begins about that gland, but in some cases seems to arise about the sublingual gland. It is usually a violent process from the start, but sometimes it is first an indolent swelling in the submaxillary region and becomes violent and begins to spread rapidly after a few days. It spreads along planes of connective tissue to the sublingual region of the mouth and to the pharynx.

The bacteria reach the submaxillary region in the lymph. A lymph-gland or perhaps several glands enlarge and are rapidly destroyed, the periglandular cellular tissue becomes involved, and after this spread takes place along connective-tissue planes rather than by lymph-paths, and other lymph-glands seldom enlarge.

The localization in the submaxillary region, the violence of the inflammation, the rapidity of the spreading, and the subsequent involvement of the pharynx and floor of the mouth are the characteristic features of Ludwig's angina (T. Turner Thomas, "Annals of Surgery," February and March,

1908). Thomas, in the article just referred to, proves by anatomical studies that the connective tissue in the submaxillary fossa is directly continuous with that in the floor of the mouth. The disease begins as a painful indurated swelling beneath the body of the jaw, the swelling rapidly increases in the neck, and may even pass to the level of the sternum. A board-like feel of this swelling is distinctive. The skin may be pale or dusky red. There may or may not be marked tenderness.

After a few hours or a day or two the floor of the mouth becomes involved; as a result of this the tongue is raised and pushed back, the mouth is kept from closing, swallowing becomes difficult, speech is impaired, the saliva dribbles constantly, and dyspnea becomes an alarming feature of the case.

In some cases the temperature is much elevated, but in most it is moderately or only slightly elevated.

If a spontaneous opening should occur it will be within the mouth. Free suppuration may occur or only a little watery pus may form and the pus may be brown and putrid. In many cases the cellular tissue becomes gangrenous, the gangrene resembling that of noma. The mortality is high. In Thomas's collection of 106 cases it is seen that 43 died (Ibid.), though with the prompt intervention which is now advised the mortality should be much below this figure at the present time. I have had 4 cases and 2 of them died.

Death may take place suddenly. Death is seldom due to septic intoxication or pyemia, but may be. It is usually due to edema of the glottis or to bronchopneumonia.

Treatment.—Operate promptly and incise freely. If there is an infective focus within the mouth, remove it. Make an incision through the swelling in the submaxillary region, carry the incision forward to the median line and divide the mylohyoid muscle. "The finger should be passed upward in the wound until only mucous membrane intervenes between it and the mouth. Gangrenous tissue is cut away, the wound is painted with pure carbolic acid, and dusted with iodoform" (T. Turner Thomas, Ibid.). Drainage-tubes are inserted and the part is dressed by antiseptic fomentations. If edema of the glottis exists, tracheotomy should be performed promptly. Stimulants are given with a free hand in Ludwig's angina.

Carbolic Acid Gangrene.—Dressings moistened with a solution of carbolic acid of a strength of from 3 to 5 per cent. if wrapped for a number of hours around a finger or toe, a hand or a foot, may cause dry gangrene. There is but little danger when such dressings are applied to the tissues of the trunk, because these thicker tissues are better nourished and cannot be completely surrounded by the wet dressings. When a dressing wet with a watery solution of carbolic acid is wrapped about the part the water evaporates, and as it does so the carbolic acid becomes more and more concentrated. A well mixed solution seldom causes gangrene. A recent aqueous solution often contains free globules of acid and is particularly apt to cause gangrene (Murphy). It is claimed that a solution of carbolic acid in glycerin never causes gangrene (Pautrier, in "Presse Médicale," March 2, 1907). Gangrene of a toe has occurred from the application of carbolized vaselin (Buckmaster's case, "Jour. Amer. Med. Assoc.," January 13, 1912). Two cases have been reported in which gangrene of a finger was caused by carbolized ointment (Brown, "Jour. Amer. Med. Assoc.," November 11, 1911; Schussler, "Jour. Amer. Med. Assoc.," August 19, 1911). In one case reported by DeWitt gangrene of the thumb resulted from injecting a ganglion of the thumb with equal parts of camphor and pure carbolic acid ("Southern Med. Jour.," June, 1909). The application of strong acid rarely causes gangrene, but Lévan found 14 reported cases in which it did (J. Lévan, in "Centralbl. f. Chir.," August 14, 1897), and Wallace has reported several more ("Brit. Med. Jour.," May 11,

1907). A solution as mild as 1 per cent. has caused gangrene. The continuous application of a solution of a strength of 3 per cent. or over is very dangerous and ought never to be practised. The author has seen 7 cases. Harrington saw 18 cases of gangrene in five years in the Massachusetts General Hospital, and collected 132 cases from literature ("Boston Med. and Surg. Jour.," May 2, 1901). Carbolic acid gangrene is due to great exudation into the cellular tissue, blocking the circulation (Housell), and the production of arterial thrombi, a condition to which the patient is predisposed by the injury and often by tight bandaging. The dressing is frequently applied by a druggist; it produces anesthesia of the part, and the dressing may not be removed for days, gangrene perhaps progressing beneath. In the author's 7 cases pain was absent and there was no smokiness of the urine or any other evidence of absorption of the drug. Dressing of lysol and alcohol may produce gangrene, but the necrosis is more superficial than that due to carbolic acid.

Treatment.—If the gangrene is very superficial, recovery may be obtained by using hot fomentations and picking the dead parts gradually away. In most cases the finger or toe is completely destroyed, a line of demarcation forms, and amputation is required.

Postfebrile Gangrene.—Dry or moist gangrene may follow any fever, but is most frequent after typhoid (may follow typhus, influenza, measles, diphtheria, scarlet fever, etc.). Keen tells us that the gangrene resulting from arterial obstruction is apt to be dry, and that from venous obstruction is usually moist. The same observer has collected 203 cases.[1] It is most usual in the lower extremities, but may appear in the upper extremities, cheeks, ears, nose, genitals, lungs, etc. Some writers have assigned as the cause weakness of cardiac action, but most observers believe an obstructing clot is the usual cause. This clot may come from the heart, but is in most cases secondary to endarteritis due to the action of the toxins of the bacilli of the specific fever. Keen shows that in some cases gangrene is due to obstruction of peripheral vessels and not of a main trunk. In rare cases gangrene arises after thrombophlebitis. Gangrene may begin as early as the fourteenth day of typhoid, but usually appears late in the disease and may arise far into convalescence. In the course of a continued fever frequent examinations should be made to see that gangrene is not arising. Particular examination from time to time should be made of the lower extremities and, in young girls, of the genitals. If gangrene arises in an extremity, apply antiseptic dressings, wait for a line of demarcation, and then amputate. If gangrene occurs in other regions, remove the dead tissue and employ hot antiseptic fomentations.

Rules When to Amputate for Gangrene.—In *dry* gangrene, due to obstruction of a non-diseased artery, wait for a line of demarcation. In *senile* gangrene, if it affect only one or two toes, let the dead parts be cast off spontaneously. If a greater area is involved or the process spreads, amputate above the knee without waiting for the line. In *ordinary moist* gangrene, if there are not severe symptoms of sepsis, and if the gangrene is not rapidly progressive, wait for a line of demarcation. In the severer cases amputate at once high up. In *traumatic spreading* gangrene amputate at once high up. In many cases of *diabetic* gangrene amputate at once high up (see page 175). In *ergot* gangrene, in *carbolic acid* gangrene, in *postfebrile* gangrene, in *Raynaud's* gangrene, and in *frost* gangrene wait for a line of demarcation.

Arteriovenous Anastomosis for the Prevention or Treatment of Gangrene of an Extremity.—This operation took origin from Carrel's famous demonstration of the reversal of the circulation in a dog's leg. The axillary artery has been anastomosed to the axillary vein; the femoral artery has

[1] Keen on the "Surgical Complications and Sequels of Typhoid Fever."

been anastomosed to the femoral vein. We know that by an anastomosis we can send arterial blood into a vein, but usually a clot soon forms at the junction. Those who advocate the operation assert that the force of the arterial blood-current overcomes the valves of the vein, and that arterial blood goes toward, even if it does not reach, the periphery. Further, that even if a clot does form, it forms slowly, circulation is arrested gradually, and collaterals distend during clotting.

The opponents of the operation assert that the valves cannot be overcome, that the blood flows off into venous branches and returns to the heart. Though it is doubtful how far toward the periphery the blood goes, we believe that the repeated impact of the arterial blood must finally overcome the valves; and in spite of great uncertainty as to the return of blood to the heart, we know that successful reversal seems to have been accomplished.

Bernheim ("Annals of Surgery," February, 1912) has collected 46 cases from literature and has added 6 operations, 2 of which were performed on the same individual (Halsted's case, Finney's case, Bloodgood's 4 cases). In the 52 operations gathered in Bernheim's table the ages of the subjects varied from twenty to eighty years. There were 13 deaths. He considers 15 of the cases successful, that is, "cases in which reversal, as far as one can judge, actually saved the limb from real or threatened gangrene." H. Morriston Davies recently reported a successful operation for gangrene. The artery and vein were completely divided and anastomosed in Hunter's canal ("Annals of Surgery," 1912).

The best plan is lateral anastomosis with proximal ligation of the vein, to prevent the deviated blood from returning at once to the heart. Bernheim and Stone devised this method (Ibid.) and Murphy advocates it. Only one-third of the artery is used for the anastomosis and some blood continues to flow in the artery toward the periphery. The artery carries blood to where the block is; the vein is supposed to carry blood much further. Bernheim points out that if a thrombus forms it will do so on the side of the artery and the limb will be no worse off.

In suitable cases the operation is justifiable and age is no bar. It is useless if veins are occluded as well as arteries, hence it is useless in advanced cases of gangrene from thrombo-angiitis obliterans. If any considerable area of gangrene exists veins are involved and the operation is useless.

IX. THROMBOSIS AND EMBOLISM

Thrombosis is the antemortem coagulation of blood in the heart or in a vessel, the coagulum remaining at its point of origin and plugging up the vessel partially or completely. The process, and also the condition significant of the process, is known as thrombosis; the clot is called the *thrombus*. This process is an essential part in the arrest of hemorrhage; it occurs in phlebitis and arteritis, and affords a frequent basis for embolism. The thrombus is composed of red corpuscles, white corpuscles, fibrin, and platelets in varying proportions. Thrombi may form in the veins, in the arteries, in the capillaries, or in the heart. Clotting is due to destruction of white blood-cells, fibrin ferment being set free, causing the union of calcium and fibrinogen and thus forming fibrin. Thrombosis is more common in the veins than in the arteries, the slow blood-current and the existence of valves favoring the deposit, though not causing it. A thrombus forms gradually, being deposited layer by layer; hence it is stratified or laminated. Figure 95 shows a thrombus in a vein. All thrombi are either *infectious* or *simple*, the latter being also called *aseptic* or *bland*. Thrombi are also spoken of as fibrinous, red, hemostatic, leukocytic, etc.

Causes of Thrombosis.—In the formation of thrombi four conditions are to be considered, viz., chemical alterations in the blood, a bacterial attack on the intima, tissue changes in the inner coat of the vessel, and slowing of the circulation. One, several, or all of these conditions may exist in a case of thrombosis. In arteries the chief causes are disease of the coats and embolism. In veins the chief causes are injury and infectious phlebitis. Capillary thrombi may be due to propagation from veins or arteries or may form in the capillaries. The latter condition is seldom seen. The essential cause of all intravascular thrombi is damage to the endothelial coat and in most instances the damage is effected by bacteria, hence most cases of thrombosis seen by the surgeon are infectious. Any condition which causes the blood to contain an excess of fibrin-forming elements favors thrombosis, in the sense that a slight injury of the vascular endothelium will be followed by clot formation. Among conditions favoring thrombosis we must note particularly slowing of circulation, however caused. A special predisposing condition is the retarded circulation in tuberculosis, influenza, and fevers, the blood-clotting behind the vein-valves after the endothelium has been damaged by toxins. Among other inciting states are inflammations; wounds; fractures; the pressure of a bandage or of a splint; varicose veins; ligation of a vessel; injury of a vessel; foreign bodies in a vessel; atheroma in arteries; sutures in a vessel; pregnancy; certain diseases, such as gout, typhoid fever, and septic processes; phlebitis or arteritis arising in the vessel or from extension of surrounding inflammation, and the entrance of specific organisms.

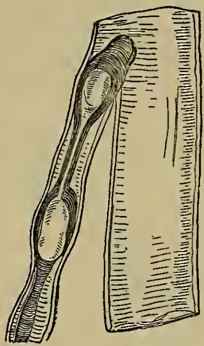

Fig. 95.—Thrombus in the saphenous vein (Green).

It has been asserted that so long as the endothelium of a vessel is uninjured a clot does not form. Slowing of the blood-current in aseptic conditions, it is now taught, will not cause thrombosis. One of the functions of the endothelial coat is to keep the blood fluid by preventing corpuscular disintegration. A thrombus can form only when fibrin ferment is set free, and fibrin ferment can be set free only when white corpuscles disintegrate. When moving blood coagulates, the third corpuscles or platelets first settle out and form a nucleus and then the leukocytes gather about it. This is known as the *white* or "*ante-mortem*" *thrombus*—the clot of moving blood. Thrombi from moving blood are rarely pure white; they contain some red corpuscles, forming *mixed thrombi.* White thrombi and mixed thrombi are stratified and are at first soft, but harden as they age. The *red thrombus* plugs vessels which are cut across or ligated; it also occurs in septic processes and is the thrombus formed after death. A *primary thrombus* remains in the original region of thrombosis. A *secondary thrombus* forms about an embolism. A *propagating* or *spreading thrombus* extends a considerable distance from the seat of initial disturbance. A thrombus soon undergoes a change. An aseptic clot usually "organizes"—that is, the clot is absorbed and is replaced by fibrous tissue. The walls of the injured vessel become filled with leukocytes, leukocytes invade the clot, the vascular endothelium proliferates, and the young cells follow the colonies of leukocytes into the thrombus. The thrombus is gradually removed by leukocytes and replaced by fibroblasts, the new tissue is vascularized and becomes granulation tissue, the granulation tissue is converted into fibrous tissue, and the fibrous tissue contracts. In some instances a thrombus is implanted on the wall of the vessel and the tube is not permanently occluded. Such a condition may be obtained by the application of a lateral ligature about a small tear in a large vein. In most instances, after the formation of an intravascular thrombus, the vessel is

converted into a narrow cord of fibrous tissue. A thrombus may degenerate and break down (fatty degeneration), giving rise to emboli, or a thrombus may undergo calcification. A calcified thrombus in a vein is known as *phlebolith.* An infected thrombus may undergo liquefaction, infective emboli being set free (Fig. 96).

A clot may propagate in both directions, that is, toward the periphery and toward the heart. It was taught for many years that when an artery is ligated a thrombus quickly forms and reaches to the first collateral branch above. This view was formulated in pre-antiseptic days. It is now known that when aseptic ligation is performed the thrombus is small and rarely reaches the first collateral branch; and is often actually absent, vascular obliteration being obtained by proliferation of connective-tissue cells and of cells from the endothelial coat. If an infection takes place the clot may reach the first collateral branch. The old rule of surgery was as follows: If an artery is cut near a large branch, tie the branch as well as the artery, in order to permit of the formation of a lengthy clot. This rule is no longer followed unless infection exists or is anticipated.

Fig. 96.—Infected thrombus of a vein (schematic).

A clot in a vein often extends a long distance. The author has seen in a postmortem examination a venous thrombus reaching from the ankle to the vena cava. A common example of thrombus in a vein is the clot formed in the uterine sinuses in a condition of puerperal sepsis, a clot which tends to extend into the iliac and femoral veins. In infectious thrombosis of the lateral sinus there is thrombophlebitis, and the clot tends to extend up to the torcular and into other sinuses and down into the jugular. *Phlegmasia alba dolens* or *milk-leg* is a condition in which the leg or the leg and thigh are swollen and painful because of venous thrombosis or sometimes lymphatic thrombosis (see page 187).

Lymphatic thrombosis occasionally occurs in the thoracic duct, axillary lymphatics, or inguinal lymphatics. It is most common in the uterine lymphatics during puerperal fever. Lymphatic thrombosis may be due to infection, to cancer, to tuberculosis, or to change in the lymph itself.

General Symptoms.—The symptoms are dependent on the seat of the obstruction and the presence or absence of infection. An organ or a part of an organ may exhibit functional aberration. The local signs in a vessel accessible to touch or sight are the presence of a clot; if it be in an artery, anemia and the absence of pulse below the clot; if it be a vein, swelling and edema below it. There is usually pain at the seat of trouble, and anesthesia below it. Moist gangrene may follow venous thrombosis, and dry gangrene, arterial thrombosis. Thrombosis of the mesenteric vein is followed by gangrene of the bowel. Infective thrombophlebitis is a spreading inflammation of a vein. A septic thrombus forms and the condition is an early step in pyemia. We see this condition sometimes in the lateral sinus of the brain as a result of suppuration in the middle ear; in any of the cerebral sinuses after infected compound fracture of the skull; and in the uterine veins during puerperal sepsis. Portal pyemia results from thrombophlebitis of branches of origin of the portal system (see page 1036). Thrombo-arteritis is a spreading inflammation of an artery in which a septic thrombus forms or in which a septic embolus lodges. It occasionally attacks an aneurysmal sac. In infectious thrombophlebitis and in arterial pyemia the symptoms are, of course, those of pyemia. A great danger of thrombosis is embolism, especially pulmonary embolism.

Infective Thrombosis of the Lateral Sinus.—(See page 805.)

Thrombosis of the Jugular Vein.—This condition is usually infectious and

secondary to infectious thrombosis of the lateral sinus or sometimes of the petrosal sinus. It is occasionally due to cancer, tuberculosis, acute rheumatism, or pyemia, taking origin from a distant focus. If it is infectious, the chills, the high and fluctuating temperature, and the great exhaustion proclaim the existence of pyemia. Locally the vein feels hard, the adjacent tissues are edematous, the branches of the jugular are visibly distended, there may be linear discoloration over the course of the jugular, and the head is held stiffly with an inclination to the diseased side.

Thrombosis of the Mesenteric Vessels (see page 988).—The arteries are affected much more commonly than the veins, and the superior mesenteric artery far more often than the inferior. Vascular disease is the cause of arterial thrombosis, and arterial thrombosis occurs chiefly in those beyond middle life. Venous thrombosis may be primary and has been observed after splenectomy, the clot having propagated to the mesenteric veins. It may occur as a result of any gastro-intestinal or general infection (pyemia, appendicitis, typhoid fever). Secondary venous thrombosis is due to portal obstruction or accompanies arterial mesenteric thrombosis.

Mesenteric thrombosis usually produces sooner or later gangrene of the gut, but does not always do so.

The period at which gangrene develops after blocking is uncertain; it may arise in thirty-six hours, it may not arise for two weeks or more. The gut becomes distended, bloody serum exudes into the peritoneal cavity, and in most cases into the lumen of the bowel. The mucous membrane undergoes necrosis and perforation occurs. The area involved varies greatly in different cases. In some cases it is very limited, and is rather apt to be in the large intestine. In other cases it is very extensive, and is apt to be in the small intestine. In a case of the author's in the Jefferson College Hospital practically the entire ileum was gangrenous and numerous perforations existed.

In mesenteric thrombosis pain arises rather suddenly and rapidly becomes severe. It is a persistent pain with paroxysmal exacerbations and is usually generalized, though in many cases it has an area of peculiar intensity. The pain is accompanied by rapid pulse, growing exhaustion, distention, subnormal temperature, tenderness, a mass appreciable by palpation in the region of the mesentery, free fluid in the peritoneal cavity, nausea, and vomiting. The condition suggests intestinal obstruction. The vomited matter consists first of the contents of the stomach, then of bile, finally becomes stercoraceous, and sometimes contains blood.

In nearly one-half of all cases blood in considerable quantity passes from the rectum.

Ballance points out that cardiac disease or arterial degeneration suggests the artery as the seat of thrombosis.

The only chance for recovery without operation is the establishment of the collateral circulation, and as the superior mesenteric vessels are terminal vessels this seldom occurs (in only about 5 per cent. of cases). (See Intestinal Obstruction from Mesenteric Thrombosis.)

Iliac Thrombosis After Abdominal Operations.—This complication is occasionally encountered and is most often met with in the left side, even when the operation was in the middle line or the right side. It is a rare complication, occurring, according to Professor Clark, 35 times in a series of 3000 operations.

Many explanations have been given of it. A great many surgeons regard it as infectious, but many cases certainly are not. Clark believes it is due to injury of the deep epigastric vein, forcible and prolonged separation of the wound edges by retractors being a common cause. The free anastomosis between the epigastric veins of the two sides accounts for the appearance of thrombosis

on one side after operation on the other. It is probable that in many slight cases the condition is not recognized, and it will not be recognized unless the clot reaches the femoral vein, and it requires one or two weeks to reach this vein if it does reach it at all. When a clot forms in the femoral vein a milk-leg develops. The entire extremity swells below the seat of thrombus, the temperature is usually normal, but may be distinctly elevated.

Thrombosis in General Infections.—In *typhoid fever* a thrombus may form in the heart, the veins, or the arteries. Thrombosis may occur in pneumonia, in influenza and in other fevers, and in tuberculosis. The vessels of a limb, a lung, the brain, or the mesenteric zone may suffer. The condition follows bacterial infection, the veins are most prone to suffer and gangrene may ensue.

Thrombosis in Appendicitis.—In about 2 per cent. of cases, according to Sonnenberg, this complication is noted. It may affect the femoral or saphenous vein of either side or of both sides, the portal vein or the vena cava, and may occur during an acute attack, but is more often noted in an interval.

It is not very unusual to find liver abscess follow appendicitis, the infection being carried by the portal vein and the condition being known as *septic pylephlebitis* (see page 1036).

Treatment.—If an aseptic thrombus forms in a large vessel of a limb, raise the limb a few inches from the bed, keep it perfectly quiet to avoid detachment of fragments (emboli), apply a bandage lightly from the toes up, and place bags of warm water about the extremity. Maintain rest for four or five weeks. The great danger is the formation of emboli, hence movements and rough handling are to be avoided. Gangrene is another danger, hence it is wise to favor venous return and the development of the collateral circulation by warmth, elevation, and bandaging. In infectious thrombophlebitis, if the vessel is accessible, tie it above and below the clot, open the vessel, remove the clot, irrigate, and pack the wound with iodoform gauze. The general treatment for a septic condition should be stimulating and supporting. Massage is unsafe in any condition of thrombosis, and is particularly dangerous in septic thrombosis. In thrombo-arteritis treat as in the thrombophlebitis. If gangrene of an extremity follows thrombosis, treat as previously directed (see page 164). Gangrene of the intestine in mesenteric thrombosis if not too extensive is treated by resection.

The treatment of infective thrombosis of the lateral sinus is set forth on page 806.

Embolism signifies vascular plugging by a foreign body (usually a blood-clot) which has been brought from a distance. The foreign body is called an *embolus*. An embolus usually consists of a separated or ruptured portion of a thrombus, atheromatous material from a diseased artery, or a bit of fibrin from a diseased heart-valve. In some cases an embolus consists of bacteria, of air, of fat, of a fragment of a tumor, or of parasites. In severe burns the blood undergoes changes and jelly-like matter is often precipitated and may cause embolism. Emboli vary in shape, in size, and in consistency. Emboli are divided into *simple*, *bland* or *aseptic* and *infectious*, *toxic* or *septic*. Emboli may arise either in the venous or in the arterial system, but are particularly prone to arise in the veins; they lodge in an artery, in capillaries, or in the veins of the liver. An embolus taking origin in one of the systemic veins passes through the right heart and lodges in a terminal branch of the pulmonary artery. If at this point it disintegrates, smaller emboli pass to the left heart and enter the arterial circulation to be deposited, as are emboli originating in the heart or arteries, in the arteries of an extermity, the kidneys, spleen, or brain. Emboli of the portal circulation lodge in the liver or perhaps pass through that organ and reach the lungs. An embolus is arrested when it reaches a vessel the diameter of which is less than its own. It is usually caught just above a bifur-

cation. When an embolus lodges, it at once partially or entirely obstructs the circulation and increases in size by thrombosis. Figure 97 shows an impacted embolus. A non-septic embolus when lodged usually "organizes," as does a thrombus, and, as described on page 185, is replaced ultimately by fibrous tissue. A soft embolus may disintegrate and permit the re-establishment of the circulation. An embolus may cause an aneurysm. A septic embolus breaks down, forms a metastatic abscess, and sends other emboli onward in the blood-stream.

An embolus is more serious than a thrombus: it causes sudden plugging, which makes dangerous anemia inevitable, and it will produce gangrene if the collateral circulation fails. Embolism of the mesenteric artery causes necrosis of the intestine. In organs with terminal arteries (spleen, kidney, brain, and lung) there is no collateral circulation and embolism causes *infarction.* For instance, if an embolus lodges in the lung it produces an area of ischemia; the removal of all propulsion upon the venous blood causes it to flow back and stagnate, and vascular elements exude and form a wedge-shaped area of red tissue, the embolus being the apex of the wedge. This is known as *hemorrhagic* or *red infarction,* and is often seen in the lung (Fig. 98). The

Fig. 97.—Embolus impacted at bifurcation of a branch of the pulmonary artery (Green).

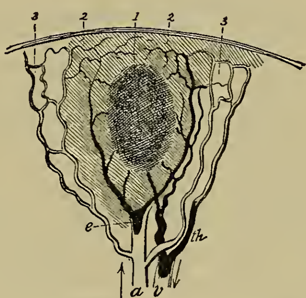

Fig. 98.—Diagram of a hemorrhagic infarct: *a*, Artery obliterated by an embolus (*e*); *v*, vein filled with a secondary thrombus (*th*); 1, center of infarct, which is becoming disintegrated; 2, area of extravasation; 3, area of collaterall hyperemia (O. Weber).

white infarction, seen in the brain and kidney, is not due to retrogression of venous blood, but is due to ischemia and resulting coagulation-necrosis. A septic embolus causes septic thrombosis and a septic infarction, and a septic infarction is followed by suppuration and the production of a pyemic abscess. That emboli of the systemic venous circulation usually lodge in the lungs explains the occurrence of pulmonary embolism after certain operations upon and during certain diseases of the regions drained by the systemic veins. Emboli formed in vessels of the systemic circulation lodge most often in the lungs, brain, kidney, or spleen. It is because emboli which pass into the portal vein lodge in the liver that operations upon the rectum may be followed by hepatic embolism and abscess of the liver.

General Symptoms.—The symptoms depend upon the organ involved and the presence or absence of infection. They are sudden in onset, and are due to loss of function, which may be permanent or which may be followed by inflammation, softening, or gangrene. In a septic embolus there are symptoms of infection and abscess forms at the seat of lodgment. In the course of pyemia a chill usually means the occurrence of embolism. Embolism of the cerebral arteries may cause aphasia, paralysis, or coma. Embolism of the pulmonary artery may cause almost instant death. Embolism of

a large artery of a limb produces symptoms similar to those of thrombus, except more sudden and decided. Below the obstruction the pulse is absent and the limb is swollen with edema, is cold, and is discolored. There is pain at the seat of obstruction. This condition is frequently followed by gangrene. Embolism of the superior mesenteric artery produces symptoms similar to those caused by acute intestinal obstruction, and results in gangrene of a portion of the intestine.

Pulmonary Embolism.—This condition occasionally follows operations and injuries and sometimes develops during certain diseases. I have seen a case after an operation for appendicitis, a case after an operation for varicocele, a case after an operation for hydrocele, a case after operation for perforated duodenal ulcer, a case after gastrostomy, and a case in a man with a large lumbar contusion to which massage was injudiciously applied. It is not very common. Albanus ("Beiträge klin. Chir.," xl) in 1140 abdominal operations found 23 cases. The emboli may be aseptic or septic. The condition is most common as a result of thrombosis of the veins of the lower extremities, appendicitis, and strangulated hernia. Certain postoperative pneumonias are embolic. Very small aseptic emboli may cause no symptoms or slight symptoms. When aseptic hemorrhagic infarction occurs there are symptoms. These symptoms are a chill or chilly sensations, moderate fever which may be transitory, dyspnea, rapid pulse, pain in the chest, sometimes rapidly advancing signs of consolidation, often a pleural friction sound, and bloody expectoration. Sometimes immediate death occurs. The mortality is always large (80 per cent.). I am satisfied that it is a much more common condition than we formerly supposed, and that some cases in which the emboli are very small are not diagnosticated and recover.

A septic embolism causes metastatic abscess and usually suppurating pleuritis, the condition being known as septic embolic pneumonia. Recovery is rare, but occasionally occurs. The symptoms are those of pyemia with the physical signs of consolidation and of pleuritis.

Embolism of the Mesenteric Arteries.—The superior mesenteric is the vessel usually affected. It may arise in pyemia, septicemia, arterial or cardiac disease. The symptoms are practically identical with thrombosis of the mesenteric vessels, except they arise suddenly. There is usually endocardial disease (see page 983).

Treatment.—Murphy removed an embolus of the femoral and iliac arteries through an incision of the femoral, and then sutured the incision ("Jour. Amer. Med. Assoc.," May 22, 1909). The operation was too late to prevent gangrene, but it emphasizes the truth that an aseptic embolism of a large artery can be treated by incision of the artery, removal of the clot, and suture of the vessel. The treatment long in vogue was as follows: In a limb, keep the part warm in order to stimulate the collateral circulation, elevate the extremity several inches from the bed, apply a bandage lightly from the periphery, and insist on perfect quiet. Massage is unsafe. If gangrene ensues, await a line of demarcation and, when it forms, amputate. In septic embolic arteritis in an accessible region it would be good surgery to act as in septic thrombophlebitis. After an operation upon veins (as the operation for varicocele, for varix of the leg, or for hemorrhoids), after any cutting operation, and after the infliction of a fracture, avoid as much as possible and for some time movements or handling, as fragments of thrombus may be detached.

In mesenteric embolism exploratory laparotomy may disclose a perforation which can be closed or a portion of gangrenous gut which can be resected.

In aseptic pulmonary embolism enforce absolute rest, give strychnin and morphin hypodermatically, and inhalations of oxygen. Trendelenburg has suggested operation for occluding pulmonary embolism (see page 900).

In septic embolic pneumonia pursue the conservative plan of treatment unless a large pulmonary abscess forms or an empyema arises. In either case operate to remove pus.

Fat-embolism in the human being was first noted by MacGibbon, of New Orleans, in 1856, and was first thoroughly described by von Recklinghausen in 1884, although Magendie, in 1827, and Virchow, in 1856, developed it experimentally in animals. It is a process which leads to an accumulation in the capillaries of liquid fat after injury to adipose tissue, high tension having forced the fat into the open mouths of veins. Fat may be forced into open veins by muscular action, by efforts at repair, or by concealed bleeding. Fat may get into the blood by means of the lymphatics and it can also enter by way of the synovial membrane. Wilms believes that fat reaches the veins by way of the lymphatics and the thoracic duct. Fat in the blood is quite a common condition, but seldom produces serious trouble, although it is occasionally fatal and is responsible for some otherwise inexplicable sudden deaths after fractures. Fat-embolism may arise during osteomyelitis, after extensive bruises, crushes, lacerations, amputations, fractures, resections, or rupture of the liver.[1] In a fatal case of mine it developed as a result of manipulation of a fracture of the neck of the femur. In another fatal case it followed amputation for cancer of the breast of a very fat woman. This fluid fat accumulates especially in the capillaries of the lungs and brain. It may plug systemic capillaries. If the patient recovers, he does so because the fat has been forced through the vessels; if he dies, the death results from mechanical hindrance to function and nutrition. When the emboli are widely scattered and not large, and when they do not lodge in vital parts of the brain or cord they may produce no symptoms and and do no real harm. Normal blood contains a small amount of finely emulsified fat (from 1 to 3 parts per 1000). In a number of physiological and pathological conditions the circulating blood contains considerable free fat. It may be found in a pregnant woman, a nursing baby, a fat individual, or in anyone during digestion. "It has been noted in the following conditions: chronic alcoholism; diabetes mellitus; certain diseases of the liver, heart, and pancreas; chronic nephritis; splenitis, tuberculosis; malarial fever, typhus fever; Asiatic cholera, and poisoning by phosphorus and by carbon monoxid. Lipemia commonly occurs as the result of lacerated wounds of the blood-vessels situated in fatty tissue, and after fractures of long bones involving injury of the fatty matter" ("Clinical Hematology," by John C. DaCosta, Jr.). In many cases of fracture in adults fat is found in the urine. I have had this demonstrated by repeated observations. When we recall how rarely simple fracture causes death it becomes evident that a moderate amount of fat in the blood is not dangerous or only becomes dangerous if it fails to flow out. In lipemia fatty embolism may occur if the amount of fat becomes excessive or if vascular damage favors plugging. At my suggestion, Dr. Wm. Carrington conducted an investigation to determine the frequency of lipuria after fractures (Essay Awarded the Surgical Prize in Jefferson Medical College in 1908). He determined that fracture

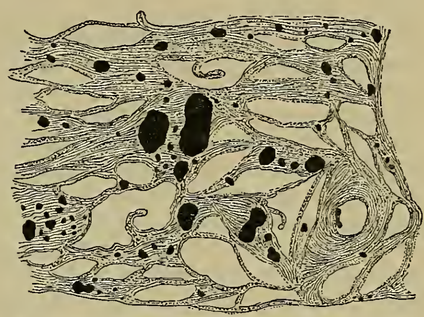

Fig. 99.—Fat-embolism of the lung after fracture of the femur. The fat-globules and masses, stained black with osmic acid, lie in the capillaries of the lung; × 150 (Hektoen).

[1] G. H. Makins, in "Heath's Dictionary."

of long bones invariably causes lipuria, fracture of small bones seldom does; that after fracture of a long bone fat appears in the urine "on different days, in different amounts, and in different forms" (this curious periodicity was first observed by Scriba in 1878); that when fat is present albumin is almost always present and blood is occasionally found; that the urea percentage falls as the fat content rises and rises as the fat content falls; that the condition is rare in young children and that fat-embolism, as a rule, is a benign process; that about the fifteenth day after a fracture fat usually disappears from the urine. Carrington, in 1908, found in literature 276 reported cases of fat-embolism.

Symptoms arise only when many emboli block a multitude of the capillaries of an organ, when a large embolism lodges, or when the capillaries of a vital region of the brain are blocked (the medullary centers). Emboli are most apt to form after or during handling of the wound or seat of injury or exhausting movement of the patient. Hence one peril of transportation after an accident, of early massage, of frequent changes of dressings, and of too early getting up after operation (Groendahl, "Deut. Zeitsch. f. Chir.," 1911, cxi). The symptoms are those of edema of the lungs and exhaustion, often with coma or delirium, and sometimes, in the beginning, are wrongly thought to be due to shock. There are restlessness, dyspnea, rapid and weakening pulse and rapid respiration, contracted pupils, and pallor followed by cyanosis. The temperature may be elevated, normal, or subnormal. Many coarse râles are heard in the chest, but percussion gives a clear note. If pulmonary edema becomes marked, the patient spits up a bloody froth. If life is prolonged a day or two, oil is found in the urine. Small amounts of oil may be found in the urine after serious injuries or operations when no symptoms of embolism exist. Nevertheless, the presence of the oil is always a cause of anxiety and is often a warning. It is maintained by Groubé that the amount of fat in the urine is in inverse ratio to the amount in the blood; the greater the amount excreted in the urine, the less the amount retained in the blood. Hence, fat in the urine makes the surgeon anxious, and a *sudden* diminution of the amount in the urine is a sign of grave danger if there develops increasing difficulty in respiration ("Rev. de Chir.," July, 1895). The inverse ratio said to be maintained between fat in the blood and fat in the urine, if it really exists, is similar to a finding of Lépine in diabetes, that is, if a diabetic is given diuretics, the sugar in the urine increases and the sugar in the blood decreases. The symptoms of fat-embolism seldom occur until at least twelve hours after an accident, and rarely before the third day, but may occur as early as three hours. The symptoms occur at a later period than those of shock and at an earlier period than those of ordinary embolism of the lung. The important point emphasized by Carrington is that after the reaction from shock, if there were shock, and for hours or days after the injury in any case, there is a period of freedom from all alarming symptoms, and that the symptoms of fat-embolism come on suddenly and without warning. If some of the oil is forced through the vessels of the lung, it will lodge in other regions and produce other symptoms. Oil may appear in the urine as above stated. Urinary suppression may occur. Delirium may arise, there may be twitching, convulsions or paralysis, or the patient may pass into coma. The eye-ground may show choked disk, hemorrhage, and fat in the vessels (Connel's case and Czerny's case). Cases of fat-embolism with severe symptoms are commonly fatal; milder cases are often recovered from. In mild cases the symptoms last but a few days, in severe cases the condition may prove fatal in from a few hours to seven days after the injury, and in from a few to forty-eight hours after the appearance of symptoms. A patient may have two or three attacks, Connel's patient had three attacks, there being an interval of a week between the first and second and between the second and third attacks.

Treatment.—Wilms, acting on his belief that fat enters the lymphatic duct and from there gets into the venous circulation, treated one case of fat-embolism successfully by making a fistula in the thoracic duct. This operation might be justifiable when dangerous brain symptoms are known to be due to fat-emboli. The usual treatment consists in absolute rest of the diseased or injured part and the administration of stimulants, such as strychnin, alcohol, and carbonate of ammonium, the use of external heat; the employment of oxygen by inhalation, and the administration of diuretics and of nitroglycerin hypodermatically. Artificial respiration may tide a patient over a crisis. If an external wound exists, free drainage must be established, and the diseased or damaged part should be thoroughly immobilized if possible. In order to prevent fat-embolism after a severe injury insist on rest. Massage used early after some injuries is dangerous, as it may force fluid fat into the vessels. Very early getting up after operation is not safe. Frequent changes of dressings are undesirable. When severe contusion causes the formation of a large cavity filled with blood, Groubé wisely advises incision to lessen the danger of fat-embolism.[1]

Air-embolism.—Air may enter a vein during a surgical operation or it may be injected accidentally while giving a hypodermatic injection, hypodermoclysis, or a saline infusion into a vein. It may follow irrigation of the pleura with hydrogen peroxid. In caisson disease it is taught by some that nitrogen is set free in the blood. It may occur when a cerebral sinus is opened, or in the uterine veins, if the uterus does not remain contracted after delivery. It is very seldom that any symptoms follow. It was long thought that such an accident must be always extremely dangerous. The experiments of my colleague, Professor Hare, indicate that quantities of air may be injected into the veins of a dog without apparent harm. The entry of a small amount of air into the veins of a human being will not be apt to induce dangerous symptoms, but it may be fatal. The more rapidly it is introduced and the greater the amount, the greater is the danger. The manner in which it can induce death is doubtful. Some maintain that it causes blood in the right side of the heart to froth, and thus prevents normal action of the valves, the heart becoming unable to propel blood through the lungs. Others maintain that air reaches the cerebral capillaries and so causes cerebral anemia. Some believe cardiac failure results from the presence of air in the pulmonary capillaries. The first view is the most probable. If a surgeon divides a large vein, air may be sucked in, and there is particular danger in such an accident if a vein at the root of the neck or a cerebral sinus is torn or incised, or if the damaged vessel lies in scar tissue and cannot collapse.

Symptoms.—When during an operation air enters a large vein there is a sucking sound, air-bubbles may be noted in the wound, and serious symptoms may or may not follow. Twice I have wounded the subclavian vein and have heard this sound, but no alarming symptoms developed. If serious symptoms are produced, they arise suddenly, and consist of extreme failure of circulation, a curious whirring or churning sound on cardiac systole audible even without a stethoscope, deadly pallor or cyanosis, gasping for air, convulsions, and possibly death.

Treatment.—Compress the vein with the finger and clamp it quickly. Suspend the anesthetic, lower the head, employ artificial respiration, give inhalations of oxygen, hypodermatic injections of strychnin, and intravenous infusion of normal salt and adrenalin.

X. SEPTICEMIA AND PYEMIA

Septicemia, or sepsis, is a febrile malady due to the introduction into the blood of pyogenic organisms or the products of saprophytic bacteria. There is no one special causative organism, and any microbe which produces inflammatory and febrile products may cause it. Either streptococci or staphylococci may be present. Pneumococci are a not very unusual cause. Septicemia arises by absorption of septic matter by the lymphatics. Clinically, we distinguish two forms of septicemia: (1) sapremia, septic or putrid intoxication, and (2) septic infection, true or progressive septicemia. In these conditions the area of infection is usually discovered by the surgeon; but when it cannot be located, the disease is called by the Germans cryptogenetic septicemia.

Sapremia, Septic or Putrid Intoxication.—This condition is due to the absorption of poisonous ptomains from a putrefying area. The bacteria do not enter the blood, but their toxins do, and as these toxins are active poisons the condition is comparable to poisoning by successive alkaloidal injections, the symptoms and prognosis depending upon the dose. Not unusually there is absorption not only of the toxins of saprophytic bacteria, but also of the toxins of pyogenic micro-organisms. Even if some of the bacteria enter the blood, they do not multiply in this fluid. Slight symptoms and recovery follow a small dose; grave symptoms and death follow a large one. The poison does not multiply in the blood, and a drop of the blood of a person laboring under putrid intoxication will not produce the disease when introduced into the blood of a well person; in other words, the disease is not infective. Considerable putrid material must be absorbed to cause sapremia. What is known as surgical fever is due to the absorption of a small amount of putrid or fermented wound fluid, and is, in reality, a mild form of sapremia. If sapremia arises, it does so soon after the infliction of a wound, and after a large rather than small wound when a considerable amount of wound fluid is pent up under pressure. It may follow labor where putrid fluid is retained in the womb, may follow an injury of or an operation upon a joint, may follow amputation where decomposing blood-clot or wound fluid is pent up within the flaps, or may ensue upon an abdominal operation or injury. In sapremia there always exist a considerable absorbing surface and a large amount of dead matter which has become putrid. Roswell Park[1] points out that sapremia arises from putrefaction of a blood-clot or wound fluids which are retained like foreign bodies in the tissues, and does not arise from putrefaction of the tissues themselves. He speaks of the condition as due to the absorption of poison from a "putrid suppository." Sapremia will not occur after granulations form. The term "putrefaction" is used because this is the usual change, but any fermentative organism may cause the disorder. Sapremia is a malignant form of surgical fever, and its existence means an ill-drained wound, and a fermenting and probably putrid collection of blood-clot or wound fluid.

In sapremia there is congestion of the stomach, intestines, and other abdominal viscera, particularly the kidneys, and also of the brain, and numbers of red blood-cells disintegrate.

Symptoms.—The patient often seems to react incompletely from the injury; he feels miserable, complains of headache, nausea, and pain in the back and limbs; or, he may react and in a day or two develop this condition of malaise. In some cases an aseptic fever is directly succeeded by sapremia. In most cases of sapremia, between twenty-four hours and two or three days

[1] "Treatise on Surgery by American Authors."

after labor, after an injury, or after an operation, there is usually a chill or a chilly sensation, though in some cases this is wanting. The temperature rapidly rises to 103° F. or even more. There are severe headache, dry and coated tongue, rapid and weak pulse, nausea and often vomiting, diarrhea, great prostration, restlessness, muscular twitching, and active delirium. The wound is found to be foul, and sometimes there is drying up of wound discharge. There is diminution or suppression of urine, and a strong tendency to congestion of various organs. Jaundice is not unusual. Petechial spots are frequently noticed upon the skin. They occur also upon mucous membranes and serous surfaces, and result from the plugging of small vessels with detritus of broken-down red corpuscles and consequent vascular rupture. Great elevation of temperature often precedes death. In some cases the dose of poison is so large that the patient passes into rapid collapse without preliminary fever. Some cases recover if the initial dose is not overwhelming and if additional doses are not absorbed. Many cases die of exhaustion. Some become linked with fatal pyemia or septicemia. Hemoglobin and red blood-corpuscles are rapidly and notably diminished. Distinct leukocytosis exists, except in those cases in which the organism is overwhelmed with the poison and is unable to react. Cover-glass preparations do not show organisms in the blood, and cultures from the blood are sterile.

Treatment consists in at once draining and asepticizing the putrid area and administering very large doses of alcohol and large medicinal doses of strychnin and digitalis. The patient should be purged and diaphoresis favored. The hot bath is valuable to cause sweating. The action of the kidneys must be maintained if possible. Purgatives, diuretics, and diaphoretics are given to aid in removing the toxin, and stimulants are used to sustain the strength of the patient during the elimination of the poison. Vomiting is allayed by champagne, cracked ice, calomel, cocain, or carbolic acid with bismuth. Food should be administered every three hours. The patient is fed on milk, milk and lime-water, liquid beef-peptonoids, beef-juice, and other concentrated foods. Quinin in stimulant doses is of value. Antipyretics are useless. The use of saline fluid by hypodermoclysis or intravenous infusion dilutes the poison and stimulates the heart, skin, and kidneys to activity. Visceral complications must be watched for and should be promptly treated if discovered. Among the possible visceral complications are nephritis, cholecystitis, enteritis, hepatitis, peritonitis, pleuritis, empyema, bronchopneumonia, pericarditis, and endocarditis. Antistreptococcic serum is useless in sapremia.

Septic Infection, or True Septicemia.—This condition is a true infective process. In sapremia the blood contains toxins of putrefactive bacteria, but not the bacteria themselves. In septic infection the blood contains both pyogenic toxins and multiplying pyogenic bacteria, the bacteria perhaps being free in the blood or in white cells. In sapremia the causative condition is putrid material lodged like a foreign body in the tissues. In septic infection the tissues themselves are suppurating, and both bacteria and toxins are being absorbed by the lymphatics. Of course, septic infection may be associated with septic intoxication or may follow it. In suppurative fever the tissues suppurate, but only the pyogenic toxins are absorbed, and not the pyogenic bacteria. In septic infection both the pyogenic bacteria and toxins enter the blood, and the bacteria multiply in the blood and produce continually increasing amounts of poison. The symptoms of sapremia depend on the dose. In septic infection only a small number of organisms may get into the blood, but they multiply enormously. The pus microbes cause true septicemia, and reach the blood chiefly through the lymphatics, but to some degree by penetrating the walls of vessels. A drop of blood from a man with septic infection will reproduce the disease when injected into the

blood of an animal; hence the disease is truly infective. The wound in such cases is often small, but may be large, and is commonly punctured or lacerated, and the disease begins later after the infliction of a wound than does sapremia. No wound may be discoverable, the infection having arisen from an unrecognized focus of suppuration—for instance, gonorrhea, middle-ear disease, dental caries, tonsillar suppuration, appendicitis, etc. The initial atrium of infection may or may not be discovered.

The bacteria which exist in the blood and organs in septicemia are usually staphylococci or streptococci, often both. Pneumococci or colon bacilli in some cases are causative. The blood is found to have lost much of its coagulating power; it remains fluid for some time after death, quantities of red corpuscles are destroyed, and minute hemorrhages take place in the brain, mucous membranes, skin, serous membranes, muscles, and various viscera. There may be inflammation of synovial and serous membranes. There is congestion of the gastro-intestinal tube and of the abdominal viscera. The lymph-glands are larger than normal and the spleen is notably enlarged. The wound contains numbers of bacteria.

Symptoms.—The type of this condition is met with in puerperal septicemia or in septicemia from an infected wound. When septicemia arises from an infected wound, red lines due to lymphangitis are usually seen about the wound, and there is enlargement of related lymphatic glands. In some cases, however, the wound and the parts about it look normal. A supposed aseptic fever after an injury may continue for an undue time and the surgeon may find that septicemia has developed. Septicemia may arise during the existence or after the abatement of sapremia, or may arise when the aseptic fever has passed away and when there has been no putrid intoxication. It begins in from four to seven days after labor or an injury, usually with a chill, which is followed by fever, at first moderate, but soon becoming high. In some cases there is a chilly sensation, but no distinct chill. There is always great prostration even before the chill. The fever presents morning remissions and evening exacerbations, and may occasionally show an intermission. When the remission begins there is a copious sweat. As the case progresses the temperature may fluctuate, and it often rises very high before death. The pulse is small, weak, very frequent, and compressible. The tongue is dry and brown, with a red tip. Sordes gather on the teeth and gums. Vomiting is frequent, and, as a rule, there is diarrhea. Low delirium alternates with stupor, and coma is usual before death. The great prostration is a noticeable and characteristic feature of the sufferer from septicemia. There are *subsultus tendinum* (twitching of the muscles of the hands and feet) and *carphologia* (picking at the bedclothing). Toward the end the face often becomes *Hippocratic* (hollow temples, pinched nose, sunken eyes, livid skin, lead-colored and cold ears, and relaxed lips). Visceral congestions occur. The spleen is enlarged, ecchymoses and petechiæ are noted, urinary secretion becomes scanty or is suppressed, and the wound becomes dry and brown. Blood examination detects a rapid and great diminution in red corpuscles and hemoglobin. The anemia is in many cases profound. There is marked leukocytosis except when the system is overwhelmed by the poison. Cover-glass preparations made from blood may show bacteria, but often fail to do so. Cultures from the blood are sterile in most cases, but not in all. A negative finding does not disprove the existence of septic infection; a positive finding is of conclusive diagnostic value. Pneumococcic septicemia is extremely violent in manifestation. In some cases death ensues before the lung has consolidated. If it is not so rapid, endocarditis, arthritis, peritonitis, meningitis, or osteomyelitis may develop.

The *prognosis* of true septicemia is very unfavorable, and in some malig-

nant cases death occurs within twenty-four hours, but mild cases often recover. Welch points out that finding the Staphylococcus pyogenes albus in the blood is not particularly ominous, but the presence of other pyogenic cocci is exceedingly threatening. Endocarditis, pericarditis, peritonitis, pleuritis, bronchopneumonia, empyema, nephritis, arthritis, cholecystitis, hepatitis, meningitis, and pyelitis are among the complications which may arise.

Treatment in general is the same as for septic intoxication. Antistreptococcic serum is employed by some surgeons, but the value of this method is as yet doubtful. It does not do any harm. It may do good. It is proper to use it, but not to the exclusion of other remedies. The usual dose is 10 c.c. injected into the abdominal wall. The injection may be repeated two, three, or even six times a day, and may be used for a number of days. Because of uncertainty as to the causative organisms polyvalent serum is used by some. Some use bacterial vaccines. Petre has injected fresh warm horse-serum to stimulate leukocytosis. Jayle ("La Presse médicale," 1905, p. 722) and Federman have also used it. All sera and vaccines are as yet of undetermined value in septic infection. Washing the blood by the intravenous infusion of salt solution often produces distinct improvement, which, unfortunately, is usually temporary. Dr. C. C. Barrows commends formalin used intravenously. The strength of the solution is 1 part of formalin to 5000 parts of salt solution. The dose is 500 c.c. I have had no experience with formalin in septicemia, but do not believe that any reagent can be safely introduced which would rapidly and directly kill the bacteria. Even if such an agent could be found, the attempt to use it would be dangerous, as dead bacteria liberate a poison, and the rapid death of immense numbers of bacteria would mean the entrance into the blood of an enormous amount of toxic matter.

Pyemia is a condition in which metastatic abscesses arise as a result of the existence of septic thrombophlebitis, the disease being characterized by fever of an intermittent type and by recurring chills. It is not actually due to free pus in the blood, but to the passage into the blood of the clots filled with toxins or, far oftener, of clots infected by streptococci, staphylococci, or both. After a wound is inflicted blood clots in the divided veins. If suppuration occurs, the clots may become filled with the toxins of pyogenic bacteria or be invaded by the bacteria themselves. Thus it becomes evident that pyemia may develop with septicemia. It may also develop when there is suppuration in a wound, but not septicemia, no lymphatic absorption of bacteria or toxins having occurred. A suppurating focus about a vein may cause thrombophlebitis and clot-formation even when no wound exists. This is seen in thrombophlebitis of the lateral sinus secondary to suppuration of the middle ear.

A vessel thrombus runs up in the lumen of a vein, and the apex of the clot softens, a portion of it is broken off by the blood-stream and carried as an embolus into the circulation. Many of these poisonous emboli enter into the blood and lodge in some vessels which are too small to transmit them, and at their points of lodgment form *embolic*, *secondary*, or *metastatic abscesses*. If the embolus contains only pyogenic toxins the danger is infinitely less than if it contains bacteria. The secondary abscess if caused by a clot containing only toxins may not lead to further dissemination of disease. If the embolus contains bacteria, thrombophlebitis occurs about it, and new infected emboli form and are sent throughout the system. Wounds of the superficial parts and bones produce pyemic infarctions and metastatic abscesses of the lungs. When these infarctions break into fragments particles may return to the heart and lodge, or may be sent out through the arterial system to form other foci in distant organs. Infected areas connected with the portal circulation (intestinal injuries, appendicitis, or suppurating piles) may produce *portal*

pyemia and multiple abscesses of the liver (see page 1036). Wounds of bones which open the medullary cavity or diploic structure are particularly apt to be followed by pyemia, and the disease may follow labor, phlegmonous erysipelas, and other conditions. Malignant endocarditis is called "*arterial pyemia*," and is due to endocardial embolic infection. In this disorder infected emboli lodge in the kidneys, the spleen, the alimentary tract, the brain, and the skin (Osler). Idiopathic pyemia is a misnomer. Some primary focus of infection must exist, as was pointed out when discussing septicemia.

Symptoms.—The wound often becomes dry and brown, and sometimes also offensive. A severe and prolonged chill or a succession of chills ushers in the disease; high fever follows, and drenching sweats occur. The chills recur every other day, every day, or oftener. A chill arises from the liberation and lodgment of emboli. During the sweat the temperature falls and may become nearly normal, normal, or actually subnormal. The temperature often oscillates violently. The general symptoms of vomiting, wasting, etc., resemble those of septicemia. In some cases the mind remains clear, in many the delirium is purely nocturnal. The skin frequently becomes jaundiced and a profound adynamic state is rapidly established. The blood changes are like those of septicemia. The spleen is enlarged. The lodgment of emboli produces symptoms whose nature depends upon the organ involved. Lodgment in the lungs causes shortness of breath and cough, with slight physical signs. Lodgment in the pleura or pericardium gives pronounced physical evidence. Lodgment in the spleen produces severe pain and great enlargement. The parotid gland not unusually suppurates.

In a suspected case of pyemia always examine an existing wound, and if there is no wound, remember that the infection may arise from gonorrhea, osteomyelitis, suppuration in the middle ear, appendicitis, dental caries, tonsillar suppuration, abscess of the prostate, etc. Chronic pyemia may last for months; acute pyemia may prove fatal in three days. The chief complications are joint-suppuration, bronchopneumonia, pleuritis, empyema, endocarditis, pericarditis, peritonitis, nephritis, cholecystitis, pyelitis, venous thrombosis, and abscesses.

Treatment is the same as for septicemia. Open, drain, and asepticize any wound and any accessible secondary abscess. The remarks made as to the use of sera and bacterial vaccines in septicemia apply also to pyemia.

Erysipeloid (*reticular lymphangitis, crab cellulitis*) was described by Rosenbach in 1887, although like cases were reported nearly fifteen years before by Morrant Baker under the name of erythema serpens. Gilchrist, in 1904, reported 329 Baltimore cases. I have seen a number of cases in the Jefferson Hospital. The condition is due to infection from handling putrid animal matter, especially fish; bites of crabs, and sticks of fish fins. Rosenbach claimed to find a special organism resembling but larger than a staphylococcus, but other observers fail to find it. The period of incubation is from a few hours to two days. Jopson describes the disease as follows ("Amer. Jour. Med. Sciences," May, 1908): "It appears as a swelling with elevated, sharply defined edges, which soon affects the entire circumference of the finger; and is commonly described as of a dark-red color, with purplish or even livid edges. The finger is tense and only moderately painful, but itching and burning are prominent symptoms. Sections of tissue excised show an inflammation of the entire corium and, to a slight extent, of the subcutaneous tissue, with infiltration of polynuclear leukocytes and small lymph-cells; edema of the epithelial cells of the epiderm, and inflammatory changes, especially marked around the sweat-glands and blood-vessels (Gilchrist). It has a characteristic tendency to spread from its usual point of origin, near the end of the finger, toward the palm, the primarily affected area fading from red to yellow, and thence to

normal. Reaching the palm, it may spread over it; but commonly, it soon affects the neighboring finger; and, when untreated, it may gradually spread to all the fingers and to the back of the hand. There is no fever or other constitutional disturbance, and the lymph-glands are almost never involved. It is more or less self-limited, commonly lasting from ten days to three weeks; and during this time there is a well-marked tendency to relapse. There is no suppuration, pustulation or vesiculation, and no scaling follows."

It is treated by applications of lead-water and laudanum, ichthyol or compresses soaked in a saturated solution of Epsom salt. Jopson applies tincture of iodin, and Gilchrist, 25 per cent. salicylic acid plaster.

XI. ERYSIPELAS (ST. ANTHONY'S FIRE)

Erysipelas is an acute, contagious, spreading capillary lymphangitis due to the streptococci of erysipelas, which grow and multiply in the smaller lymph-channels of the skin and the subcutaneous cellular layers and also in the lymph-channels of serous and mucous membranes. Erysipelas, though contagious, is, as a matter of fact, seldom conveyed as such from one patient to another. Pantou and Adams ("Lancet," Oct. 9, 1909) present this truth convincingly. In St. Thomas's Hospital from 1896 to 1905 erysipelas cases were kept with other cases in the septic wards. In 1906 isolation was begun. The records of 1907 show that isolation had no effect in diminishing the number of cases of erysipelas arising in the septic wards. *Cutaneous erysipelas* is characterized by a rapidly spreading, acutely beginning dermatitis, by a remittent fever due to absorption of toxins, and by a tendency to recurrence. It is always preceded by a wound, a scratch, or an abrasion, which may have been trivial and may never have been noticed. The so-called idiopathic erysipelas is preceded by a breach of surface continuity so small as to escape notice. The initial point of infection may be in the mouth, the nostril, the pharynx, the auditory meatus, between the fingers or toes, at the margin of a nail, or in a cutaneous furrow. The involved area in cutaneous erysipelas seldom suppurates, but sometimes does, very thin, watery pus being formed. If thick pus forms it means mixed infection with staphylococci, but the formation of thin pus does not require a mixed infection, as the streptococcus is identical with the *Streptococcus pyogenes*. In some cases of erysipelas, staphylococcus infection follows and even actually replaces streptococcus infection. The rapid spread of erysipelas is due to the fact that the streptococci prevent coagulation of exudate and are not actively attacked by leukocytes. Erysipelas is most common in the spring and fall, and is most usually met with among those who are crowded into dark, dirty, and ill-ventilated quarters; it attacks by preference the debilitated and broken-down (as alcoholics and sufferers from Bright's disease). The disease may become endemic in special places or localities. The poison of erysipelas will produce puerperal fever in a lying-in woman. The streptococcus was first obtained in pure cultures by Fehleisen. This organism is widely diffused. The question of identity with the Streptococcus pyogenes is discussed on page 50.

Forms of Erysipelas.—*Ambulant*, *erratic*, *migratory*, or *wandering* erysipelas is a form which tends to spread widely over the body, leaving one part and going to another. *Bullous* erysipelas is attended by the formation of bullæ. In *diffused* erysipelas the borders of the inflammation gradually merge into healthy skin. *Erythematous* erysipelas involves the skin superficially. *Metastatic* erysipelas appears successively in various parts of the body. *Puerperal* erysipelas begins in the genitals of lying-in women, producing puerperal fever. *Erysipelas simplex* is the ordinary cutaneous form. *Erysipelas neo-*

natorum begins in the unhealed navel of a newborn child and spreads from this point. *Typhoid* erysipelas occurs with profound adynamia. *Universal* erysipelas involves the entire body. *Cellulitis* is often erysipelas of the subcutaneous layers. *Phlegmonous* erysipelas involves the skin and the cellular tissues, and causes suppuration, and often gangrene. *Edematous* erysipelas is a variety of phlegmonous erysipelas with enormous subcutaneous edema. *Lymphatic* erysipelas is characterized by rose-red lines due to lymphangitis. *Venous* erysipelas is marked by the dark color of venous congestion. *Mucous* erysipelas involves a mucous membrane. Erysipelas may attack the fauces, producing the very grave condition known as *faucial* erysipelas.

Clinical Forms.—The clinical forms are cutaneous erysipelas, cellulocutaneous or phlegmonous erysipelas; cellulitis, and mucous erysipelas.

Cutaneous erysipelas most frequently attacks the face. A fever suddenly appears, rises rapidly, reaches a considerable height, is remittent in type and sometimes distinctly fluctuating, and usually terminates in four or five days by crisis. At the time of febrile onset spots of redness appear on the skin. These spots run together, and soon a large extent of surface is found to be red and a little elevated. Any wound, ulcer, or abrasion which exists becomes dry and unhealthy, and its edges redden and swell. The erysipelatous area of redness and swelling extends either in spots with intervening healthy skin or in an uninterrupted line. The margin is usually sharply defined from the healthy skin, and the color fades at the original focus as the disease advances at the periphery of the red area. The border shows the most intense redness, the most marked inflammatory swelling (if there is swelling), and the greatest pain. The point of origin shows the least redness, the least swelling, and the least pain. Thus erysipelas reverses the rule of an ordinary inflammatory process. Milian calls this tendency of erysipelas "the law of centrifugal maximum" ("La Presse médicale," Nov. 5, 1910). The color fades at once on pressure and returns at once when pressure is removed. There is burning pain, which is most intense at the border and which is increased by pressure. In the hyperemic area vesicles or bullæ form, containing first serum and later it may be seropus, but there is rarely genuine suppuration in cutaneous erysipelas. Edema affects the subcutaneous tissues, producing great swelling in regions where there is much loose cellular tissue (as in the eyelids). Anatomically related lymphatic glands may become large and tender. In an ordinarily strong person the color of an erysipelatous area is bright red or, more rarely, dark red. A dusky color precedes suppuration. A blue color precedes gangrene or indicates profound cardiac or pulmonary involvement. Erysipelas spreads now in one direction, now in another, influenced, according to Pfleger, by the furrows of the skin. As facial erysipelas spreads it involves the ear. All subcutaneous inflammations stop short at the ear and cannot invade it because of the close adhesion of the skin to the cartilage. Milian calls this the "ear sign." When the disease ceases to spread, the swelling and redness gradually abate, and after they disappear desquamation takes place, and the blebs become dry and crusted.

In strong subjects the constitutional symptoms of cutaneous erysipelas are often slight. In the old and debilitated the symptoms are typhoidal, there is a dry tongue, dyspnea and hebetude, delirium comes on, and death is usual. Possible complications are meningitis, pneumonia, septicemia, pleuritis, pyemia, myocarditis, endocarditis, arthritis, and albuminuria. Erysipelas neonatorum is very fatal. The mortality in infants is certainly 50 per cent. (Sir Watson Cheyne's "Weightman Lecture for 1908"). In some instances an attack of erysipelas will cure an old skin eruption, a new growth, an ulcer, or an area of lupus. This is the *érysipèle salutaire* of our French confrères.

Treatment.—Isolate the patient. Asepticize the wound, if there be a wound. Examine to determine if there is diabetes or Bright's disease. Administer a purge. Cases of cutaneous erysipelas occurring in a fairly healthy, young or middle-aged subject, tend to get well without treatment. The late J. M. DaCosta advocated the administration of $\frac{1}{8}$ to $\frac{1}{6}$ gr. of pilocarpin. Debility absolutely contra-indicates this drug. If a person is debilitated, free stimulation is necessary. Tincture of chlorid of iron is usually administered in doses of from 20 to 40 min. well diluted, and given three or four times a day. Tonic doses of quinin are also given. Nutritious food is given at intervals of three or four hours. For sleeplessness or delirium use chloral or the bromids; for very high temperature cold sponging is required. Early in an attack, when the area is limited, the application of Bier's cup may do good. To prevent spreading some have advised injection of the healthy skin near the blush with a 2 per cent. carbolic solution or with fluid containing $\frac{1}{16}$ gr. of corrosive sublimate. A band of iodin painted on the skin may arrest the progress of the disease, and so may a ring streaked around a limb or about an erysipelatous area by lunar caustic. Kraske has suggested a method of preventing the spread of cutaneous erysipelas which is often effective. The patient is anesthetized. At about 2 inches from the margin of the redness a series of cuts are made into the skin, to a sufficient depth to cause free oozing. Each cut is crossed by another cut and a ring of scarifications is made to surround the region of the erysipelas. After the oozing ceases the scarified area is soaked for one hour with a solution of carbolic acid (1 : 20) or corrosive sublimate (1 : 2000). The part is dressed with pads wet with carbolic acid (1 : 40) or corrosive sublimate (1 : 2000). This operation causes the formation of a protective barrier of leukocytes. For a number of years I have used with satisfaction a treatment taught me by my old master, Prof. S. W. Gross. It is as follows: Paint the part and well around the part several times a day with a mixture of equal parts of tincture of iodin and alcohol. If a wound exists, keep it open and disinfect it with the iodin once a day. Cover the part with lint wet with lead-water and laudanum, and, if it be an extremity, bandage it from the toes or fingers to well above the erysipelatous area. The iodin is germicidal and quickly enters the lymph-spaces. The lead-water and laudanum allays the burning pain. Saturated solution of Epsom salt is a useful preparation. It is applied on gauze which is kept constantly moist. It quickly allays the burning pain and seems to limit the spread of the infection. Some advocate a daily inunction of Credé's soluble silver. A good application is a 50 per cent. ichthyol ointment with lanolin. A very useful method is von Nussbaum's. The author applies it somewhat modified, as follows: wash the part with ethereal soap, irrigate with a solution of corrosive sublimate (1 : 1000), dry with a sterile towel, apply an ointment of ichthyol and lanolin (50 per cent.), and dress with antiseptic gauze. Some use iced-water cloths. Hot fomentations are distinctly harmful. Some apply borated talc or salicylated starch. Ringer advised painting every three hours with a mixture composed of 30 gr. of tannic acid, 30 gr. of camphor, and 4 dr. of ether. Antistreptococcic serum has been used in erysipelas, and most beneficial results have been claimed for it. It is asserted that under its influence the temperature soon becomes normal. My personal experience with the serum treatment has not convinced me of its value, although some cases seem to be benefited. Schorer studied 100 cases of erysipelas in Bellevue Hospital and determined the opsonic index and its relation to treatment by inoculation of dead streptococci. He concluded that a vaccine does not prevent migration or recurrence, but seems to shorten the duration of the disease ("Amer. Jour. Med. Sciences," Nov., 1907). Ross and Johnson regard treatment by a specific vaccine as very efficient ("Jour. Amer. Med. Assoc.," March 6, 1909).

Cellulocutaneous or **phlegmonous erysipelas** is characterized by high temperature (104°–106° F.), the rapid onset of grave prostration, irregular chills, sweat, and a strong tendency to delirium. The constitutional condition may be one of suppurative fever, sapremia, septicemia, or pyemia. The parts are red, as in cutaneous erysipelas, and the tumefaction is vastly greater. The swelling is brawny, comes on early, increases with exceeding rapidity, induces a high degree of tension, and frequently becomes associated with sloughing or even cutaneous gangrene. The lymphatic glands are swollen, but the inflamed lymphatic vessels are hidden by the tumefaction. In most cases suppuration occurs, and when this happens the parts become boggy and the pus is widely disseminated in the subcutaneous and intramuscular tissues, and even into muscle-sheaths and tendon-sheaths (*purulent infiltration*). When the disease abates sloughs form, which leave ulcers upon being cast off. In bad cases muscles, vessels, tendons, and fascia may slough away. The commonest complications are suppression of urine, bronchopneumonia, congestion and edema of the lungs, meningitis, congestion of the kidneys, and acute pleurisy. Septicemia or pyemia may occur. We sometimes meet with this form of erysipelas after extravasation of urine. It is not a pure streptococcic infection. There is a mixed infection with other pyogenic cocci, and often with organisms of putrefaction.

Treatment.—At once asepticize and drain any existing wound, and dress such a wound with hot antiseptic fomentations. If there are inflamed lymph-vessels or glands above the area of cellulocutaneous infection, paint the skin above them with iodin and smear it with blue ointment or rub in Credé's ointment of soluble silver. Make numerous incisions into the inflamed tissues. These incisions should be near together, and each cut should be 2 or 3 inches long. Spray the wounds with hydrogen peroxid by means of a atomizer, wash with a solution of acetate of aluminum (2 per cent.), and pack each wound with iodoform gauze. Dress with many layers of gauze wet with a hot solution of acetate of aluminum (2 per cent.). The gauze is covered with a rubber-dam and a hot-water bag is laid upon the dressing. If sloughs form, cut them away and employ hot antiseptic fomentations. Change the dressings often. In some cases it may be necessary to employ continuous irrigation with warm antiseptic fluid, or continuous immersion in a hot aseptic or antiseptic bath. It is not unusually necessary to operate for the removal of enlarged lymphatic glands. The Bier treatment is a valuable addition to our resources. In rare cases amputation is demanded. When granulations begin to form, treat as a healing wound. The constitutional treatment is that previously set forth as applicable to septicemia, viz., purgation, the use of diuretics and diaphoretics, the administration of strychnin, quinin, digitalis, alcoholic stimulants, and nourishing food. In severe cases employ hypodermoclysis or saline infusion into a vein. Antistreptococcic serum may be employed.

Cellulitis (Fig. 100) is a microbic inflammation of the cellular tissue. It may be due to staphylococci, to streptococci, to other pyogenic bacteria, or to mixed infection with two varieties of pyogenic organisms. The commonest form is streptococcic infection, and this is a variety of erysipelas. A streptococcic infection may be followed and replaced by a staphylococcic infection. Infection with the *Bacillus aërogenes capsulatus* causes *gangrenous cellulitis*. Cellulitis is prone to arise in damaged tissues, for instance, in a crushed part, a limb the seat of a compound fracture, or tissue containing extravasated urine. In tissue the resistance of which has been lessened by diabetes, Bright's disease, irritating discharges, or trophic lesions, cellulitis is rather apt to develop. In cellulitis of the subcutaneous tissue the micro-organisms find entrance by means of a wound. Swelling precedes redness.

The swelling is not so marked as in phlegmonous erysipelas, and the redness is darker and is less distinct than in cutaneous erysipelas. The redness of cellulitis is about the wound; it spreads, but does not fade at the center as does ordinary erysipelas; red lines due to lymphangitis ascend the limb from the infected wound, and the anatomically associated lymphatic glands enlarge. In the wound and its neighborhood there is severe throbbing pain. The constitutional symptoms of infection develop rapidly. In trivial cases the lymphatics dispose of the poison and suppuration does not occur. In severe cases pus forms about the wound and lymphatic glands may suppurate. In staphylococcic infection pus is thick, in pure streptococcic infection it is thin. Phlegmonous erysipelas may develop, and septicemia or pyemia may arise.

Treatment.—Open, disinfect, and drain the wound. Paint iodin upon the skin over inflamed lymphatic vessels and glands and cover with ichthyol ointment, or rub Credé's soluble silver ointment into the skin over the inflamed lymph-glands and vessels. Dress the wound and the adjacent inflamed area

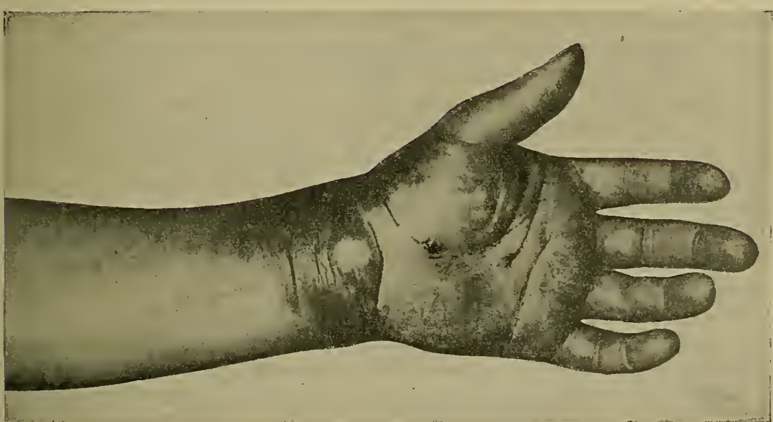

Fig. 100.—Acute cellulitis of palm and forearm following a slight wound.

with hot antiseptic fomentations. Secure rest of the part. It may be necessary to make incisions as in phlegmonous erysipelas. In some cases it is necessary to remove breaking-down glands. The constitutional treatment is that employed for septicemia.

XII. TETANUS, OR LOCKJAW

Tetanus is a microbic disease invariably preceded by some injury and characterized by spasm of the voluntary muscles. The wound may have been severe, it may have been so slight as to have attracted no attention, it may have been inflicted upon the alimentary canal by a fish-bone or other foreign body, or may have been situated in the nose, urethra, rectum, vagina, or ear. It is possible that infection can occur through a mere abrasion of a mucous membrane. Sir David Semple has recently sought to demonstrate that tetanus does not of necessity depend on spores or bacilli introduced at the time of the injury. He believes that spores may be taken up from the intestine and deposited from the blood in the anaërobic area created by a wound or contusion ("Lancet," May 20, 1911, March 9, 1912). As yet this view lacks general acceptance. It has long been taught that so-called idiopathic tetanus is

either not tetanus at all, or the term expresses the fact that we have not found the traces of an injury which did exist. Sir David Semple maintains that spores may enter into trivial wounds and remain in the healed area for months, to possibly become active as a result of exposure to great heat or cold, to fatigue, or to bruising of the part. Semple's view would explain so-called idiopathic tetanus (see "Lancet," May 20, 1911). Tetanus arises most frequently after punctured and particularly after lacerated wounds of the hands or feet. In a surgical experience of over twenty-five years in connection with the Philadelphia Fire Department I have known hundreds of firemen to injure their feet by stepping on nails and not one developed tetanus. In fact, the only case of tetanus among them since 1871 arose in a man who lacerated his hand with glass. Before tetanus appears a wound is apt to suppurate or slough; but in some instances the wound is found soundly healed when the tetanus begins. The toy pistol produces a peculiarly dangerous wound. In the United States many cases of tetanus follow the celebration of the Fourth of July, a large percentage of the causative wounds being from the toy pistol. The Fourth of July, 1903, was responsible for 466 reported and no one knows for how many unreported cases in the United States. Since that date the prophylactic use of antitetanic serum has become the rule of practice in suspected injuries and there has been a notable diminution in the number of cases. In 1909 there were 150 cases; in 1910 there were 72 cases; in 1911 there were 18 cases; in 1912 there were only 7 cases ("Jour. Amer. Med. Assoc.," Sept. 7, 1912). Of the 7 cases, 6 died (86 per cent.). The fact that the bacillus of tetanus is anaërobic explains the comparative frequency with which punctured and lacerated wounds are attacked, for in such wounds the bacilli are deeply lodged in recesses or cavities into which air does not penetrate or are covered with discharges which exclude air. Suppuration favors the growth of tetanus bacilli because the pyogenic organisms consume oxygen. Occasionally, though fortunately very rarely, tetanus follows vaccination. It is essential that vaccine virus should be carefully selected and prepared. When care is taken, the operation is absolutely safe. When tetanus follows vaccination, it arises from infection of the wound either at the time of vaccination or, as is far more common, at a later period from scratching or some other fouling. The tetanus organism is not introduced in the vaccine, but obtains entrance during or subsequent to the operation of vaccination, because of utter neglect of the vaccine lesion and in consequence of the accumulation of filth upon and about it. In no reported case have the symptoms of tetanus appeared earlier than two weeks after vaccination (Wm N. Welch, "N. Y. Med. Jour.," Jan. 16, 1909). The organisms or its spores have never been discovered in tubes or in points, and, as Rosenau points out, the organism cannot grow and cannot form toxins on dry points or in glycerinated virus. The most scrupulous care is taken to prevent contamination of vaccine virus, and it is examined for tetanus toxin and tetanus bacilli before it is placed on the market. Tetanus has followed the injection of gelatin. Commercial gelatin often contains the bacilli and should never be used without careful fractional sterilization (see page 422). Roberts reports a case of fatal tetanus in a patient with chronic ulcer of the leg ("Lancet," vol. i, 1912). Evler infected himself while operating on a case of tetanus ("Berliner klin. Wochenschr.," Sept., 12, 1910). Tetanus has followed a burn, a frost-bite, a hypodermatic injection of quinin, child-birth, abortion, and the use in a wound of contaminated catgut. Most cases of postoperative tetanus depend upon infected catgut. The disease sometimes arises when no catgut is used (J. B. Smith's case, "Brit. Med. Jour.," May 6, 1911). Cases have arisen from such trivial operations as ligation of piles and hypodermatic injection of quinin. Peterson ("Jour. Am. Med. Assoc.," Jan. 8, 1910) collected 49 cases of postoperative tetanus reported since 1890. In 40 the peritoneal cavity had

been opened. In only 18 cases suture material was named (catgut, 3; catgut and kangaroo-tendon, 2; catgut with other material, 7; silk, 4; silk and silk-worm-gut, 1; silk and silver wire, 1). No case appeared before the fourth day, most on the ninth day. Drainage should tend to prevent it. Tetanus may appear within twenty-four hours after an accident, but it may not arise until many days or even several weeks have elapsed. Rose reported a case which began within twenty-four hours. Kuhn ("Berliner klinische Wochensch.," 1901) reports a fatal case of tetanus beginning twelve hours after an injection of gelatin. Such a rapid case could only be due to the gelatin having contained a large quantity of tetanus toxin (Schuckmann). Samuel D. Gross, in his "System of Surgery," speaks of 1 case occurring in a man five weeks after injury, and another in a girl four weeks after injury. Jacobson and Pease are of the opinion that "such cases as have been recorded with periods of incubation under three days must be accepted with considerable reserve" ("Annals of Surgery," Sept., 1906). Tetanus prevails more in certain localities than in others, but it is met with all over the world from the Arctic Zone to the Tropics, and may arise in either sex, in any race, and at any age. Colored people are very susceptible, and the disease may exist endemically, and does so in certain portions of New Jersey and of Cuba. In our country the greatest prevalence, according to Anders, is in Pennsylvania, northern New York, Long Island, Virginia, Georgia, and Louisiana. Anders collected 1201 cases and Pennsylvania stands first on his list with 224 cases ("Jour. Am. Med. Assoc.," July 29, 1905). It is stated that in certain districts of Nigeria the soil contains so many tetanus spores that the natives poison their arrows by sticking them into the ground (Allan C. Parsons, in "Brit. Med. Jour.," Jan. 23, 1909). Tetanus is due to the growth in a wound of a bacillus which was first described by Nicolaier and was first cultivated by Kitasato. It is the most widely distributed of all the pathogenic bacteria. It is very difficult to cultivate and cannot be cultivated at all unless air is absolutely excluded. Tetanus bacilli or their spores are found particularly in garden soil, in the dust of walls, walks and cellars, in street dirt, and in the refuse of stables. There is much suggestive evidence that virulent tetanus bacilli come from the intestinal canal of animals; that the bacteria lose their virulence when they have been long outside of the intestinal canal; and that the highest degree of virulence is obtained by those which have passed frequently through intestinal canals. The above view is known as the fecal theory and is strongly advocated by Somani.[1]

It is taught that in tetanus the bacilli do not enter into the blood, and toxic products produced by them are not directly absorbed by the blood or lymph. Porter and Richardson ("Boston Med. and Surg. Jour.," Dec. 23, 1909) in 2 cases obtained cultures of the bacilli from lymph-glands which received drainage from the wound region. This is a highly important observation. The toxic products alone without any bacteria enter the muscular end organs of motor nerves, ascend within the nerves, and reach the spinal cord and medulla (Brunner, Marie), become fixed in the nerve-cells of the spinal cord and medulla, and produce the symptoms of the disease. Metschnikoff found tetanus toxin in the cord. Emulsion made from the region of the masticatory nuclei of the floor of the fourth ventricle is peculiarly rich in highly potent toxin (Trosier and Georges Roux, quoted in "Lancet," Jan. 15, 1910). Tetanus is an intoxication and not an infection, and a drop of blood of an animal with tetanus, if injected into another animal, will not produce the disease. Tetanus toxin poisons the nervous system as would strychnin or some other vegetable alkaloid. It is probably the most powerful of known poisons. It has been estimated that $\frac{1}{278}$ gr. is sufficient to kill an adult weighing 165 lbs. ("American Medi-

[1] "Verhandl. d. X internat. med. Cong.," Berlin, 1890, Bd. v, Abth 15, p. 152.

cine," Nov. 30, 1901). The great power of the poison is shown by the report of Dr. Nicholas's case ("Comptes rendu de la Société de Biologie," 1893). Dr. Nicholas had been using a syringe to inject filtered cultures of the bacilli of tetanus and he accidentally pricked his finger with the needle. In four days tetanus began, and he barely escaped with his life in spite of the fact that the fluid was free of bacteria and the dose of toxin was extremely minute. The nature of the virulent poison which is produced at the seat of inoculation is uncertain. Some believe it to be alkaloidal, like the vegetable alkaloids; some, that it is a toxalbumin; others maintain that it is an enzyme or ferment (Nocard, Courmont, and others). In a very few instances the injection of perfectly sterile antidiphtheritic serum into human beings has caused death with all the symptoms of tetanus. The serum must have been obtained from horses in whom tetanus was incubating, and the blood-serum injected must have contained a fatal dose of tetanus toxin. In tetanus an ascending neuritis occasionally, though seldom, exists in the peripheral nerve near the lesion. The toxin is carried to the cord by the motor nerves only, and it is not only absorbed by the lymph-channels of the nerve, but ascends along the axis-cylinders of the nerve itself and reaches the motor cells of the spinal cord (Meyer and Ransom, in "Arch. exper. Path. u. Pharmakol.," 1903). On reaching the cord it attacks the motor nerve-cells, producing changes similar to those produced by certain infections, and ascends in the motor tracts of the cord to the medullary nerve-centers. While toxin is ascending the axis-cylinders a certain amount is taken up by the lymphatics, enters the blood, and reaches the spinal cord by other nerve-fibers (Jacobson and Pease, in "Annals of Surgery," Sept., 1906). The essential basis of tetanus is spreading irritation of the motor portion of the spinal cord accompanied by extreme reflex excitability which is due to poisoning of sensory neurones (Meyer and Ransom). The irritation of the motor cord produces tonic contraction of the muscles; the excitation of the sensory neurones is responsible for clonic convulsions. There are no instances on record of second attacks of lockjaw, but it is not believed that one attack confers any prolonged immunity.

Local Tetanus.—In some cases local symptoms precede widespread evidences of tetanus. Experimental tetanus in animals "exhibits almost without exception as its earliest manifestations those of a purely local character and which are at first restricted to the neighborhood of the inoculation. This is now understood to be due to the absorption of the toxin by the motor nerve of the part. The conditions favoring the local appearance of tetanus are a short motor nerve, as in head injuries; an injury to a nerve-trunk permitting the rapid absorption of a large amount of toxin; the production of a meager amount of toxin or the presence of something which prevents the admission of a large amount of toxin into the circulation (Nathan Jacobson and Herbert D. Pease, Ibid.). Cases with local symptoms in the beginning are apt to have had long periods of incubation, are apt to be cured, and usually endure a considerable time.

Mortality.—It is a very fatal disease. Acute tetanus has a mortality of from 75 to 90 per cent.; chronic tetanus, from 40 to 50 per cent.; postoperative tetanus, of over 85 per cent. (Peterson's estimate in "Jour. Am. Med. Assoc.," Jan. 8, 1910).

Local tetanus is apt to terminate in recovery. Tetanus produces death by overwhelming the patient with toxin by exhaustion resulting from repeated convulsions, by spasm of the glottis, or fixation of the respiratory muscles.

Symptoms.—**Acute tetanus** begins within ten days of an accident. The usual period of incubation is from three to five days. Evler had the rare and dreadful experience of contracting the disease from a victim of tetanus on whom

he was operating, and the extreme good fortune to recover. He reports his own case and says that various short and transient early symptoms occur which the patient is apt to attribute to the healing wound. Among these he mentions restlessness, sleeplessness, bad dreams, oppression of breathing, frequent and difficult micturition, headache, fatigue, vertigo, chilliness, darting pains in various regions, and perhaps pains about the injured part. If an extremity is the seat of wound, it may swell and remain swollen even when elevated, and it feels hot, but is not discolored. Before long the wound becomes tender and glands often swell. There may be painless contractions and tremors of injured extremity. Single groups of muscles may undergo tonic contraction ("Berliner klin. Wochensch.," Sept. 12, 1910). In most cases of tetanus the first symptom noted by the patient is stiffness of the jaw on opening the mouth. In some cases the first symptom is stiffness of the neck, and the patient believes he has "caught cold." In any case the neck soon becomes stiff, and finally both the neck and jaw become as rigid almost as iron. The fixation of the jaw is called *trismus*. The muscles of deglutition become rigid on attempts at swallowing. The muscles of the back, legs, and abdomen are thrown into tonic spasm, but the arms rarely suffer. If the infected injury is on the hand or foot, that extremity usually is found to be rigid. Spasm of the face muscles causes the *risus sardonicus*, or sardonic smile (contraction particularly of the *musculus sardonicus* of Santorini). The contraction of the muscles of the back is often so powerful as to bend the patient into a curve like a bow and allow him to rest only on his occiput and heels. This condition is known as *opisthotonos*. If he is bent forward, so that the face is drawn to the legs, it is called *emprosthotonos*. If his body is curved sideways, it is designated *pleurosthotonos*. An upright position is *orthotonos*. The spasm may be so violent as to cause muscular rupture.

The characteristic condition in tetanus is one of widely diffused tonic spasm, aggravated frequently by clonic spasms arising from peripheral irritations. These irritations may be drafts, sounds, lights, shaking of the bed, attempts at swallowing, contact of the bed-clothing, the presence of urine in the bladder or of feces in the rectum, or various visceral actions. The clonic spasms begin early in the case and become more frequent and more violent as the disease progresses. The muscles become more rigid and the attitude produced by the tonic contraction of the muscles is temporarily exaggerated. The forcible contraction of the jaw may loosen or break teeth. The spasms of the diaphragm, of the glottis, and of the muscles of respiration may produce death and always produce great dyspnea. The man laboring under a tetanic convulsion presents a dreadful picture; he is bent into some unnatural attitude, the face is cyanotic and wet with drops of sweat, the lips are covered with froth which is often bloody, the eyes bulge and are suffused, and the countenance expresses deadly terror and suffering. The agonizing "girdle pain" so often met with is due to spasm of the diaphragm. Each clonic spasm causes a hideous scream by the constriction of the chest forcing air through a contracted glottis. During the progress of the disease constipation is persistent, and retention of urine is the rule (because of sphincter spasm). The mind is almost invariably entirely clear until near the end—one of the worst elements of the disease. There is obstinate insomnia. Headache is common. Hearing, at first hyperacute, is later impaired. Deafness may arise. Pulse is slow and full, with high tension. In very rare cases delirium arises. I have seen it twice, due, I fancy, in each case to the drugs employed. It might, of course, be due to previous alcoholism. Swallowing in many cases is impossible. Talking is very difficult and it is impossible to project the tongue. The muscles throughout the body feel very sore. The temperature may be normal, but it is usually a little elevated, and always arises just before death. Hyper-

pyrexia sometimes occurs (108°–110° F.), and the temperature may even ascend for a time after death. An injection of serum raises the temperature several degrees. In about 80 or 85 per cent. of cases of acute tetanus death occurs within five days, and many of these patients die within two or three days. Very few puerperal cases recover and practically no cases which follow abortion recover. Of late years the mortality in acute tetanus has slightly diminished. If a patient lives a week, his chance of recovery is good. Death may be due to exhaustion or to carbonic-acid narcosis from spasm of the glottis or fixation of the respiratory muscles.

Chronic tetanus comes on late after a wound (from ten days to several weeks). The symptoms are not so severe as in acute tetanus. The muscular spasm is widespread, but it may not be persistent, intervals of relaxation permitting sleep and the taking of food. Chronic tetanus long had a mortality of 40 or 50 per cent., but modern methods of treatment, it has been claimed, have considerably reduced it. According to the report of Jacobson and Pease it is still from 35 to 50 per cent. ("Annals of Surgery," Sept., 1906). The disease may last for some weeks.

Trismus neonatorum, or *trismus nascentium*, the lockjaw of the newborn, is due to infection of the stump of the umbilical cord, and is practically invariably fatal. *Hydrophobic tetanus*, *head tetanus*, or *cephalic tetanus* is a condition in which the spasms are confined chiefly to the face, pharynx, and neck, although the abdominal muscles are usually also rigid, and in which there is palsy of the seventh nerve. It follows head injuries, and gives a better prognosis than does general tetanus.

Two other forms of tetanus have been produced in animals by experimenters. One is *cerebral tetanus*, produced by injecting tetanus toxin into the brain and characterized by mental symptoms (Roux and Borrell, in "Annals Inst. Pasteur," July, 1897). Another is *tetanus dolorosa*, produced by injecting toxin into the posterior roots of the spinal nerves, and characterized by violent spasms of pain without motor symptoms.

Diagnosis.—Tetanus may be confounded with strychnin-poisoning, with hysteria, with tetany, or with hydrophobia. Wood's table (see page 209) makes the diagnosis clear between tetanus, strychnin-poisoning, and hysteria.[1]

Tetany is distinguished from tetanus by the milder nature of the spasms, by the greater limitation of the rigidity, by the fact that spasms begin in the hands or feet, not in the jaw and neck, and in most cases by periods of distinct intermittence.

In hydrophobia tonic spasm does not exist, and if clonic spasms occur they are secondary to suffocative attacks.

Treatment.—Far better even than to treat tetanus well is to prevent it. Careful antisepsis will banish it as a sequence of surgical operations as thoroughly as it has banished septicemia. Every infected wound must be disinfected with the most scrupulous care. Every punctured wound is to be incised to its depths and thoroughly cleaned and drained. In a very suspicious wound, such as a Fourth of July injury or a wound from a dung fork, or the entrance into the tissues of a splinter from a stable floor, after the removal of foreign bodies and thorough antiseptic cleansing, dust the wound with antitoxin powder or, better, give hypodermatically 2000 or 3000 units of antitetanus serum. It seems reasonably certain that tetanus antitoxin has prophylactic power; in fact, Jacobson and Pease say that "as a prophylactive measure it merits our fullest confidence" (Loc. cit.). Obviously, this cannot be done for every wound. The procedure is not a certain preventive. Reynier injected antitoxin into a patient on whom he was about to operate because

[1] "Nervous Diseases," by Prof. H. C. Wood.

Tetanus.	Hysteric Tetanus.	Strychnin-poisoning.
	Commences with blindness and weakness.	Begins with exhilaration and restlessness, the special senses being usually much sharpened. Dimness of vision may in some cases be manifested later, after the development of other symptoms, but even then it is rare.
Muscular symptoms usually commence with pain and stiffness in the back of the neck, sometimes with slight muscular twitching; comes on gradually. Jaw one of the earliest parts affected; rigidly and persistently set.	Muscular symptoms commence with rigidity of the neck, which creeps over the body, affecting the extremities last. Jaws rigidly set before a convulsion, and remain so between the paroxysms.	Muscular symptoms develop very rapidly, commencing in the extremities, or the convulsion when the dose is large seizes the whole body simultaneously. Jaw the last part of the body to be affected; its muscles relax first, and even when, during a severe convulsion, it is set, it drops as soon as the latter ceases.
Persistent muscular rigidity very generally, with a greater or less degree of permanent opisthotonos, emprosthotonos, pleurosthotonos, or orthotonos.	Persistent opisthotonos and intense rigidity between the convulsions and after the convulsions have ceased, the opisthotonos and intense rigidity lasting for hours.	Muscular relaxation (rarely a slight rigidity) between the convulsions, the patient being exhausted and sweating. If recovery occurs, the convulsions gradually cease, leaving merely muscular soreness, and sometimes stiffness like that felt after violent exercise.
Consciousness preserved until near death, as in strychnin-poisoning.	Consciousness lost as the second convulsion comes on, and lost with every other convulsion, the disturbance of consciousness and motility being simultaneous.	Consciousness always preserved during convulsions, except when the latter become so intense that death is imminent from suffocation, in which case sometimes the patient becomes insensible from asphyxia, which comes on during the latter part of a convulsion and is almost a certain precursor of death.
Drafts, loud noises, etc., produce convulsions, as in strychnin-poisoning; may complain bitterly of pain.	Crying spells alternating with convulsions.	The "slightest breath of air" produces convulsion. Patient may scream with pain or may express great apprehension, but "crying spells" would appear to be impossible.
Eyes open and rigidly fixed during the convulsion.	Eyes closed.	Eyes stretched wide open.
	Partial spasm in the leg, producing in Wood's cases crossing of the feet and inversion of the toes. If all the muscles were involved, eversion would occur, as the muscles of eversion are the stronger.	Legs stiffly extended with feet everted, as the spasms affect all the muscles of the leg.

there was a case of tetanus in the wards, and yet this man developed tetanus ("Gaz. des Hôpiteaux," July 16, 1901). Thirty light cases have been reported in which prophylactic injections failed to prevent the disease. When in spite of such injections the disease does arise, it is apt to be mitigated in violence. Nevertheless it is sure that animals can be rendered immune to tetanus, and the prophylactic power of antitoxin is warmly advocated by many eminent men. It is extensively and most successfully used by veterinarians to prevent tetanus after castration of horses, and this success is a guide-post to us. The following table is most suggestive (quoted by Heineck in "Surgery, Gynecology, and Obstetrics," Jan., 1909, from Scherck's article in "Jour. Am.

Med. Assoc.," 1906, vol. xlvii, p. 500). It sets forth the Fourth of July injuries treated in St. Louis dispensaries:

Years.	No. of cases.	Antitetanic serum as a preventive.	Death from tetanus.
1903	56	no	16
1904	37	yes	none
1905	84	yes	none
1906	170	yes	none

Puerperal tetanus is prevented by antiseptic midwifery, and tetanus neonatorum by the antiseptic treatment of the stump of the cord. In order to obviate all danger of the development of tetanus after vaccination perform the little operation with cleanliness and care properly for the wound and for the pustule. The skin should be cleansed with soap and water, rubbed with alcohol, and washed with boiled water. It should be gently scraped with a knife (which has been boiled) until serum exudes. The virus, taken from a hermetically sealed tube, is applied to the raw surface and allowed to remain exposed to the air until dry. A piece of sterile gauze is laid over the part and is held in place by a bandage. This dressing is changed as may be necessary, and is used until granulation begins, at which time the use of any simple ointment is admissible. Do not apply a shield. The evil of shields is pointed out by Robert N. Willson ("American Medicine," Dec. 7, 1901).

When tetanus exists, always look for a wound, and if one is found, open it; if there are sloughs, cut them away, wash the wound with peroxid of hydrogen and then with hot normal salt solution, dry the wound with gauze, paint the surfaces of the wound with bromin, and secure drainage by packing with iodoform gauze. Dennis disinfects the wound with a solution of trichlorid of iodin (0.5 per cent.).

Surgeons of a former day were accustomed to amputate for tetanus if the wound was upon an extremity. When we reflect that the poison-producers are in the wound and not in the circulation, it seems a reasonable treatment. As a matter of fact, it never does any good, because, when the symptoms begin, the toxin has already entered into the nerve-cells and become fixed. Kitasato has shown that if a mouse is inoculated with tetanus near the root of the tail, excision of the tail and cauterization of the stump will not prevent tetanus unless it is performed within one hour of the inoculation. Nocard inoculated sheep near the root of the tail with tetanus spores, and although the moment symptoms appeared he amputated well above the point of inoculation, the animals died of the disease. We must regard amputation as a useless method of treatment. The cases of Porter and Richardson in which bacilli were found in adjacent glands suggest the wisdom of removing any enlarged glands which chould have received lymph from the wound.

Keep the sufferer from tetanus in a darkened, well-ventilated, and quiet apartment, so as to exclude as far as possible peripheral irritation. Watch for the occurrence of retention of urine, and use the catheter if necessary. Secure movements of the bowels by administering salines, castor oil, croton oil, or enemas. Stimulate freely with alcohol, and give fluids by hypodermoclysis. Give plenty of concentrated liquid food unless swallowing causes convulsions, then feed by the rectum. If swallowing causes convulsions some surgeons give an inhalation of nitrite of amyl before an attempt is made to swallow. If this treatment does not make swallowing possible, then partially anesthetize the patient and feed him by means of a pharyngeal tube passed through the nose. It may become necessary to abandon mouth feeding. Large doses of the bromid of potassium, or of this drug with chloral, give the best results, as far as drug treatment is capable of giving results. If bromid is used, give about 1 dr. every four to six hours. Chloretone has warm advocates.

It is given in large doses. It abates rigidity and diminishes the number and severity of clonic convulsions. Other drugs that have been used with some success are gelsemium, morphin, curare, infections and fomentations of tobacco, physostigmin, anesthetics, cocain, and cannabis indica. An ice-bag to the spine somewhat relieves the girdle pain. Hot baths have been advised. It is said that venesection followed by the intravenous infusion of saline fluid does good. This procedure is followed by a free flow of urine and by lessening of the number of the paroxysms. It may be repeated several times during a few days (E. J. McOscar, in "American Medicine," Sept. 14, 1901; A. V. Moschcowitz, in "Med. News," Oct. 13, 1900).

Yandell says, in summing up Cowling's report on tetanus:[1] "Recoveries from traumatic tetanus have been usually in cases in which the disease occurs subsequent to nine days after the injury. When the symptoms last fourteen days recovery is the rule, apparently independent of treatment. The true test of a remedy is its influence on the history of the disease. Does it cure cases in which the disease has set in previous to the ninth day? Does it fail in cases whose duration exceeds fourteen days? No agent tried by these tests has yet established its claim as a true remedy for tetanus."[2]

It is now claimed by some observers that we have a remedy which fulfils the requirements of Yandell in the tetanus antitoxin serum. Behring's serum is said to be six times as strong as Tizzoni's, but it is difficult or impossible to estimate the exact power of either. Behring and Kitasato succeeded in immunizing animals, and Tizzoni and Cattani assert that the antitoxin is an enzyme. The antitoxin destroys the activity of the toxin and is obtained from an immunized horse.

If injected subcutaneously it is absorbed very slowly, and even twenty-four hours or more after such an injection a considerable amount remains unabsorbed in the tissues. It is not absorbed at all by the nervous structures. It is eliminated rapidly and unaltered in the urine, feces, and sweat. It seems to be harmless and its immunizing powers are certain. Its curative power is very much less certain. Hypodermatic injections are practically useless. Intravenous injections are of more service, but even then the antitoxin only grasps the toxin in the blood and fails to reach that in the nerves, nerve-cells, and nerve-tracts. Some practise intramuscular injections, but 7 acute cases so treated died, a mortality of 100 per cent. (Jacobson and Pease, "Annals of Surgery," Sept., 1906). Injection into the theca of the cord (intraspinal injection) by means of lumbar puncture is an attractive method, but the inability of nerve-elements to absorb antitoxins when the pia intervenes is an argument against it, though in 1 violent acute case of my own, occurring in a boy, recovery followed this method. In 7 acute cases treated by this method the mortality was 57.1 per cent. (Jacobson and Pease, Ibid.). John Rodgers injected antitoxin into the cauda equina and nerves and apparently hopeless cases recovered ("Med. Record," July 2, 1904). Injection into a nerve (intraneural injection) is a more rational method, but even this plan is only of service in localized tetanus, the main nerve about the part tetanized being injected (Küster, in German Surgical Congress of 1905). However antitoxin is given, the dose must be large if any good is to be done. Serum is usually prepared as follows: A horse is injected repeatedly with the toxins obtained from cultures of tetanus bacilli, the strength of the injections being gradually increased. Eventually the animal becomes immune to tetanus. Some days after the final injection a cannula is placed in the jugular vein of the immunized animal, blood is drawn into a sterile vessel and is permitted to coagulate during twenty-four hours, and at the end

[1] "American Practitioner," Sept., 1870.
[2] Quoted by Hammond, in his "Diseases of the Nervous System."

of this period the serum is separated from the clot, is evaporated to dryness in a vacuum over sulphuric acid, and the powder is placed in hermetically sealed glass tubes. In order to use the serum, dissolve the powder in sterile water, in the proportion of 1 gm. to 10 c.c. The fluid serum sold in the shops bears this proportion to the powder. The serum can be given subcutaneously or intravenously, or can be injected into the brain or under the cerebral dura or the spinal arachnoid, or into a nerve. If used subcutaneously, from 20 to 30 c.c. of the fluid serum should be injected into the abdominal wall, and this dose should be given every six or eight hours until there is improvement. Then from 5 to 10 c.c. should be given every six or eight hours. As the symptoms abate the dose is lessened and the intervals between the doses are increased. In a violent cases of tetanus the first dose should consist of 40 to 50 c.c., and this can be repeated in four or five hours. In a case of tetanus which recovered, reported by Mixter, enormous doses were given. This patient received in the aggregate 3400 c.c. of serum, or 285 c.c. a day.[1] In 47 acute cases treated by subcutaneous injection the mortality was 82.6 per cent. In 30 acute cases treated by a combination of either subcutaneous, intraspinal, intravenous, or intracranial injections the mortality was 93.1 per cent. (Jacobson and Pease, in "Annals of Surgery," Sept., 1906). Roux and Borrel maintain that the toxins of tetanus pass from the blood into nervous tissue and are fixed in the nerve-cells. As the antitoxin when given hypodermatically or intravenously remains in the blood, it can only antidote the poison in the blood and not that in the nerve-cells. These observers advise that the antitoxin be placed where the toxins are active—that is, that it be thrown into the cerebrum (intracerebral injections). The skull is trephined or opened with a small drill, a blunt needle is passed to the depth of 1½ inches into the frontal lobe, and the serum is slowly injected. Abbe follows Kocher; uses a local anesthetic and bores a very small hole through the skull midway between the outer angle of the orbit and the middle of a line running across the head from one external auditory meatus to the other. The serum should be concentrated. One gram of dry antitoxin is dissolved in 5 c.c. of water, and this amount is the proper dose. The opposite frontal lobe should also be injected either at once or the next day. Even when serum has been injected into the cerebrum it should also be given subcutaneously. Abbe employed intracerebral injection in 5 severe cases and 3 of them recovered. He is a strong believer in the method (Ibid.). Moschcowitz has collected 38 cases so treated and claims that one-half of them recovered. Cerebral abscess followed in 1 case ("Med. News," Oct. 13, 1900). Tuffier has reported a successful case in which he injected 10 c.c. of serum into each frontal lobe ("Gaz. heb. de Med. et Chir.," July 4, 1901). The method has of late been practically abandoned in spite of the early favorable reports.

The value of the tetanus antitoxin in acute tetanus is more than doubtful. In the Russo-Japanese War its use was abandoned, and d'Autma found it of no value in the tetanus cases which followed the Italian earthquakes of 1908. A serum injection in tetanus raises the temperature and may cause depression of the circulation, severe headache, vomiting, diarrhea, perhaps, in very rare cases, death. Under its use the mortality from acute tetanus is said to fall from nearly 90 to 75 per cent., but the figures above given do not sustain this contention. Neither do the figures indicate that the mortality in chronic tetanus has been greatly influenced by it.

Kitasato has shown that injections of iodoform render animals immune, and Sonnani has maintained that this drug placed in a wound prevents the disease. If antitoxin is not obtainable, give hypodermatic injections of iodoform, 3 to 5 gr. *t. i. d.*

[1] "Boston Med. and Surg. Jour.," Oct. 6, 1898.

Bacelli's treatment was introduced by Bacelli, of Rome, in 1892. It consists in the hypodermatic injection of carbolic acid, which is thought to grasp tetanus toxin and mitigate its virulence or even make it inert. The drug is also thought to be sedative and to lower temperature. Tetanus toxin is destroyed by carbolic acid (shown by Tizzoni and Cattani in 1890). Kitasato pointed out in 1891 that cultures of tetanus bacilli can be rendered sterile in thirty minutes by a 5 per cent. solution of carbolic acid. The usual dose is 15 minims of a 3 per cent. solution every two hours. Three times this amount can be given in a day. To avoid irritation Maragliano uses a 5 per cent. solution in sterile olive oil. Favorable results are claimed for the plan. Bacelli has collected 190 cases (all severe or very severe). There were 94 severe cases and 92 recovered ($2\frac{1}{2}$ per cent. mortality). There were 38 very severe cases and 22 recovered (see Bacelli, in "Berliner klinische Wochenschrift," June 5, 1911). Even the occurrence of carboluria does not cause the surgeon to suspend the treatment. These results are the best ever given in tetanus and will cause us to try the treatment.

The hypodermatic injection of an emulsion of fresh brain-matter has been advocated on the ground that brain-matter and tetanus toxin have a mutual affinity (Krokiewicz). The results are not conclusive

Mathews reports cure in 2 cases following the very gradual introduction into a vein of a solution containing sodium chlorid, sodium citrate, sodium sulphate, and chlorid of calcium ("Jour. Am. Med. Assoc.," August 29, 1903). Cure of acute tetanus has followed the intraspinal injection of a solution of magnesium sulphate, which drug, Meltzer has shown, strongly stimulates inhibition. Blake has reported such a case ("Jour. of Surgery, Gynecology, and Obstetrics," May, 1906). If magnesium sulphate is used, 2 c.c. of a 25 per cent. solution are injected into the subarachnoid space of the cord, after first removing an equal quantity of cerebrospinal fluid. Some hours after such an injection there is marked muscular relaxation lasting a number of hours. Not unusually there is lowering of respiratory rate. When the improvement ceases another dose is given. Heinecke (Ibid.) reports a successful case and collects 12 other cases so treated, 7 of which died. Smithson used this drug and, although the patient died, there was not a convulsion after the injection.

Murphy reports the recovery of a case after spinal puncture and injection of morphin and eucain into the theca of the cord ("Jour. Am. Med. Assoc.," August 13, 1904). The only case of acute tetanus I have ever had recover was treated by intraspinal injection of antitoxin. I have known 3 cases of chronic tetanus to recover: 1 was treated by chloral and bromid only, 2 were treated by chloral and bromid and antitoxin subcutaneously.

XIII. SURGICAL TUBERCULOSIS

Tuberculosis is an infective disease due to the deposition and multiplication of tubercle bacilli in the tissues of the body. The term *surgical tuberculosis* is applied to all of those numerous tuberculous lesions that may demand surgical treatment. Such lesions may exist in different structures, often seem clinically to be strictly localized processes, and in many instances may be extirpated, drained, or sterilized. Among the conditions placed under the heading of surgical tuberculosis are: Tuberculosis of glands, of bones, of joints, and of the skin. These lesions are most common in children, the majority of cases are curable, and they are not so often associated with or followed by pulmonary phthisis as are some other tuberculous lesions. They tend in many cases to remain local and, beyond doubt, a considerable number

of them are due to infection with bovine bacilli. Tuberculosis is characterized either by the formation of tubercles or by widespread cellular proliferation (diffuse tubercle) or by fibrinous exudation, which is very rich in cells. Tuberculous conditions tend to caseation, sclerosis, or ulceration.

A *tubercle* is a non-vascular infective focus, appearing to the unaided vision as a semitransparent gray or yellowish mass the size of a mustard-seed. The microscopic tubercle is the most characteristic evidence of the disease. The microscope shows that a gray tubercle consists of a number of cell-clusters, each cluster constituting a *primitive tubercle.* A typical primitive tubercle shows a center consisting of one or of several polynucleated giant-cells surrounded by a zone of epithelioid cells which are surrounded by an area of leukocytes. When the bacillus obtains a lodgment the fixed connective-tissue cells multiply by karyokinesis, forming a mass of nucleated polygonal or round cells. These cells are connective-tissue cells and are derived particularly from endothelium and are called *epithelioid cells* from their resemblance to epithelial cells. Early in the development of a tubercle blood channels lined with epithelioid cells exist, but continued cell proliferation blocks the channels and at the same time the blood-supply of the growth is further limited by the pressure of proliferating perivascular cells and the proliferation of the endothelial cells of adjacent vessels. Some of the epithelioid cells proliferate, and others attempt to, but fail for want of blood-supply. Those which fail to multiply succeed only in dividing their nuclei and enormously increasing their bulk (giant-cells). Giant-cells, which may also form by a coalescence of epithelioid cells, are not always present. Giant-cells are not certain evidence of tuberculosis, for they occur in syphilitic lesions. The presence of irritant bacterial products induces surrounding inflammation and numbers of leukocytes gather about the epithelioid cells (Fig. 101).

Fig. 101.—Synovial membrane, showing giant-cells (Bowlby).

The bacilli, when found, exist in and about the epithelioid cells, and sometimes in the giant-cells. When bacilli enter the tissues they are often killed. If they enter in large numbers or are peculiarly virulent they induce chronic inflammation, granulation tissue forms, and the cells of the focus often have the characteristic arrangement described above. The bacilli are not pyogenic and suppuration means secondary infection. If mixed infection of any considerable area occurs, the patient is apt to develop fever and to perish from exhaustion, amyloid disease, dissemination, or a terminal infection. In rare cases the tuberculous area is destroyed and cure is brought about. A tuberculous focus tends strongly to degenerative changes because of the local anemia and the presence of bacilli. If numerous active bacilli are present *caseation* takes place. This is coagulation necrosis due to the action of bacteria upon a non-vascular area. It starts at the center of a tuberculous focus and spreads toward the periphery and finally forms masses like cheese. When caseated material is mixed with serum *tuberculous pus* is formed.

A caseated focus may be surrounded or encapsulated by fibrous tissue. When this happens the tuberculous process may remain latent for months or years, perhaps awakening into activity as the result of a traumatism or lowered general resistance. A caseated focus may be cured by growth of fibrous tissue which replaces the tuberculous focus. This is cure by sclerosis. A caseated area may calcify. Even when tuberculous pus forms encapsulation

may occur, the fluid being absorbed, and the remains being surrounded by fibrous tissue. Whenever tubercle bacilli consume all available food they die or remain latent. If they die the granulations are converted into fibrous tissue and the part is healed. If they remain latent they may at any time become again active. Infiltrated tubercle is due to the running together of many minute infective foci, or to widespread infiltration without any formation of foci. Infiltrated tubercle tends strongly to caseate. The description of a tubercle previously given relates to the common *reticulated tubercle.* Two other varieties exist.

The *fibrous tubercle* is much richer in dense connective tissue than is the ordinary tubercle. It forms when bacilli are greatly weakened or killed. When this happens embryonal cells cease to degenerate, and ordinary inflammation results in fibrous tissue formation. Fibrous tubercle is evidence of an effort at cure.

Hyaline tubercle results from hyaline degeneration of the reticulum of an ordinary tubercle and is the early stage of coagulation necrosis.

Knowledge of recent years proves that the bacillus of tubercle may fail to cause the supposed essential lesions outlined above, but may induce instead tissue changes identical with those due to various other organisms. Some of these changes are acute, some are chronic. In some there is hyperemia, in some serous exudation, in some fibrous exudation, in some cellular hyperplasia, perhaps with parenchymatous degeneration, or perhaps with sclerosis causing cirrhosis (Rudolph Matas, in "Southern Med. Jour.," Oct., 1911). Matas says that this group is non-tuberculomatous, atypical, and non-specific.

The Incidence of Tuberculosis.—Tuberculosis is the most widespread of diseases, being particularly common in northern countries, in civilized regions, and in great cities. Both men and domestic animals suffer from it, and it is occasionally met with in captive wild animals. It may even occur in cold-blooded animals. It is rare in savage races and extremely rare in wild animals dwelling under natural conditions.

Many people possess lesions of tuberculosis who present no clinical evidence of it. Careful necropsies, with microscopical studies and observations with the aid of tuberculin, prove this. The greatest death-rate of those infected is in childhood and early adult life (Burkhardt, in 1903, quoted by Hamman and Wolman in their book on "Tuberculin").

How many persons die of tuberculosis is a much debated point. Some writers clain that consumption of the lungs alone kills one-third of all that die; and if the deaths from various other tuberculous lesions are added to this, it will be seen what an enormous part the disease plays in the mortality tables. Many observers hold that one-third of the human race suffer from tuberculosis, and that in every country the remaining two-thirds free from the disease are every moment in danger of acquiring it. Evans has maintained that of the 35,000,000 deaths that occur yearly in the world, 5,000,000 are the result of tuberculosis. Pflügge thinks that one-seventh of the race die of tuberculosis. Sherman G. Bonney, in his work on "Pulmonary Tuberculosis," asserts that "from 85 to 95 per cent. of the human race have been at some period of life the subject of tuberculous infection" and that 1 person in 7 dies of the disease.

This enormous incidence of the disease, however, is disputed by some authorities; notably, by G. Cornet (Nothnagel's "Encyclopedia of Practical Medicine"). This observer states that apparently one-seventh of all deaths result from tuberculosis, and that some pathologists have reported that in one-third of all necropsies tuberculous lesions are found; but that these statistics are obtained from institutions where only the very poor are cared for, and that the percentage of tuberculosis is vastly lower in the better classes of

the community. The exact figures, however, are difficult to determine. It is certain that enormous numbers of people are affected with tuberculosis. I believe many affected ones recover, for Naegeli points out that almost all who perish after thirty from non-tuberculous conditions show healed lesions of tubercle. Of 420 adults, 391 (93 per cent.) showed signs of tuberculosis. Spengler claims that every human adult was at some period of life a host for tubercle bacilli. Bollinger stated that in one-fourth of all postmortems upon adults evidences of tuberculous disease are found at the pulmonary apices. Baumgarten asserts that one corpse out of every three showed a tuberculous focus, latent or healed. Tuberculin tests confirm the views of Burkhardt and Naegeli and contradict the opinions of Cornet. Franz injected 400 recruits who had passed their physical examination for the army and 61 per cent. reacted. Von Behring maintains that all of us are "a little tuberculous" (Jonathan Wright, in "New York Med. Jour.," April 2, 1904). Pflügge maintains that from 50 to 70 per cent. of the human race are predisposed to tuberculous infection, and if infected will die of it unless an intercurrent malady destroys them.

The Bacillus of Tuberculosis.—The tubercle bacillus was discovered by Robert Koch in 1882. It is a little rod with a length about equal to one-half the diameter of a red corpuscle. It is non-motile, does not form spores, and requires oxygen in order to grow, but it may obtain oxygen from body-cells or fluids. Tubercle bacilli exist in all active tuberculous lesions, and the more active the process the greater their numbers. They may not be found in a tuberculous area, having once existed, but having died for want of nourishment. For instance, in a cold abscess they are frequently absent. Bacilli may be destroyed by a secondary infection, for example, by a pyogenic infection. Even when present, tubercle bacilli may be overlooked. Differential staining may exhibit the bacilli. In the material from an active tuberculous lesion, even if bacilli are not found, injection of the tuberculous matter into a guinea-pig will be followed by the production of the disease, and in these lesions bacilli can be demonstrated. Bacilli may be widely distributed throughout the body. It has long been taught that they may occasionally though seldom be demonstrated in the blood in cases of acute miliary tuberculosis. We have discussed the tubercle bacillus on page 52. The bacillus of leprosy, the smegma bacillus, and the tubercle bacillus are similar, but not identical. Each is an acid-fast bacillus; that is, if stained with an anilin color, mineral acids will not wash out the stain. All acid-fast bacilli are capable of producing lesions that, to some extent at least, resemble tuberculous lesions; but the lesions produced by all, except the tubercle bacillus and the leprosy bacillus, tend to recovery. It is possible that all acid-fast bacilli are branches from a common stem.

The tubercle bacilli obtained from different animals differ considerably, both in morphology and in virulence. Koch asserted, in 1901, that the bacilli of human tuberculosis differ radically from those of bovine tuberculosis, that human tuberculosis cannot be given to cattle at all, and that it is so difficult to transfer bovine tuberculosis to the human being that the danger from infected cattle is utterly trivial and may be disregarded. Ravenal and others have positively opposed this view of Koch's, and there have been reported what appear to be undoubted cases of the transference of tuberculosis from animals to man. There is still dispute upon this point, but most writers believe that bovine tuberculosis and human tuberculosis are essentially the same, although the bacilli present temporary differences due to altered environment. The bacilli of bovine tuberculosis are certainly far less dangerous to man than are the bacilli of human tuberculosis, and the bacilli of human tuberculosis are vastly less dangerous to cattle than are the bacilli of bovine tuberculosis. Human bacilli introduced into cattle may produce chronic

lesions, but they are always non-progressive. The histologic lesions seen in man and cattle are identical and so are the degenerative changes, and, as Baumgarten showed, cattle react to tuberculin obtained from human bacilli.

Nocard reports 2 cases of individuals who wounded themselves while cutting the flesh of tuberculous cattle. Both developed generalized lesions and died. Ravenal strongly opposes the view of Koch and maintains that the bacillus of bovine tuberculosis is highly pathogenic for man ("University of Penna. Med. Bull.," xiv, 238, 1901). The same author has reported 4 cases of undoubted inoculation tuberculosis in the hands of veterinarians. Similar cases have been placed on record by other observers. The entire question is one of immense importance. If Koch is right, there is practically no danger to man in eating tuberculous meat or in drinking tuberculous milk. Most observers endorse the words of the report of the British Commission of 1904. This commission positively maintained that bovine tuberculoiss can be communicated to man.

The bacilli of bovine tuberculosis, when they find lodgment in human tissues, are apt to produce local lesions and seldom disseminate, and vice versâ. It has been proved that many cases of tuberculous cervical adenitis in children, but only 3 per cent. of cases in adults, are due to bovine bacilli. Fifty per cent. of cases of abdominal tuberculosis in children and 20 per cent. in adults are due to bovine bacilli. Some bone cases and a considerable number of joint cases in children depend on bovine bacilli, but very few in adults are so caused. Pulmonary tuberculosis very seldom depends upon bovine organisms. It is thus clear that human infection with bovine bacilli is most common in the young, and that surgical tuberculosis is far more apt to have such origin than other forms. Such infections frequently tend to spontaneous cure.

Distribution of the Bacilli.—These bacilli are parasites, and not saprophytes; and the real source of infection is a tuberculous person or animal. Wherever there are tuberculous men or animals the bacilli get into the air. The number that get into the air depends upon the number of animals affected, the seat of the tuberculous lesion in each, the care taken by the victims, and the control exercised by the community.

Tubercle bacilli from an infected individual may get into the atmosphere from the urine, the sputum, the feces, the sweat, the milk, or caseous or purulent material. The bacilli from dried sputum enter the dust, in which, fortunately, they are usually destroyed quickly by the complete dryness, the oxygen of the air, and the sunlight; but under some circumstances they may retain their virulence for weeks or even for months. The infected area itself is usually the direct source of the bacteria from a given case of tuberculosis, but this is not invariably so; for a tuberculous woman with a healthy mammary gland may secrete milk containing tubercle bacilli, a consumptive free from genito-urinary tuberculosis may occasionally pass urine containing bacteria, a cow may give tuberculous milk when the udder is not diseased, and tubercle bacilli may enter the bile of a tuberculous patient. The Third Interim Report of the Royal Commission on Tuberculosis states positively that the milk of tuberculous cows may contain bacilli even when the udder is not diseased. It is probable that flies and insects may transmit infection (Lord, in "Boston Med. and Surg. Jour.," 1904, cli); and it is certain that putrefaction does not surely destroy tubercle bacilli. This is proved by the fact that living bacilli may be passed in the feces of an animal that has been fed on tuberculous meat, and that they may be found in the feces of an individual suffering from intestinal tuberculosis. We are thus justified in concluding that slaughterhouse waste, if improperly disposed of, is a danger to the community.

Routes of Infection.—An individual may acquire tuberculosis by inhaling tuberculous material (*inhalation tuberculosis*), by swallowing tuberculous

material (*ingestion tuberculosis*), and by inoculation with tuberculous material (*inoculation tuberculosis*). Infection of the lungs may be brought about by the inhalation of dried tuberculous sputum or dust carrying tubercle bacilli. Ingestion tuberculosis may follow the eating of tuberculous meat, the drinking of tuberculous milk, or the consumption of uncooked articles on which tubercle bacilli have gathered. It has been shown that the lacteals may take up tubercle bacilli from the intestine, even if there is no intestinal lesion; and that bacilli can pass through the thoracic duct and into the blood, and lodge in some tissue, particularly the pulmonary tissue, so inducing tuberculosis. They are apt to lodge at any point of least resistance; and if not caught up in the lungs, will tend to be arrested in an irritated gland or in some region that has been the seat of a trifling injury—for instance, in an epiphysis that has been strained. It is a peculiar fact that a trivial injury constitutes a point of least resistance; but a severe injury, such as a fracture of a bone, does not do so. Baumgarten was a strong believer in the idea that bacilli enter the organism with the food and von Behring now warmly advocates the same view, teaching that bacilli enter the organism of every person in early life. They may be destroyed by tissue resistance, but if not destroyed have a period of latency and, finally, perhaps after years, become active and cause the disease ("Deutsche Med. Woch.," Sept. 24, 1903). Calmette and Vanstenberg ("Annales de l'Institut Pasteur," 1906) have long insisted that infection is chiefly by the alimentary canal and that inhalation infection is rare.

It is certain that inoculation may be followed by tuberculosis. The inoculation of tubercle bacilli in the intestine may produce intestinal ulceration. It has been shown experimentally that rubbing the bacilli into the nasal mucous membrane may produce a local area of disease. Inoculation of the skin may result from a wound, the bacilli being carried into the wound itself. The victims of cutaneous inoculation are usually butchers, veterinary surgeons, physicians who have made postmortem examinations, and workmen who handle hides. In these cases, as a rule, an ulcer promptly forms at the point of inoculation; but in some few cases the wound heals soundly and tuberculous lesions develop in several or many weeks later in the wound area or in the neighborhood. In still rarer instances no apparent inflammation or ulceration occurs in or around the seat of inoculation, but the anatomically related lymph-glands become tuberculous. In other cases adjacent bone or an adjacent joint becomes tuberculous. Disease of the lungs may follow cutaneous inoculation.

A number of cases of inoculation tuberculosis have been reported. Not a few pathologists have developed anatomic tubercle (see page 247). Schmidt records a case of tuberculous ulcer on a woman's lip due to a bite from her tuberculous husband. It is recorded that a tuberculous person inoculated others while tattooing them, the needle having been moistened with saliva. Letulle's case of inoculation tuberculosis was a woman, who, while scrubbing the floor of the room in which her tuberculous husband had died, ran a splinter into her hand. The wound became tuberculous. Bosanquet ("Lancet," Jan. 13, 1912) refers to a laundress who infected a whitlow with tuberculosis while washing infected linen. I have treated a physician who inoculated his finger while making culture studies with tuberculous material. In this case the axillary glands became tuberculous and were removed. I have also seen a tuberculous ulcer of the forearm in an attendant of a lunatic asylum who had been bitten by a tuberculous patient. Inoculation tuberculosis occasionally follows circumcision, as practised by an orthodox rabbi, the operator being tuberculous. A ritual operator (as Bosanquet calls him) stops bleeding either by applying his mouth to the wound, or by squirting wine from his mouth upon the wound. There have been reported apparent cases of direct inoculation of the genito-urinary tract during sexual intercourse.

If there has been some definite injury of the tissues, inoculation may follow a simple rubbing of tubercle bacilli into a part.

When the mother's ovum is tuberculous, the disease may be directly transmitted to the fetus, producing the condition known as congenital tuberculosis. Rosenberger found bacilli in the blood from the umbilical cord of the placenta of a tuberculous mother. This proves that congenital tuberculosis may exist even when the ovum is not known to be tuberculous, and also that a child born of a tuberculous mother is, if not immune to the bacteria, tuberculous from the moment circulation is established between embryo and mother. Baumgarten believes that bacilli may pass the placenta, enter the fetus, and remain latent for years. Latent bacilli have been found in normal lymph-nodes (Harbitz, in "Jour. Infect. Diseases," vol. ii, 1904); this proves that latency is possible. However common the direct transmission of bacilli may be, the direct transmission of the disease is unusual, but the transmission of an hereditary predisposition to infection is not unusual. In spite of recent assertions to the contrary, I believe that there is such a thing as hereditary predisposition to tuberculosis. The experience of the human race uniformly confirms the belief in predisposition. In some cases of tuberculosis we can satisfy ourselves clinically as to the cause of the infection. For instance, when an individual is injured with an object known to carry tubercle bacilli, if an ulcer of the skin forms, and the adjacent lymphatic glands enlarge, the deduction is obvious. In other cases it is impossible to make up our minds as to the cause of a tuberculous lesion. For instance, we can only guess that a person has inhaled tuberculous material or has eaten tuberculous food. If in inoculation tuberculosis no lesion arises at the point of entry, the opinion as to the causation will be founded merely upon guesswork.

It seems certain that when the bacilli of tuberculosis enter into the body, if they are not destroyed by the body-resistance, they may produce a local lesion at the site of inoculation, or pass to the nearest lymphatic glands or to some point of least resistance, and there establish disease. The first lesion is known as the primary focus, and from this focus disease may be disseminated to the most distant parts. The bacilli enter readily if there is a wound or an abrasion; but in exceptional circumstances they may enter through unbroken skin and undamaged mucous membrane. Any structure may become tuberculous, but some structures are much more liable to do so than others. The lungs are very liable; the conjunctiva is very resistant.

The bacilli are generally distributed by the lymph, but may enter the blood. Those which do enter the blood may pass out in the urine or feces, may produce local lesions, or may induce advancing and widespread tuberculosis. Dissemination by the lymph-stream is known clinically to occur, and it means slowly advancing tuberculosis with localization of lesions. In dissemination by the lymph-stream, the dissemination is usually in the normal direction of the lymph-current; but if the lymph-vessels become blocked, lymph-regurgitation may occur, and then the dissemination takes place in a direction opposite to the normal flow of the lymph-current.

Latent Lesions.—By a latent lesion we mean a non-progressive or a healing lesion which gives no clinical evidence of its progress. Such a lesion is most apt to be in a lung or in a gland. It may serve to furnish bacilli to distant parts and hence be responsible for secondary lesions. It may give toxin to the blood and thus induce distant trouble. The frequency of latent lesions becomes evident when we test apparently healthy adults with tuberculin. Although we state that a latent lesion causes no symptoms, we had better say presents no symptoms to suggest tuberculous involvement of the part. Hollos, of Hungary, insists that such an area contains toxin-forming bacilli, and that the poisons taken up from it by the circulation cause a chronic toxemia productive of

numerous symptoms. Such symptoms are usually thought to be due to anemia or neurasthenia. This subject has been brilliantly discussed by Matas in the "Southern Med. Jour.," Oct., 1911.

Products of the Tubercle Bacilli.—A great variety of products are formed by the tubercle bacilli, and among them we may mention alkaloids, toxalbumins, fatty acids, and ferments. Experimental injection of the toxalbumins produces inflammation; and of the alkaloids, fever. It has been shown by Maragliano that injection of the toxalbumins actually lowers the temperature. Beyond any doubt, the culture material in which tubercle bacilli are growing contains poison; and the bodies of the bacilli themselves contain poison. The poisons in the culture-medium are called *extracellular poisons*, and those within the bacilli are called *intracellular poisons*. It is quite probable that the former poisons are identical with the latter, and have merely passed from the bacilli into the culture-medium.

Tuberculin.—It was proved some time ago that dead bacilli are toxic and, if experimentally injected, induce a toxic condition in the animal, cause inflammation of the kidneys, and sometimes produce subsequently cold abscess at the seat of injection. In 1890 Koch collected the poison from dead bacteria in the form of a liquid, which he called tuberculin.[1] A number of different methods of extracting such poison have been suggested; hence, there are a number of different tuberculins, not one of which contains living bacilli. Koch has made several himself. His early tuberculin was made by making a glycerin-bouillon culture of tubercle bacilli, evaporating on a water-bath to one-tenth of its volume, and filtering out the dead bacilli. The filtrate contained tuberculin mixed with glycerin. It is now known as original or old tuberculin or OT. Later Koch prepared tuberculin from virulent cultures of bacilli, dried, ground up, and mixed with water, the fluid being centrifuged for forty-five minutes. When centrifuged, two layers separate. The upper layer, which is white and opalescent, contains the elements soluble in glycerin, is like the old tuberculin, and is called TO. The lower layer contains an emulsion of insoluble elements of high immunizing power, and is called TR. In 1901 Koch presented another tuberculin of dried bacilli in equal amounts of glycerin and water. It is called bacillary emulsion or BE. This is really a vaccine.

It was discovered by Koch that tuberculous animals are much more strongly affected by an injection of tuberculin than are healthy animals. The most positive reaction is noted in the tuberculous area; but, as a rule, there is also a reaction in the area where the injection is made. We get no reaction from the administration of tuberculin by the stomach,[2] but occasionally can obtain it by the inhalation of the dried material. If a moderate dose of tuberculin is injected into a non-tuberculous animal, there may be a trivial redness at the point of injection and a slight and temporary rise of temperature; or there may be no evidence of reaction whatever. An injection in a tuberculous animal, however, is followed by distinct inflammation at the seat of injection, and a positive reaction in the tuberculous area. This area undergoes congestion or inflammation, leukocytes collect around it, and the part tends to necrosis and is liable to break down. It is not that the bacilli are killed, but, rather, the tissues containing the bacilli die.

In addition to the changes already mentioned there is elevation of temperature. If the dose has been small, there may be only a slight feeling of coldness to usher in the rise of temperature; but if the dose has been large, there is usually a distinct chill. This chill comes on eight to twelve hours after the

[1] "Deutsch. med. Wochenschr.," 1891, xvii.

[2] Latham and S. Solis-Cohen claim results from oral administration. Moller and Heinemann seem to demonstrate that those clinicians are mistaken ("Deutsche med. Woch.," Oct. 5, 1911.

injection and is accompanied and followed by elevated temperature. The fever lasts from four to twenty-four hours, and the temperature may be elevated from 2° to 5° F. The febrile condition is accompanied by pain in the head, limbs, and back, with increased rapidity of the circulation, restlessness, weakness, and usually nausea. As the temperature passes to normal all the symptoms disappear. The slight elevation of temperature which may be noted after tuberculin has been injected into a non-tuberculous animal is not ushered in by a chill, and does not exceed 1° F. unless a very large dose has been given. We thus note that the injection of tuberculin may be of the greatest possible value in diagnosis.

A person with a thoroughly healed lesion does not, and a far-advanced case may not, react to tuberculin.

Much has been written on the reaction of non-tuberculous human beings to tuberculin. Such reaction is said to occur in leprosy, in convalescents from acute illnesses, in syphilis, and in actinomycosis. Many supposedly healthy people react to tuberculin. Some react to a moderate dose, some only to a large one. We are now convinced that the tuberculin reaction is specific and that any one who exhibits it possesses a tuberculous focus, active, latent, or healing. Reaction means infection, but not of necessity disease with clinical evidences. Young children, especially infants, are very refractory to tuberculin because young children are seldom tuberculous.

A real, complete reaction to tuberculin has three elements:

1. A constitutional reaction manifested by fever.
2. A local reaction manifested by the indication of swelling and redness, a nodule, or an infiltrating area in the region of puncture (stick reaction). Sometimes adjacent glands swell.
3. A focal reaction, that is, inflammation about the lesion. ("Tuberculin," by Hamman and Wolman.)

A good many observers have grown fearful of injecting tuberculin, believing that it is liable to cause the tuberculous focus to spread, or actually to lead to the development of disseminated tuberculosis. Virchow was of this opinion. That such a condition may follow the use of large doses seems certain, but moderate or small doses appear to be entirely safe. Flick has pointed out that if a blister is applied to a tuberculous person a distinct febrile reaction appears a number of hours after the application. This is due to the absorption of toxic material, probably tuberculin, from the blister. It is known that in a tuberculous animal certain excretions (urine) and serous exudates contain tuberculin. Mérieux and Baillon show that if a tuberculous person is blistered the fluid of the blister, injected into a tuberculous animal, produces a definite reaction. This proceeding is of diagnostic value. A fluid containing tuberculin comes from the blister upon the tuberculous person and he is proved to be tuberculous by injecting the blister fluid into another tuberculous animal.

Resistance of Bacilli.—Among the antagonistic elements we have mentioned oxygen, dryness, and sunlight. Moist heat, at the temperature of boiling water, is rapidly fatal. A 5 per cent. solution of carbolic acid is one of the most powerful of germicides. Full-strength alcohol is next in point of power. Corrosive sublimate is not a satisfactory germicide. Formaldehyd is fatal only after long exposure. Iodoform and ether is a reasonably powerful mixture.

That the virulence of tubercle bacilli varies under different circumstances is sure. Under some circumstances they may be extremely powerful; under others, nearly innocuous. The liability to infection depends, probably, in part, on individual predisposition, and certainly, to a great extent, on the number and the virulence of the bacteria.

Immunity.—It seems likely that some persons are immune to tuberculosis. Such persons may come from an ancestral line in which all the predis-

posed died of tuberculosis, so that the immediate ancestors of the line were non-susceptible. The tendency to immunity may be strengthened by proper marriages, and may be weakened by improper marriages; or immunity in a line may be destroyed by the continuance of unfavorable conditions. Spengler claims to find in red blood-corpuscles of healthy men an immunizing body. It is sometimes noticed that during the progress of a localized tuberculous infection a deep-seated tuberculosis (for instance, phthisis) improves. This exhibits a progressive development in the powers of the organism to resist infection by stimulation of the apparatus for opposing infection. That numbers of people get entirely well of tuberculosis is certain and that many such people have secured prolonged immunity is probable. Paretic dements seem to possess a high degree of immunity to tuberculosis (Rosanoff, in "Jour. Amer. Med. Assoc.," February 13, 1909). Of course, the term "immunity" is only relative. No one can be absolutely immune; for when subjected to extremely unfavorable circumstances, or when a number of virulent bacilli are introduced, any one may become tuberculous.

Predisposition.—Personally, I believe that there is such a thing as a predisposition toward tuberculosis, just as there is toward many other diseases. Such a predisposed individual possesses temporarily or permanently a condition of the body-cells, body-fluids, or both, that either makes easy the entrance of the bacilli or prevents strong opposition to their multiplication when they have entered. A person is predisposed to an infectious disease when the opsonic index is low, for this indicates lack of phagocytic power in the leukocytes. Predisposition may be increased by some extraneous circumstance, such as occupation, residence, etc., that brings the individual into frequent or prolonged contact with virulent bacteria.

There is certainly such a thing as congenital tuberculosis, and any tissue may be involved in the congenital trouble. Rosenberger showed that blood in umbilical veins from the placenta of a tuberculous mother contained bacilli ("Amer. Jour. Med. Sciences," 1909). Young children are very liable to tuberculosis of the acquired form. According to Professor Behring, many children become infected with tuberculosis in their early years by eating tuberculous food; but such a tuberculosis often remains latent for a considerable length of time, and then develops. This liability depends probably upon the fact that the digestive organs of the child are not so strongly protective against bacteria as are those of the adult.

Do certain individuals possess a special predisposition to develop tuberculosis, and is this hereditary? Hereditary predisposition was once regarded as practically the only cause of the disease, but many thinkers now regard it as of slight importance, although I do not see how we can deny its existence. To do so is to run counter to the experience of the human race in all countries and at all times. We all see how common tuberculosis is in the descendants of tuberculous persons. Hutley studied 432 cases of tuberculosis. In 23.8 per cent. one or both parents had the disease (the father alone in 11.5 per cent., the mother alone in 9.9 per cent., and both in 2.4 per cent.). Some maintain that in 30 per cent. of consumptives, one parent or both parents have been consumptives, and in 60 per cent. a parent or a grandparent has suffered from tuberculosis. Of course, the above statements do not prove that the cases in a family are due to heredity; but that there must be such a thing as hereditary predisposition is indicated by the fact that there are many families living under similar conditions to the tuberculous families, without there having occurred, through several generations, a single case of tuberculosis among their members. A feature that makes us unable to reach a certain conclusion is that tuberculosis is contagious and several members of a family may be infected from one member, even when there is no predisposition to the trouble

by heredity. The mere living in one house may account for the infection. A fact strongly in favor of the hereditary influence is that in a family whose ancestors have been tuberculous and whose members have not lived together, but have been scattered widely over the earth, member after member may die of the disease.

Unhealthy environment particularly predisposes to tuberculosis; and the element of poverty—leading as it does to taking improper or insufficient food, dwelling in an unhygienic room or in an overcrowded building, pursuing an exhausting occupation, working for long hours, and obtaining insufficient amusement and outdoor exercise—also has a most powerfully unfavorable effect. As a class the poor dislike ventilation, take insufficient exercise in the open air, do not get enough sunlight, work in a dusty atmosphere, take insufficient nourishment and eat improper food, live in damp and dirty rooms, are subjected to grinding competition and cruel anxieties, and many of them drink quantities of whisky. City life is a predisposing cause of tuberculosis for many of the foregoing reasons, and particularly because many city workers follow an indoor occupation. The enemies of tuberculosis are sunlight, fresh air, nourishing food, and outdoor exercise, and the limiting of any of these factors favors the development of the disease.

Tuberculosis may occur in any region that man inhabits; although in some regions it is rare, and in others it is excessively common. Its great frequency in some regions is probably due less to climate than to environment, occupation, and heredity; and the greatest predisposition is found in the town dweller. There is much more tuberculosis among males than among females.

Many diseases and conditions predispose to tuberculosis. It is very common in chronic drunkards, in the insane, in the occupants of prisons, almshouses, and reformatories; among negroes in the North, particularly those engaged in indoor occupations; among American Indians subjected to the blighting influences of civilization by formula and routine; and in the sufferers from tertiary syphilis, diabetes, and Bright's disease. Any exhausting malady may be followed by tuberculosis.

Relation of Trauma to Tuberculosis.—(Inoculation Tuberculosis is discussed on page 218.) This question is often in dispute and has become of much medicolegal importance. Several times of late, in the courts of Philadelphia, it has been the subject of acrimonious controversy. Suitors affirm the relationship, corporations deny it, and experts wrangle till judge and jurymen do not know what to believe.

There can be no doubt that tuberculosis often becomes manifest in a part after that part has been subjected to traumatism. No one denies this. In fact, in over one-sixth of all cases of bone and joint tuberculosis traumatism is set down as causal.

I do not mean that trauma causes the tissue changes characteristic of tuberculosis. Such changes are always and only produced by the action of tubercle bacilli. I do mean that the injury puts the part in such a condition that the bacilli of tubercle attack the injured tissue, having been unable to attack it when it was in a state of health. The injury creates an area of least resistance. In such an area the cellular activities are no longer able to withstand the action of bacteria. Without an injury it is highly improbable that tuberculosis would ever have arisen in the part. At least the injury determined the localization and multiplication of bacilli and the origin of an active tuberculous focus, and to this extent the injury was causal.

Osteomyelitis is due to pyogenic cocci. It may arise in a bone subjected to traumatism. Traumatism is stated to be a cause. Why should a tuberculous process be placed in a different category? Where do the tubercle bacilli come from? Some maintain that if tuberculosis follows traumatism of a part, there

was a latent and undiscovered tuberculous process in the part before the accident, and that all the accident did was to light up a latent focus into activity; in other words, to precipitate an inevitable event. This contention is true in some few cases; we believe it to be untrue in a large majority of cases.

Some believe that though there may have been no local latent focus, there is, at least, somewhere in the body an area of tuberculosis to furnish the bacilli. This view is true of many, but we do not believe of all, cases. It gains in probability from the established fact that tuberculous bone or joint disease is most apt to arise in those known to have tuberculous infection somewhere about them. It is certain that in many cases there is no demonstrable focus of tubercle anywhere to be found except in the injured part. It is hard to prove a negative, and it is impossible in any case to deny arbitrarily that an unrecognizable distant latent focus may exist.

We know, however, that many cases never give any sign of distant tuberculosis before the accident, and never give any sign of it afterward. We do know that bacilli can exist for a considerable time in blood or lymph when there is no demonstrable lesion of tuberculosis. From such blood or lymph bacilli may be deposited in the injured part and become active for harm.

We do know that bacilli may live for a long time in glands or bone-marrow without producing any evidence of a lesion of bone or of gland (Petrow, Lannelongue). If bone-marrow or gland containing bacilli is injured, these bacilli become active and establish an area of disease. Without the injury it is improbable that there would have been disease.

Local tuberculosis follows slight rather than severe injury. I have seen it after a strain of an epiphysis, never after a fracture. I have seen it after a sprain of a joint, never after a dislocation. After a severe injury tissue reaction is so marked that bacilli are destroyed. It is particularly in bone and joint tuberculosis that traumatism is held to be causal. Whitman tells us that out of nearly 3400 cases occurring in the clinics of Bruns, Koenig, Mikulicz, and Hildebrand over 500 were attributed to trauma. I have seen a number of such cases, most of them involving the knee, foot, or wrist. I have seen tuberculosis of the glands of the groin arise after a bruise, tuberculous pleuritis and tuberculosis of the chest-wall follow a chest contusion, and sacro-iliac tuberculosis follow a sprain. Tuberculous meningitis has followed head injury. I have seen several cases of tuberculosis of the testicle after contusion. When injury is followed by a tuberculous lesion, the definite signs and symptoms of that lesion do not appear for from three to six weeks after the accident. We may conclude that tuberculosis may arise at the seat of an injury; that in some cases there may have been an antecedent lesion at that point; in some cases there is a distant active lesion; in some cases a distant latent lesion; in some the bacilli must have been lying inactive in the part or must have lodged there from blood or lymph, after the accident and because of it. R. L. Dixon reported a number of such cases ("Physician and Surgeon," Jan., 1909). Hueter and Schüller insist on the tendency of trauma to localize tuberculosis. Ribera Y Sans (quoted in "Practical Medicine Series," vol. in Surgery, 1912, edited by John B. Murphy) states that in 45 per cent. of cases of tuberculosis of the larger joints the condition is preceded by trauma. In an appended note by Murphy we learn that that surgeon believes that tubercle bacilli tend to escape from the circulation at the site of a slight trauma and to light up disease. Bosanquet ("Lancet," Jan. 13, 1912) says that in expressing an opinion "as to the probability of a tubercular lesion being due to a preceding accident, I think we must put disease of joints in a class by itself. There is a considerable mass of evidence, that in some way or other injury does lead to tubercular arthritis, and if the occurrence of the accident is clearly established and it is followed at a reasonable interval by the tuberculosis, we may accept the causal connection as probable." He

regards "a reasonable period of time" as not over three months. During the interval there should have been some pain in or stiffness of the joint.

The Term "Scrofula."—Many surgeons positively oppose the use of the term scrofula, but I believe that there is clinical value in retaining it. The surgeons that have entirely abandoned it think that, after all, it is exactly synonymous with tuberculosis. I use it to designate the persons that are predisposed to tuberculosis through possessing a type of tissue of low resisting power. These tissues fall a ready prey to the bacteria of tuberculosis. Such tissue vulnerability is usually hereditary; and, as a rule, one, or even both parents are tuberculous, are in ill health, or are themselves predisposed. Occasionally this type of tissue is acquired, a child having at first been apparently entirely healthy, and later, owing to poor food, insufficient air, and bad hygienic surroundings, developing scrofula.

That scrofula is not simply osseous, articular, or glandular tuberculosis is proved by the fact that a person that we recognize as scrofulous may never throughout his life develop a recognizable tuberculous lesion. Some surgeons think that scrofula is latent tuberculosis, and will, under the influence of an exciting cause, burst into activity. This is possible, but unproved. We do know that some so-called scrofulous lesions are not tuberculous; for instance, facial eczema, corneal ulceration, granular lids, and mucous catarrh. These lesions are rather expressive of poor health, improper food, and deprivation of fresh air.

The subjects of scrofula, besides being prone to the non-tuberculous lesions above mentioned, are particularly prone to develop tuberculous lesions; and such a lesion may arise in any part that has been the seat of a slight injury or of a non-tuberculous inflammation. The parts most apt to become tuberculous are the bones, the joints, and the glands.

There are two types of the so-called scrofulous, that is, two types of those that are predisposed. The common type is known as the *phlegmatic,* or *lymphatic;* and it is this type that is particularly described by our surgical forefathers. In the phlegmatic type the individual is stolid of expression, and has thick, coarse skin, a muddy complexion, dark, coarse hair, a thick neck, thick lips, a thick nose, and a heavy lumbering gait. He is dull of apprehension, with feeble emotional reaction, and but little capacity for concentration or interest. The other type is much more seldom met with. It is what is called the *sanguine type,* or what the elder Gross spoke of as the *angelic type.* Such a child is frequently beautiful and graceful in its movements. Its skin is transparent and clear, and the color comes and goes. The eyes are blue, the lashes long, and the hair silky. The tendency is to thinness, rather than fat; the mind is not dull, but precocious, and the temperament is nervous. In both these types of scrofula the condition of lymphatism exists.

Lymphatism, or the Lymphatic Constitution (**Status Lymphaticus**).—The term was introduced by Potain to designate a condition in childhood in which there is a very strong disposition to the development of disease of the lymphatic structures, or in which at birth there was excessive development of these structures. As a matter of fact, the condition, though most common in infancy and childhood, can exist in adults. The enlarged glands may be tuberculous from the beginning; but, as a rule, they are not so in the beginning, but tend to become so. Inflammation of a mucous membrane is followed by enlargement of the anatomically related lymphatic glands. These enlarged glands are frequently met with in the neck. We find them associated with enlarged tonsils and pharyngeal adenoids.

Usually lymphatism is congenital, but it may be acquired when children are placed under unfavorable conditions. Lymphatic children frequently have rickets and are invariably anemic, yet there is considerable or much sub-

cutaneous fat (Escherich). In infancy it is the bronchial and mesenteric glands that are particularly apt to enlarge; in childhood, it is the glands of the neck. Usually the tonsils are enlarged and the nasopharynx contains adenoids. The spleen is usually palpable. In lymphatic children it is not uncommon to have a persistent and hypertrophied thymus gland. The gland, however, is not obvious, but rather hides at the root of the neck (Humphrey, in "Lancet," Dec. 26, 1908), and may be missed at necropsy. During life the thymus is sometimes observed as a pulsating mass at the root of the neck. Even if it cannot be seen its presence can usually be determined by percussion and by the *x*-rays (Hochsinger) (see page 1247). In about half the cases a goiter is obvious, and, as pointed out by Berg, many of those with goiter have symptoms of Graves's disease. As the child increases in age, the lymphatic enlargements are likely to disappear unless tuberculous infection has occurred. After a child has reached the age of seven or eight years non-tuberculous glands of the neck cease to enlarge, and by the time of puberty they have usually disappeared. Buxton ("Lancet," Aug. 6, 1910) states that young persons suffering from this condition are tall and thin; possess clear, fair, and pale skins; the temperament is blended, there is mental slowness yet intelligence, there is shyness and strong self-feeling. They cannot withstand cold, are very emotional, and yet may be able to appear calm. The pulse is normally 50 to 60, but is made rapid and irregular by trifling excitement. I do not believe that the condition can be certainly diagnosticated during life. McCardie regards hypertrophied lingual follicles, and the existence of lymphoid masses in the wall of the pharynx, the pyriform sinus, and in the anterior surface of the epiglottis as significant of the existence of lymphatism.

If an operation is performed on the victim of lymphatism the wound is very liable to become infected, and the bleeding from the wound is very trivial. The victims of lymphatism are more apt than other persons to die under a general anesthetic, and occasionally one of them dies during natural sleep. (See Dr. Geo. Blumer, in the "Bulletin of the Johns Hopkins Hospital," Oct., 1903.) Cases have died from injection of diphtheria antitoxin (see page 46). This disease accounts for most otherwise inexplicable cases of sudden death in children and young persons, and such deaths are respiratory and not cardiac (Humphrey, in "Lancet," Dec. 26, 1908).

The Diagnosis of Tuberculosis.—Whenever he sees a persistent area of chronic inflammation in any structure of the body the surgeon must think of the possibility of its being tuberculous. A thorough investigation must be made into the local disease and the body generally; and it is of particular importance to determine whether there is any other diseased locality, and whether there is any evidence of tuberculous disease anywhere in the body. The patient's history must be investigated, and any possible tendencies or predispositions inquired into. Tuberculosis does not cause leukocytosis except, perhaps, occasionally and moderately in tuberculosis of serous membrane, and even in this condition there is no increase in polymorphonuclear cells. A mixed infection causes only a trivial increase in polynuclear leukocytes.

In many cases of tuberculosis the diagnosis can be made from purely clinical investigation. This is the case, for instance, in many tuberculous ulcers, abscesses, and glands. In some cases the diagnosis can be made only by making differential stains of material obtained from the suspected focus, or by removing a section of the inflammatory area by Mixter's cannula, and studying it carefully under the microscope. Cultures may be taken from any material obtained from the suspected focus.

In doubtful cases animal inoculation is necessary to make a diagnosis. The material is injected into a guinea-pig; and if it be tuberculous, the animal will develop miliary tuberculosis within a few weeks. With apparently sterile

fluid obtained from a tuberculous focus the disease can be induced in guinea-pigs by inoculation. Blistering a tuberculous person causes elevated temperature (see page 221). If the fluid of the blister be injected into a tuberculous animal a distinct reaction occurs (see page 221).

In a suspected case of tuberculous meningitis of the brain or of tuberculous disease of the membranes of the cord, the theca of the cord should be tapped (lumbar puncture), and the fluid obtained should be carefully examined. Of course, if, in a case of tuberculous cerebral meningitis, the foramina in the floor of the fourth ventricle have been blocked by exudate, no characteristic fluid will be obtained by tapping. It is usually found, however, that even in tuberculous cerebral meningitis there is increased tension of the fluid in the subarachnoid space of the cord, that this fluid is present in unnaturally large quantity, and that it is turbid through the presence of pus and lymphocytes. Sometimes it contains bits of fibrin and sometimes blood; and in many cases the bacilli of tuberculosis. Exploratory abdominal incision is sometimes necessary to determine the existence of tuberculous peritonitis.

The *x*-rays are of great aid in making a diagnosis of osseous, articular, and, perhaps, certain forms of pulmonary tuberculosis. The area of tuberculosis is lighter than the surrounding healthy structures when seen in a skiagraph.

The Tuberculin Test.—This test may sometimes be used to advantage in making an early diagnosis of recent lesions. Some physicians will not use it, believing that it is very dangerous. However tuberculin is used, it is much more reliable diagnostically in children than in adults. Apparently healthy infants never react. Apparently healthy children under six or seven years of age seldom react. In many adults free from demonstrable signs of tuberculosis, tuberculin gives a distinct reaction because many adults have encapsuled, quiescent, or retrogressive lesions of tuberculosis. I have already expressed the belief that if given in moderate doses it is safe; that is, it is safe if the disease is not too far advanced. Very large doses, or the giving of the remedy at all in greatly advanced tuberculosis, would not be safe. Some conditions contra-indicate its use, among them are the following: Addison's disease, recent pulmonary hemorrhage, and suspected bilateral renal tuberculosis (Howes and Floyd, in "Publications of Mass. Gen. Hospital," 1908). A contra-indication is the finding of cocci in the sputum. It should only be given when other diagnostic methods fail to give certain information, and is only to be used by a man trained in its use. Too large a dose may cause a severe chill, high fever, and great exhaustion, may arouse a latent focus to activity, and may actually cause dissemination of the disease.

The elements of the reaction following a tuberculin injection are:

1. Constitutional (fever, etc.).
2. Local (redness or nodule at the point of puncture).
3. Focal (inflammation at the seat of lesion).

If fever exists we never seek to obtain the constitutional reaction by an injection of tuberculin. The result would be misleading. We never inject tuberculin when there is mixed infection.

A temperature of 99.5° F. or over, when the patient is quiet in bed, contra-indicates the employment of the test. The test should be used as directed by John B. Howes and Cleveland Floyd (Ibid.). These rules are as follows: Koch's old tuberculin is used and the preparation must not be over two months old. One c.c. (100 mg.) of the material is drawn up in a pipet and is dropped into 10 c.c. of a $\frac{1}{2}$ per cent. solution of carbolic acid. Each cubic centimeter of this solution contains 10 mg. of tuberculin; 1 c.c. of solution No. 1 is mixed with 9 c.c. of a $\frac{1}{2}$ per cent. solution of carbolic acid. Each cubic centimeter of solution No. 2 contains 1 mg. of tuberculin.

One c.c. of solution No. 2 is mixed with 9 c.c. of the very dilute carbolic solution. Each cubic centimeter of solution No. 3 contains .1 mg. of tuberculin.

The patient is kept in bed for three days before beginning the test, and also during the test, and during all of this time the temperature is taken every two hours. The injection is to be made at an indifferent point. The first dose is .1 mg. of tuberculin (1 c.c. of solution No. 3). If there is no reaction, wait for three days and then give 1 mg. (1 c.c. of solution No. 2). If No. 2 gives no reaction, wait three days and give 10 mg. (1 c.c. of No. 1 solution); if No. 2 gives a slight reaction, inject 5 mg. ($\frac{1}{2}$ c.c. of No. 1 solution).

We have previously described the tuberculin reaction; that is, the temporary local congestion or inflammation in the tuberculous area, and the chilly sensation or chill, followed by marked elevation of temperature (see page 221). The constitutional signs of reaction are chilly sensations or chills, sweats, skin eruptions, headache, pain in the back and joints, diarrhea, nausea, malaise, cardiac palpitation, and dyspnea. Howes and Floyd regard even $\frac{1}{2}°$ F. of fever as significant of reaction if there are also constitutional symptoms and local signs. The focal reaction is the most important. In certain tuberculous lesions we can see the focal reaction; for instance, in lupus. In lupus the diseased skin begins to swell and redden a few hours after the injection. The reddened tissue may actually necrose. The ulcerated area becomes crusted. The swelling and redness disappear in a few days. In joint tuberculosis the skin over the joint becomes red. In a tuberculous ulcer of the mouth we can see the changes; and in a lesion of the larynx the laryngologist can observe them with the laryngoscope. By means of a cystoscope the local reaction can be seen in a tuberculous ulcer of the bladder.

Epstein in 1891 pointed out that redness and swelling at the seat of injection constitute a specific reaction.

The tuberculin test should not be used in advanced pulmonary tuberculosis because it is unsafe. In advanced cases it fails to cause any reaction because the tissues are unable to produce antibodies when acted on by toxin (Howes and Floyd, in "Publications of the Mass. General Hosp.," 1908). As a matter of fact, there is never any need of using the test in an advanced case, because the diagnosis is perfectly clear without it. We should never give extremely large doses in making the tuberculin test. If, after the careful use of tuberculin, there is no reaction, it is usually a safe conclusion that there is no tuberculosis. The tendency is more and more to use as a diagnostic test the local rather than the constitutional reaction.

Various methods have been devised for obtaining a local reaction (ophthalmo-tuberculin reaction, von Pirquet's reaction, Moro's reaction). The local reaction is obtained without danger of dissemination of infection and can be used even if fever exists.

Calmette's Ophthalmo-tuberculin Reaction.—It was pointed out that when tuberculin is injected into a tuberculous individual a reaction arises at the seat of injection. It has been shown that if tuberculin is placed in the conjunctival sac of a tuberculous individual a reaction occurs, and this method is valuable because even a trivial reaction is easily observed. The introduction of tuberculin into the conjunctival sac is usually spoken of as Calmette's method. This test can be used even if fever exists and even if a skin eruption exists. It is not as satisfactory in surgical as in medical cases. The old tuberculin of Koch is used. It is carefully freed from irritant materials, a 1 per cent. solution is made in normal salt solution, and 1 drop of this is placed in the eye. Baldwin regards 1 per cent. as dangerously strong and uses $\frac{1}{2}$ per cent. No constitutional symptoms develop, but in four or five hours, if the subject be tuberculous, the conjunctiva of the lids becomes injected, the corneal vessels distend, lacrimation arises, and the lids may swell (Howes and Floyd, Ibid.).

The reaction attains its height in from twelve to twenty-four hours and disappears in from forty-eight to seventy-two hours after its first appearance. In a non-tuberculous person no redness, or only a trivial and temporary redness, is noted. There is never a constitutional reaction even in a case of advanced tuberculosis. Of course, this test is contra-indicated if there is a tuberculous lesion of the lids or eye, if there is ulceration of the cornea, or if conjunctivitis exists. I have never become convinced that the method is entirely free from danger to the eye, and I own that I rather fear to use it. Cases of permanent ocular injury are on record. Baldwin ("Jour. Am. Med. Assoc.," February 20, 1909) made over 1000 tests. He says that the test has some value in diagnosis, no value in prognosis, and as yet cannot distinguish "active latent" from healed tuberculosis. He says danger to the eye is slight.

Von Pirquet's Cutaneous Tuberculin Reaction.—After the skin has been cleansed with alcohol 2 drops of old tuberculin are applied a short distance apart. The skin is then abraded or scarified between the drops and through each drop. The abrasion between the drop is a control experiment. The tuberculin is permitted to remain for ten minutes and is then wiped off. In a tuberculous individual local redness will appear in ten or twelve hours, and in twelve hours more the area will be swollen and perhaps edematous. This condition disappears in a few days, leaving, perhaps, as a legacy a trivial induration. There is very seldom a febrile reaction.

Moro's Cutaneous Tuberculin Reaction.—The material used is 5 c.c. of old tuberculin and 5 gm. of lanolin. It is rubbed into the abdominal skin and if the individual is tuberculous red papules or nodules or numerous vesicles appear in the area where the inunction was made. A severe reaction or a moderate reaction will be noted within twenty-four hours. A slight reaction appears in from twenty-four to forty-eight hours. The eruption of a slight or a moderate reaction disappears in a few days. After a severe reaction the skin may remain red for several weeks. In suspected surgical tuberculosis Moro's reaction is generally used. There is no febrile reaction.

Blistering a Tuberculous Person.—(See page 221.)

Injecting a Tuberculous Animal with Blister Fluid from a Person Suspected to be Tuberculous.—(See page 221.)

Massage of a Tuberculous Focus.—Wright has shown that gentle massage of a tuberculous focus may be followed by a reaction like that which follows the diagnostic use of tuberculin. In such a case the massage drives tuberculous products into the blood and, perhaps, if the massage is frequently repeated, auto-immunizes the individual.

Animal Inoculations.—This method of diagnosis is seldom employed and only in unusually obscure cases.

The Agglutination Test.—This test, as applied to the blood-serum of a tuberculous individual, is decidedly uncertain.

Prognosis.—Many cases of tuberculosis are cured. This is indicated by the frequency with which we find healed tuberculous lesions in necropsies on individuals dead of other diseases. We reach the same conclusion from the clinical study of many cases. The prognosis of a single tuberculous focus, especially if it can be extirpated or sterilized, is very good; provided that the general health is good, that there is not much anemia, that the digestive processes are well performed, that mixed infection is absent, that there are no albuminoid changes in the viscera, and that the patient is able and willing to live the life that is necessary for his welfare. Unfavorable prognostic indications are inability to eat, disturbance of digestion, deepening anemia, progressive loss of weight, high fever, and sweats. Of course, the prognosis is influenced by the patient's temperament, his willingness to brook control, his monetary status, and his habits. The danger is greatly increased by multiple lesions.

The dangers of mixed infection and of albuminoid disease have been previously discussed.

In very young children the prognosis is most unfavorable; but in older children it is very much better; in fact, it is better in them than in adults.

Tuberculosis of the skin gives a very fair prognosis; and glandular, bony, and articular tuberculosis are frequently recovered from; but, of course, any tuberculous lesion, however limited in area, is a profound menace.

Another fact to be borne in mind is that many cases apparently cured are not really cured; and that the disease strongly tends to reappear in the same region or in a nearby region, or to reappear later in another part of the body. We should, further, remember that in many cases in which there is apparently one lesion only, there are, in reality, distant lesions undiscoverable by clinical methods. In any case of tuberculosis the higher the opsonic index the better the prognosis, the lower the opsonic index the worse the prognosis.

Another important fact is that when an individual has a latent focus of tuberculosis, especially if this latent focus is in the lungs, should a surgical operation be performed for some other purpose, and the patient be kept in bed for a considerable length of time, the latent focus may become active. I have always believed that in latent pulmonary tuberculosis the administration of ether or chloroform might awaken the disease into activity. It therefore becomes evident that in such persons operations of necessity are the only ones that should be undertaken. Such an operation, if possible, should be done under nitrous oxid or a local anesthetic; and the patient should be got about again at the earliest possible moment.

Tuberculin in Prognosis.—Wolff-Eisner maintains that advanced and rapidly advancing cases fail to show an ophthalmo-tuberculin reaction, hence, when the existence of tuberculosis is proved clinically, a negative ophthalmo-tuberculin reaction indicates a bad prognosis. Most observers reject this contention. "Of two individuals with moderately advanced disease and in equally good general condition, tuberculin cannot predict with more assurance than other clinical methods the state of affairs a year hence" ("Tuberculin," by Hamman and Wolman).

Treatment.—One of the first thoughts of the surgeon is to provide against the contamination of healthy individuals by the infected. Any infected excretion or suspicious discharge from the patient must be disinfected at once and dressings that are removed from the patient should be burned.

We are not in this section discussing the treatment of tuberculosis of the lungs, which belongs to the medical man, and in which climate is of great importance. In cases of surgical tuberculosis, however, the patient may do better in some climates than in others; and the change, by stimulating the appetite and causing sleep and giving renewed hope, will be beneficial. In surgical tuberculosis climate is not the factor that it is in tuberculosis of the lungs; but if there is pure atmosphere, an equable temperature, and plenty of sunlight, the climate will lure the patient out-of-doors, and will thus be greatly to his advantage.

A life in the open air is the most essential thing in the treatment of surgical tuberculosis; but, as Professor Halsted points out, it is not of much use to tell a great many persons to live in the fresh air. They will not do it unless they are made to; and it is hard to make them unless they live in quarters especially built with this object in view. Therefore, other things being equal, if patients with surgical tuberculosis have the means, it is a good plan to send them to a sanatorium in the mountains or at the seashore, where they can obtain the persistent, unbroken life in the open air that is the cure of the disease. The patient should spend his days in the fresh air, and he should sleep at night directly exposed to the air; and if the atmosphere is free from dust and foul

odors, so much the better. The poorer patients must get the fresh air at home, if they cannot be sent to some camp or colony. In large cities adjacent to the seaside resorts poor people can usually be sent for a short time, at least, to the seaside; and I am a very great believer in the beneficial effects of Atlantic City and other seashore resorts.

It is frequently necessary to do an operation in a great city, although we operate much less than formerly for these conditions. If an operation is done in a great city, the patient is kept in the fresh air as much as possible during his convalescence. If it is feasible, he is sent away to a colony or sanatorium to recuperate. It would be an excellent thing if, in many of those cases in which operation is necessary, the operation could be performed at the camp or the sanatorium. One advantage of the camp or sanatorium is that the patient is watched and regulated daily, and is led to do things that otherwise he would neglect. Many patients endeavor to avoid going out when they should go out because they are afraid of taking cold; and many of them are simply neglectful and do not want to take the trouble to do it.

It cannot be soo strongly insisted on that in surgical tuberculosis fresh air is of as much importance as in tuberculosis of the lungs. It increases the vital resistance, it stimulates opsonic power, and it causes the patient to eat more nourishing food and to sleep better at night. Frequently we see children that have had sinuses for months get rapidly well when they adopt an open-air life; and, although albuminoid changes, when they once exist, will never pass away, further albuminoid changes may not take place if the patient lives properly.

A patient with surgical tuberculosis can have no more injurious environment than a dark, damp room, especially if it is in a crowded tenement and up a narrow court. The value of sunshine is also beginning to be appreciated (*heliotherapy*). We know that it limits the growth of tubercle bacilli. It is not the heat that benefits the person, but the chemical rays of sunlight. These rays have some germicidal influence, have considerable penetrating power, and seem to influence decidedly the nutritive processes. Tuberculous joints, even when sinuses exist, are often much benefited by exposure to the direct rays of the sun. It is often advisable to expose the entire body except the head. Leysin begins with a three-minute exposure and gradually increases it up to two or three hours. During exposure traction is usually maintained on the joint. Excessive sunlight is, however, not beneficial. In summer it exhausts the patient and even in winter it produces eye-strain and headache. Major Woodruff, U. S. A., insists that excessive sunlight is actually harmful, particularly to blondes ("The Effects of Tropical Light on White Men"). Tuberculosis is dreadfully fatal in certain tropical countries and is more fatal to blondes than brunettes. Open-air treatment is more valuable in winter than in summer, perhaps because cold stimulates respiration and because the winter sunlight is not debilitating.

The tuberculous structures require rest. We have long known how disastrous it is to confine a person to bed in a dark, ill-lighted, and improperly ventilated room. We can, however, confine a person to bed with perfect safety if there is a free flow of fresh air. We must confine certain cases to bed; for instance, cases of tuberculous peritonitis, and some cases of bone tuberculosis and of joint tuberculosis. A patient with tuberculosis who has fever ought to be in bed. We can put such patients to bed without any fear of the disease becoming worse or spreading if the supply of fresh air is plentiful and if the patient is kept warmly covered and wears a skull-cap. Of course, a draft is to be avoided. Patients that are confined to bed do excellently in a tent, in a cottage sanatorium, or on a porch that has been altered for the purpose.

At the very first possible moment the patient should be sent out-of-doors;

and in many cases of tuberculous disease (for instance, vertebral disease) the tuberculous part is supported by means of a brace or a splint.

We thus see the twofold nature of the modern treatment of surgical tuberculosis: rest for the tuberculous part and a life in the open air. Exercise is of importance also, although it should never be taken in excess. If the patient is confined to bed, he should be massaged and rubbed with alcohol, the tuberculous part being usually avoided. Forcible manipulation must never be applied to a focus of tuberculosis because it may lead to dissemination. Gentle massage of a tuberculous part may do good. Wright has shown that it is followed by a reaction like that produced by tuberculin—a reaction due to the absorption of tuberculin from the seat of disease. If a person has fever he must not attempt active exercise, but must be confined to bed.

One should overfeed tuberculous patients if the stomach tolerates it, but not on any single article, or even on any particular one. The diet should contain a sufficiency of fats, proteins, and carbohydrates; and the food should be agreeable to the taste and readily assimilable. Otherwise, disgust will be engendered; and with disgust come indigestion and loss of appetite. The very life of the patient may depend on his remaining able to take a sufficiency of nourishing food.

There is no specific diet for tuberculosis, although many have been suggested. One of the most valuable foods is milk, taken raw or mixed with other articles, such as lime-water or sodium bicarbonate, and frequently with brandy. The use of an exclusive diet of boiled milk is to be deprecated, and in children it sometimes leads to the development of scurvy. Practically anyone can take milk if proper efforts are made.

Soft-boiled eggs are useful; and bread or toast should be eaten with plenty of butter, which is an agreeable form of fat. Vegetables and fruits are desirable.

If the patient can take cod-liver oil without impairing his appetite or digestion, it should be given, provided the weather is not too hot. Cod-liver oil produces diarrhea in very hot weather. Children learn to take it very well. To many adults, however, it is, and remains, absolutely abhorrent. The chief value of cod-liver oil is that it is a fat, and it seems improbable that it contains any elements specifically antagonistic to tubercle. If used, large doses should not be given, as they will not be digested. The common dose for an adult is a teaspoonful two or thee hours after meals. Thirty drops three times a day is usually given a child, and an infant should receive 15 drops three times a day.

We know of no drug or medicine that can with safety be used at the present time with any real hope that it will specially destroy tubercle. Drugs are, of course, given, but they are of secondary importance.

Tonics are used, and in children the syrup of the iodid of iron has considerable reputation. Remedies may be needed to improve digestion or control night-sweats, etc. I do not believe that beechwood creosote or carbonate of guaiacol internally, or iodoform inunctions, or painting the surface with guaiacol confer any real benefit in tuberculosis.

Alcohol is often required. It is not needed in all cases, but is in many. We should avoid it in children, however, unless there is a particular indication for its use. When a tuberculous patient is weak, milk-punch or egg-nog is of service; and in any case of mixed infection alcohol is required in full doses. If fever exists, and the administration of alcohol makes the pulse more rapid and the delirium worse, and causes flushing of the face, the dose is too large and should be diminished. Any patient that smells strongly of alcohol is getting an overdose.

Tuberculin in Treatment.—Many able investigators in many lands are striving to work out a safe and satisfactory specific treatment for tuberculosis.

Landerer proved that immunity to tuberculosis can be produced in the lower animals by injection of living bacilli. We dare not practice this on human beings. Injections of tuberculin finally produce immunity to that product. The original plan of using tuberculin therapeutically was to obtain definite reactions again and again. This plan was founded on the belief that the reaction did the good and that cure might be obtained in this way in a few weeks. This utterly reckless plan was most disastrous, produced many deaths, and caused widespread distrust and final abandonment of tuberculin. Tuberculin treatment was not an error, the plan adopted was, as the material was given in large doses to any and all tuberculous patients. Just at present we are witnessing a revival of faith in tuberculin. The object now is to stop short of obvious reaction, believing that reaction is unsafe, as it may at any time get beyond control and do harm. Treatment is begun with very small doses which produce no reaction. Larger and larger doses are very gradually attained until immunity to tuberculin is established.

When an animal becomes immune to tuberculin the body cells resist and finally destroy the tubercle bacilli (Braun, in "Boston Med. and Surg. Jour.," July 23, 1908). From six months to a year is required for the treatment. The essence of treatment is the very small dose and the very gradual increase, reaction being scrupulously avoided.

Many different tuberculins have been recommended. The best known ones are Koch's old tuberculin (O. T.), Koch's new tuberculin (T. R.), Koch's bacillary emulsion (B. E.), the bouillon filtrate of Denys (B. F.), von Ruck's watery extract, and bovine tuberculins. There seems to be no sound clinical reason for insisting on the use of any particular form of tuberculin. Bovine tuberculin does not seem more useful than human tuberculin in tuberculosis of the abdomen, glands, and liver, structures so often the seat of infection with bovine bacilli. Whatever form is chosen is given subcutaneously in the back and near to the skin, so that a local reaction may be quickly recognized. If after any dose there is even a slight elevation of temperature or even a trivial local reaction the dose must not be advanced until that dose can be given without reaction. Loss of weight means that doses are too large. Judiciously small doses are entirely safe even when tuberculosis is complicated. One or two injections are given each week until the maximum dose without reaction is attained. The maximum dose when attained may be given at weekly intervals for months. Another plan is to reach the maximum dose, stop the treatment for months, and then start it again, beginning with the smallest dose.

The initial dose and the maximum dose of certain tuberculins are given in the following table taken from the valuable work of Hamman and Wolman on "Tuberculin." The dose is expressed in cubic centimeters instead of grams:

Tuberculin.	Initial Dose.	Maximum Dose.
O. T.	0.000,000,1 to 0.000,001 c.c.	1 c.c.
T. R.	0.000,001 to 0.000,1 c.c.	2 c.c.
B. E.	0.000,001 to 0.000,1 c.c.	2 c.c.
B. F.	0.000,000,01 to 0.000,000,1 c.c.	1 c.c.
Béraneck's	Of A/32, 0.05 c.c.	Of H 1 c.c.

Wright gives very small doses of emulsion of powdered bacilli, not with the idea of causing directly body immunity to tuberculin, but to produce immunity by strengthening the phagocytic power of the leukocytes.

When this plan is followed the dose is determined by the opsonic index, and the dose is only raised to a sufficient degree to establish the positive phase

without producing even the most trivial subjective symptoms. One dose causes an increase of immunizing power in the body for about a fortnight and then another dose is given. Many clinicians deny positively the need of giving the dose by the opsonic index. When tuberculin is given by either of the above plans it is entirely safe, and I believe, beyond doubt, is of value in suitable cases. It is not to be used in advanced cases or in febrile conditions. For lupus, tuberculous glands, tuberculous bones, or tuberculous joints one dose a week is given. It is of real service in these conditions, but general treatment must not be discontinued because tuberculin treatment is employed. It may be used after operation to prevent recurrence. When given in this way it is safe, never produces trouble at the site of injection, seems to arrest some cases of tuberculosis, improves the local trouble in many, and benefits the general conditions of most. According to Trudeau tuberculin strengthens the individual's immunity to tuberculosis. According to Wright it causes an increase in deficient opsonins. Tuberculin is of unquestionable value in some cases of lupus.

Ringer has recently strongly advocated the use of tuberculin ("Jour. Am. Med. Assoc.," May 2, 1908). Maragliano treats tuberculosis with the serum of animals which have been injected with dead bacilli and toxins, and he believes that this serum contains quantities of antibodies and antitoxins. The animal is injected many times until its serum becomes highly agglutinative. Maragliano believes that this highly agglutinative serum when introduced into the human body causes the protective mechanism of the body to produce quantities of antibodies and antitoxins. Most clinicians do not favor the use of Maragliano's serum.

The Local Treatment of Tuberculosis.—When certain drugs are directly inserted into a tuberculous focus they possess an antagonistic influence. Iodoform is the most powerful of these drugs; guaiacol, balsam of Peru (Landerer), bismuth, and chlorid of zinc (Lannelongue) have a similar action. Iodoform has little or no influence when placed on a free surface exposed to the air, but when in the form of an emulsion it is injected into a tuberculous area, the air being excluded (see page 30), this drug is powerfully antituberculous. Chlorid of zinc seems to act by causing the development of quantities of fibrous tissue, which encapsulates or, perhaps, replaces the tuberculous focus. Some surgeons inject tuberculous nodules with camphorated naphtol. Every region of tuberculosis requires local rest, perhaps by the use of a splint or a brace.

Special Methods of Surgical Treatment.—The surgeon may endeavor to extirpate a tuberculous focus, or to drain it thoroughly and to sterilize the area. Extirpation is sometimes, although not very frequently, possible. Complete extirpation is a valuable method, but partial extirpation is dangerous. If a part only of a tuberculous focus is extirpated, many lymph-tracts and blood-vessels are opened; and the incomplete operation may lead to the dissemination of the disease. The methods of surgical treatment suited to different forms of tuberculous disease will be discussed in different sections of this book.

Bier's Method by Congestive Hyperemia (see page 112).—Bier believes that passive hyperemia is of the greatest possible benefit. Active hyperemia is obtained by heat, and is especially valuable to induce the absorption of the products of a non-tuberculous chronic inflammation. Passive hyperemia is particularly useful in tuberculosis of joints, tuberculous ulcers, cold abscesses, and tuberculous disease of the tarsus, carpus, and phalanges. If a limb is affected, passive hyperemia is obtained by placing a rubber band around the limb above the part, the band being applied with sufficient firmness to interfere with venous return, but not so tightly as to block arterial entry. This band should be applied daily, and should be kept in place for an hour or so at each application, but pain should not be produced. In the intervals between

the treatments the limb should be at rest. Bier uses special apparatuses for obtaining congestive hyperemia in various parts of the body.

I have seen cure or very great improvement follow this treatment in a number of cases. It is founded on the old idea of Laennec that cyanosis and tubercle are antagonistic. Why this method is beneficial is much debated. Some think that the imprisoned blood takes on increased bactericidal power; some, that the number of leukocytes is greatly increased; some, that quantities of leukocytes migrate; and some, that the amount of bactericidal blood-serum is increased. Bier believes that it depends upon phagocytosis. It would seem possible that the cells in this locality, under the influence of the congestive hyperemia, may form powerful antitoxins.

Heliotherapy.—(See page 231.)

The Finsen Light.—Finsen pointed out that the chemical rays in sunlight are powerfully germicidal, and that this germicidal power can be notably increased if the rays are concentrated on a part by the use of particular apparatus. He also showed that enormous numbers of chemical rays can be obtained from electric light. The Finsen treatment to-day consists in applying the actinic rays obtained from electric light. They act most powerfully on lupus, but require a very long time to effect a cure.

The *x-rays* are of value in treating certain tuberculous conditions. They are of most use in lupus, their effects in this disease being nearly as powerfully curative as those of the Finsen light, and much more rapid.

The **tuberculous abscess** is called also the *cold*, the *lymphatic*, the *congestive*, the *scrofulous*, the *strumous*, the *wandering*, or the *migrating abscess;* and it is very commonly called the *chronic abscess*. The Germans call it *Senkungsabscess*. Tuberculous abscess is the best designation, as this indicates the cause of the trouble.

The term "cold abscess" is often used because the cutaneous surface over the disease is not warmer to the touch than is the skin of the corresponding part of the opposite side of the body. The term "lymphatic abscess" was employed because it was once thought that such abscesses arose only from lymphatic structures. Scrofulous abscess was the name given it when scrofula was supposed to be a definite disease, the common phase of which was this form of abscess. The term "chronic abscess" is employed because the condition usually develops slowly, and does not present the evidences of acute inflammation; an acute pyogenic abscess developing, as a rule, rapidly, and presenting positive signs of inflammation. I agree with the late Professor Ashhurst that the term "chronic," in this connection, is improper, as it tends to give a wrong idea. It refers merely to time; and we know that a genuine pyogenic abscess that is deep seated may be rather slow in developing, and that a tuberculous abscess that is superficial may develop with considerable rapidity. When used properly, the term "chronic abscess" means that real pus exists, this pus having arisen from the pyogenic infection of the granulation tissue of a lesion of syphilis, tuberculosis, or actinomycosis. In other words, a genuine chronic abscess is secondary pyogenic infection of an infective granuloma. The terms "wandering," "migrating," "gravitating," and "congestive" have been used because the fluid products of a tuberculous inflammation are liable to wander a considerable distance away from the primary focus of disease. For instance, a tuberculous abscess that is discovered in the groin may have arisen from tuberculous caries of the vertebræ. This tendency to wander is not due to gravity, as one of the names of the condition would suggest; but the wandering always takes place in the line of least resistance.

It will be seen from the foregoing that a true tuberculous abscess is not an abscess at all, because it does not contain genuine pus. It is a collection of the degenerated products of tuberculous inflammation; and a tuberculous abscess

may be defined as a circumscribed cavity of new formation, containing the degenerated products of a tuberculous inflammation. These products may have been formed in that region or may have passed to that point from some adjacent or distant focus of tuberculous disease. If a supposed tuberculous abscess is found to contain genuine pus, there must have been mixed infection with pyogenic bacteria; and such mixed infection either causes violent and dangerous inflammation or leads to the formation of a true chronic abscess, in which there is no sign of acute inflammation. The tubercle bacillus is not pyogenic. It can produce inflammation, but not pus, and pus can be formed in a tuberculous focus only by secondary infection with pus bacteria.

Situations of Tuberculous Abscesses.—These abscesses are particularly apt to form as the result of tuberculous disease of bones, joints, lymph-glands, and subcutaneous connective tissue, but the brain, any viscus, or any tissue in the body may present the condition.

Age.—No age is exempt, but children are most prone to the trouble; and the period of greatest liability is before the age of twenty years.

Contents.—The usual terms for the contents are scrofulous, curdy, or caseous pus. As previously stated, it is not true pus, but it resembles pus when viewed by the naked eye. Examination of this fluid by staining methods, by cultures, and by inoculations shows that it contains no pyogenic bacteria. It consists of liquefied and caseated tubercle, masses of coagulated fibrin, and bits of necrotic tissue. The tuberculous material is whitish, yellowish, or yellowish green, thick, and without odor. Floating in this pus are portions of caseous matter, which, as the elder Gross said, resemble bits of soft-boiled rice. Occasionally the tuberculous material, especially if it comes from disease of a lymph-gland or of a bone, is almost watery and nearly colorless, and contains curd-like masses, consisting of tuberculous granulations, coagulated fibrin, and necrotic tissue. It was previously stated that tuberculous pus is free from odor. This is not true of tuberculous pus from the ischiorectal fossa, which is highly putrid; but in an ischiorectal abscess, as a matter of fact, there is usually mixed infection with pyogenic organisms, as well as with the organisms of putrefaction. If tuberculous pus is permitted to stand, the curdy mass settles to the bottom, and a thin serous fluid remains above.

Formation of Tuberculous Abscess.—The growth of tubercle bacilli in the tissues causes chronic inflammation. The cells of the tissues, especially the fixed cells, proliferate and form granulation tissue. This granulation tissue consists of multitudes of cell clusters, and each cluster is called a primitive tubercle (see page 214). Each individual tubercle enlarges; myriads of new ones form, and many of the old ones fuse. These new cells, however, do not become vascularized. In the earliest stage of their formation there are blood-channels, but these become closed through endothelial proliferation and through the pressure of cells external to them. The tuberculous area then becomes absolutely avascular. This avascular mass of cells is composed of what are known as epithelioid cells, and the cells obtain nourishment by imbibition. The nourishment is very incomplete. As the nodule enlarges the nourishment grows more and more insufficient. Finally, the adjacent blood-vessels that furnished the fluid for imbibition become occluded, and nourishment is no longer possible. The toxins of the tubercle bacilli, acting upon this area of greatly lowered nutritional activity, produce coagulation necrosis, and caseation follows this. The caseation begins at many points near the middle of the tuberculous nodule. Each area of caseation enlarges. Several of them fuse, and eventually many caseated areas coalesce. The tuberculous lesion may be spreading at the periphery at the same time that it is undergoing caseation at the center. The bacilli in the caseated material soon die for want of nourishment. When an area of caseated tubercle is liquefied by the addition of serum,

what we call caseous or curdy pus is produced, and the lesion is then known as a tuberculous abscess.

The **wall of the abscess** is formed by compressed or solidified tissues. In a very recent case the wall is soft and will readily collapse. In an old case it is dense or actually fibrous and will not collapse. This wall of compressed tissue is not, as used to be thought, a pyogenic membrane which secretes the tuberculous material, but it actually surrounds the tuberculous material and hinders its diffusion. As Roswell Park says, it is not a pyogenic membrane, but it is a prophylactic membrane. The inner surface of the wall of the compressed tissue is lined with tuberculous granulations, which at different points show different stages of the tuberculous lesion. This layer of tuberculous granulations is known as *Volkmann's membrane.* The fluid in the abscess may contain a few living bacteria, but often none can be found; and certainly the bacteria are not multiplying in this fluid, but they exist in numbers and multiply in Volkmann's membrane. When tuberculous matter has been long retained and is thoroughly encapsuled the bacilli soon die for want of nourishment, and because a culture from a supposed tuberculous area fails to show the bacilli of tuberculosis we have not obtained conclusive evidence that the area is not tuberculous. We know this same fact to be true of the fluid of tuberculous empyema.

From the abscess wall there may be one, two, several, or many sinuses tracking out. These sinuses are lined with granulation tissue exactly like the Volkmann's membrane in the main abscess; and they may spread by a sort of crawling progression for long distances, perhaps passing through dense fascia, and at their terminations may form secondary tuberculous abscesses. The wall of an abscess may contain expansions or loculi. If an abscess spreads to some distant place, the tuberculous infection, of course, goes with it, and it is the tuberculous infection that causes the spread. The wandering of a tuberculous abscess is in the line of least resistance, and is not the result of gravity. Injury, breaking, or contusion of this granulation tissue, if unaccompanied with the removal of all the tissue or the killing of all the germs it contains, may diffuse the infective matter and actually cause disseminated tuberculosis. We sometimes see such dissemination after spontaneous opening, non-aseptic operation, or forcible squeezing; and particularly after an imperfect operation that removes only a part of the tuberculous area.

Terminations of Tuberculous Abscess.—The abscess may slowly and gradually enlarge, and finally open of itself, either on the skin or on the mucous surface, or into some viscus or joint. It may become encapsuled by fibrous tissue, there being absorption of the fluid and shrinking of the entire focus, the caseous part perhaps remaining or becoming calcified. The tuberculous abscess may actually be replaced by fibrous tissue, and this constitutes a permanent cure. When the tuberculous area is merely encapsuled by fibrous tissue, some living bacilli may remain latent in the wall; and long afterward, as the result of injury or of some other damage, an abscess may re-form at the old site of disease. Sir James Paget called this condition *residual abscess.* As a rule, the abscess, as it shrinks, tends toward cure. The bacilli usually die for want of material to nourish them, but occasionally they remain latent for a long period of time. When they do die, the tuberculous granulation tissue may become healthy tissue, be vascularized through the entrance of blood-vessels, and be converted into scar-tissue. Tuberculous abscess may also be cured by a surgical operation.

Secondary Infection of a Tuberculous Area by the Bacteria of Suppuration.—This is liable to occur when the abscess undergoes spontaneous evacuation, and may occur when it has been opened by the surgeon. It occasionally occurs when the abscess has neither undergone spontaneous evacuation nor has

been opened by the surgeon, having been infected apparently as a point of least resistance. When such infection does occur, there is, in all probability, some area of ordinary suppuration elsewhere in the person's body, and the bacteria of suppuration have entered the body fluids. Pyogenic infection is apt to produce violent inflammation and profuse suppuration—a condition that is extremely dangerous, because septicemia is very liable to develop. In some very rare cases suppuration destroys the tuberculous area and cures the tuberculous disease. More commonly, however, it produces illness, and in large abscesses it may cause death. Because of this liability to secondary infection surgeons were long opposed to operating on tuberculous abscess unless it was evidently going to evacuate itself. In some cases secondary infection produces a true chronic abscess (see page 235). Infection by streptococci is much more dangerous than is infection by staphylococci. Acute inflammation with dangerous constitutional symptoms is particularly apt to arise if the walls of the abscess contain very little tuberculous tissue, if they have been bruised or damaged by powerful chemicals, if there is poor drainage (and there is certain to be poor drainage if loculi exist, or if the incision is small and blocked with plugs of fibrin or necrotic tissue), if a partial or imperfect operation has been performed, if a number of virulent bacteria have been introduced, or if the vital resistance is at a low ebb.

Secondary Infection by the Bacteria of Putrefaction.—This complication is extremely grave and may produce death. It is commonly associated with pyogenic infection. The wound fluid becomes intensely putrid, violent acute inflammation arises, and the absorption of materials from the wound induces the systemic condition known as sapremia or putrid intoxication.

Signs and Symptoms of Tuberculous Abscess.—A purely tuberculous abscess presents no evidence of inflammation except swelling; and, owing to the absence of heat, it has received its name of cold abscess. The cutaneous surface looks and feels normal or is paler than normal until the structures just beneath the skin or the skin itself become involved. When this happens, livid discoloration appears, but the lividity presents a very different appearance from the dusky discoloration of an acute abscess. Neither is the skin edematous or glossy as it is in acute abscess.

There is rarely tenderness in the region of the abscess, and still more rarely spontaneous pain. Pain and tenderness, although frequently absent in the area of a tuberculous abscess, may be complained of at the primary focus of disease. Tenderness is especially likely to be noted at the primary focus; and in cases of joint tuberculosis and of bone tuberculosis it is nearly always present. There may or may not be pain at the primary focus, but referred pain is frequently complained of. For instance, in tuberculous disease of the hip-joint the pain may be referred to the inner side of the knee; and severe bellyache is frequently observed in Pott's disease of the spine. At the point to which pain is referred, however, there is seldom tenderness. For instance, in the bellyache, particularly of Pott's disease of the spine, the belly is not tender, although the spine may be. In sacro-iliac tuberculosis the pain is often referred to the distribution of the sciatic nerve, but the nerve is seldom tender on pressure. In a psoas abscess we find that pain in the spine can be induced by pressing on the spinous process of the diseased vertebra, by concussion to the heels or the head when the spine is held stiff, and especially by flexion of the spine; but the spinal pain is lessened or completely abolished by extension, fixation, and rest. The primary focus of disease, if spinal or articular, produces rigidity in the adjacent muscles, and rigidity secures rest by inhibiting movement, but it also impairs the function of the part. In an intra-abdominal tuberculous abscess there is rigidity of the abdominal muscles.

In a tuberculous abscess fluctuation is usually obtained readily, because

the fluid is not surrounded by a thick mass of granulation tissue and also because a considerable amount of fluid is usually present. A notable characteristic of a tuberculous abscess is the tendency to wander, and it may appear with suddenness at some distant point. Abscesses of the spine wander long distances, but the wandering is not the effect of gravity, and is due to the disposition of the tuberculous matter to travel in the line of least resistance. The temperature of the body may be entirely normal if the infection is purely tuberculous. As a rule, however, there is a slight evening elevation; and the patient is weak and pale, grows tired readily, sleeps poorly, and has a wretched appetite and impaired digestion. The blood examination sometimes shows a notable diminution in the number of red blood-cells, and the hemoglobin is usually lowered to 60 or 70 per cent. There is no leukocytosis. In multiple tuberculous foci, and particularly in tuberculosis in children, there is a marked decrease in the red blood-cells. If secondary infection occurs, there is a rapid and progressive diminution in the number of red cells and usually a trivial increase in polynuclear leukocytes.

A tuberculous abscess underneath the deeper fascia may break through the fascia by making a small opening, and a large secondary abscess may arise in the subcutaneous tissue. The entire abscess is thus shaped like an hourglass, the opening through the fascia being the narrowest point. Such an abscess is called a *shirt-stud abscess*. A tuberculous abscess is liable to form one, several, or many sinuses, and the end of each sinus may expand into a secondary abscess. The surgeon must always make a careful examination to try to determine whether the abscess is the primary disease focus or whether the tuberculous matter has wandered from a distant point. He must also make a thorough examination to see whether anywhere in the body there are other regions of disease. He will often find such a region of disease; for instance, in the lungs. In many cases, however, there is no clinical evidence that other areas of tuberculous disease exist.

A deeply arising tuberculous abscess usually requires weeks or months to reach the overlying skin or mucous membrane and undergo spontaneous evacuation. That spontaneous evacuation is imminent is shown by livid discoloration and thinning of the skin. Finally, at the area in which the skin is thinnest a little tit is elevated. This condition is known as pointing and a rupture occurs at this point, tuberculous pus running out. Spontaneous evacuation is a peril, because it is liable to be followed by secondary pyogenic or putrefactive infection. After spontaneous evacuation has occurred, a true chronic abscess may form; but there may instead be violent acute inflammation, manifested locally by pain, heat, and dusky discoloration. If acute inflammation does arise there develops a fever, which presents evening exacerbations and morning remissions, and is accompanied by an exhausting sweat during the night or early morning. Fatal septicemia or sapremia may follow spontaneous evacuation.

Results of a Tuberculous Abscess.—It may undergo spontaneous cure, and the cure may be lasting, but long after an apparent cure a new abscess may form (the residual abscess of Sir James Paget). A tuberculous abscess may remain stationary for a very long time, and then perhaps diminish in size and be cured, or extend in size and rupture. After spontaneous rupture, suppuration may cure the tuberculous area by annihilating the tuberculous tissue; but, as a rule, after spontaneous rupture there is either an acute septic process or a chronic suppuration, constituting a genuine *chronic* abscess.

Amyloid Disease.—The pyogenic infection of an area of chronic tuberculous, especially a bony area, if it induces long-lasting suppuration, may lead to the development of *albuminoid*, *amyloid*, *waxy* or *lardaceous disease*. Pyogenic infection of a tuberculous area, though by far the commonest, is not the only cause of amyloid disease. It may arise when there has been no pyogenic infec-

tion of the tuberculous area. It may arise after prolonged ordinary suppuration. It may follow bone syphilis, and may be due to cancer, Bright's disease, malaria, chronic dysentery, or prolonged lactation. In this condition a peculiar material is deposited in the middle coat of the smaller arteries and later the inner coat is involved. The albuminoid substance resembles fibrin and there has been much dispute as to its nature. One theory is that this deposit takes place from blood-serum which has been dealkalinized because the flow of pus has removed potash salts from the blood. Krakow seems to have demonstrated that the albuminoid material is a combination of chondroitin-sulphuric acid and histon. This acid, carried by the blood or lymph, "combines with a protein of the fixed tissues" (W. Taylor Cummins, "Proceedings of Patholog. Soc. of Philadelphia," Dec., 1910).

In rare cases this deposit is only a local mass. The corpora amylacea of the prostate and nervous structure are due to albuminoid deposit. Such a deposit may take place directly in a tuberculous focus or a syphilitic lesion.

In the vast majority of instances the disease is general, involving blood-vessels, the membrana propria of mucous membranes, the liver, the kidneys, and especially the spleen. The lymph-glands, tonsils, stomach, intestines, heart, and connective tissues are less often involved. The amyloid material is deposited between the cells and not in them. The tissues of a subject of amyloid disease are very prone to suppurate from even slight infection.

In all or nearly all cases the spleen is involved. The victim of general albuminoid disease is pale, greatly exhausted, emaciated, and very anemic; suffers from diarrhea and usually develops capillary hemorrhages beneath the skin and mucous membranes. The albuminoid material can be detected chemically in the urine if the kidneys are involved. Albuminoid degeneration is incurable and is usually fatal; but if the patient is subjected to proper treatment soon after it begins it may be arrested and never progress.

Diagnosis of Tuberculous Abscess.—The fluctuation, the absence of evidences of acute inflammation, the tendency to wander, and, in some cases, the sudden appearance, mark the diagnosis. The surgeon always examines with care to see whether there is some distant tuberculous focus from which the abscess may have wandered, or whether the abscess itself is at the primary seat of disease. The advancing impairment of the general health, the lessened amount of hemoglobin, the normal or almost normal temperature, and the absence of leukocytosis are points in the diagnosis of the condition. In a doubtful case the aseptic use of the tubular exploring needle is important, the fluid that emerges being studied by the microscope after staining, by cultures, and perhaps by inoculating it into guinea-pigs. The fluid that is withdrawn may contain no bacteria that can be demonstrated; but if it is sterile, one should strongly suspect tuberculosis. Various diagnostic tests for tuberculosis will be found on pages 226, 227, 228, 229, and 230.

Prognosis.—Advanced albuminoid degeneration makes the prognosis of tuberculous abscess hopeless and any extent of albuminoid degeneration is unfavorable. Secondary pyogenic infection, as already stated, may produce death or a lingering suppuration. The prognosis is worse in very young children than in adults; and in any case it is unfavorable if the exhaustion deepens, if the anemia is marked, if there are tuberculous lesions in distant parts or in important organs or structures, if the patient is unable to take enough food or if he cannot digest what he does take, and if the regions of tuberculosis cannot be extirpated or sterilized. Under other circumstances the prognosis is favorable.

Tuberculous Abscesses in Various Regions.—**Tuberculous abscess of the head of a bone** (see Brodie's Abscess, page 497) arises in the cancellous structure of a long bone, most often in the head of the tibia, and is fre-

quently noted as having been preceded by a trivial traumatism. The focus of tuberculosis seldom induces severe symptoms unless secondary pyogenic infection occurs. A tuberculous nodule forms as a result of tuberculous osteomyelitis. The bone about the nodule is hyperemic, the bony trabeculæ are thickened, and the cancellous spaces "are devoid of fat cells, and they contain a swollen semifibrous material" (Warren's "Surg. Pathol."). The center of the nodule becomes cheesy, the bone trabeculæ are absorbed, and the bone becomes cheesy and broken up, the cheesy mass containing bone fragments. Finally the area becomes filled with tuberculous pus, the cavity which contains it being lined with tuberculous granulations. Distinct sequestra may form and the bone about the diseased focus undergoes sclerosis. In tuberculous abscess of bone pain is continued, but is not usually very severe, is of a boring character, and is worse when the patient is in bed. Attacks of synovitis arise from time to time in the adjacent joint. The bacteria of tuberculosis obtain access to the bone by means of the blood, and find in the bone a point of least resistance. There is no such thing as an acute abscess of bone. A pyogenic inflammation, of such severity that it would cause an acute abscess in soft parts, in bone causes acute necrosis. A less violent pyogenic infection causes a very chronic suppuration.

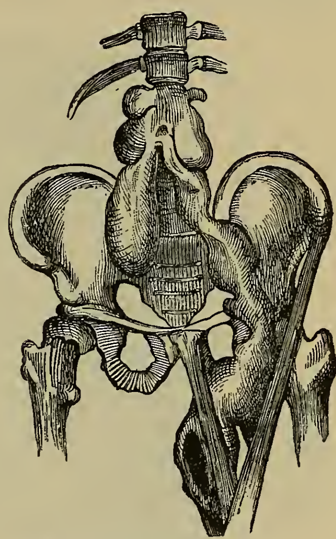

Fig. 102.—Psoas abscess (Albert).

Retropharyngeal or **postpharyngeal abscess** is often tuberculous. Such an abscess is usually due to caries of the cervical vertebræ, but can arise in the connective tissue of the parts or as tuberculous adenitis. An abrasion of the mucous membrane may admit the bacilli to the connective tissue or the glands. A swelling projects from the posterior pharyngeal wall, and there is great interference with respiration and deglutition. Caseous matter from caries of the cervical vertebræ may reach the posterior mediastinum by following the esophagus, or may appear in front of or behind the sternomastoid muscle in the neck (Edmund Owen). A tuberculous abscess back of the pharynx is apt to undergo pyogenic infection, in which case the patient develops fever, sweats, pain, and prostration.

Dorsal Abscess.—The tuberculous matter in dorsal abscess arises from dorsal caries, flows into the posterior mediastinum, and reaches the surface by passing between the transverse processes. The tuberculous matter from dorsal caries may run forward between the intercostal muscles or between these muscles and the pleura, pointing in an intercostal space, at the side of the sternum, or by the rectus muscle. It may burst into the gullet, windpipe, bronchus, pleural sac, or pericardium. It may descend to the diaphragm and travel under the inner arcuate ligament to form a psoas abscess, or under the outer arcuate ligament to form a lumbar abscess. A psoas abscess may point above Poupart's ligament or in the lumbar region. If it extends below Poupart's ligament it usually points external to the femoral vessels (a characteristic which is said to distinguish it at once from an ordinary femoral hernia), but may burrow in any direction.

Iliac abscess arises from lumbar caries, the swelling lying in the iliac fossa and pointing above Poupart's ligament.

Psoas abscess is usually due to lumbar caries, but may arise from dorsal

caries. The fluid usually points in Scarpa's triangle external to the femoral vessels, but may descend much lower (Fig. 102). A psoas or iliac abscess, by following the lumbosacral cord and great sciatic nerve, forms a gluteal abscess. These abscesses may open into the bowel, bladder, ureter, or peritoneal cavity. A hernia is almost never mistaken for a psoas abscess, but a psoas abscess is sometimes mistaken for a hernia (Fig. 103). J. Torrance Rugh points out that without a search for spinal kyphosis or muscular rigidity the mistake may be made, but that the presence of a mass in the iliac fossa continuous with the external lump eliminates the possibility of the condition being hernia.

Lumbar Abscess.—In a lumbar abscess the fluid produced by dorsal caries descends beneath the outer arcuate ligament, or the fluid from lumbar caries which collected anterior to or in the quadratus lumborum muscle passes between the last rib and iliac crest in the triangle of Petit, the small space bounded by the crest of the ilium, the posterior edge of the external oblique muscle, and the anterior edge of the latissimus dorsi muscle.[1]

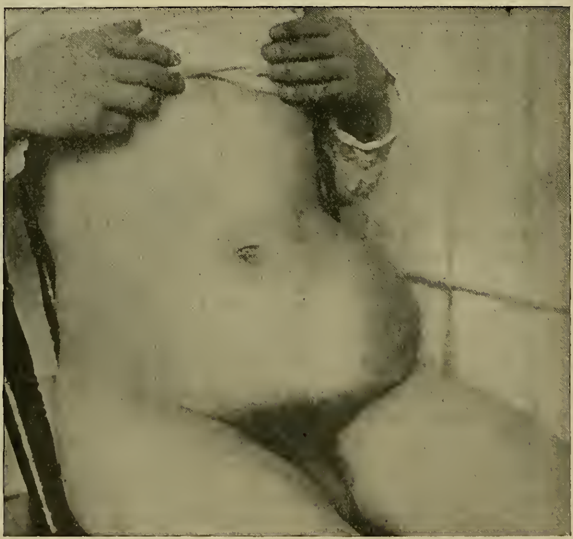

Fig. 103.—Case of cold abscess of the abdominal wall which had been treated as a hernia.

Tuberculous abscess of the neck results from tuberculosis of the cervical glands. It is not often that such an abscess attains any considerable size. It tends strongly to spontaneous rupture, and, if this is permitted to occur, a livid, corrugated scar results.

Tuberculous Abscesses of Joints.—(See Section XIX.)

Tuberculous Abscess of Rib.—It is not uncommon to find a tuberculous abscess of moderate size about a tuberculous rib. The pleura may become involved secondarily.

Tuberculous mediastinal abscess may result from the downward passage of a cervical abscess; from tuberculosis of the sternum, ribs, vertebræ or pleura, or from tuberculous mediastinal glands.

Tuberculous abscess of the breast is a caseated and liquefied a ea of tuberculosis of the breast. A lump is detected, which slowly enlarges and finally ruptures, sinuses being formed. The axillary glands are apt to be implicated. The patient may belong to a tuberculous stock, as a rule gives a history of

[1] For a lucid description of these abscesses see Owen's "Manual of Anatomy," from which much of the above is condensed.

previous tuberculous troubles of various sorts, and has usually borne children. Tuberculous abscess of the breast causes little or no pain.

Treatment of Tuberculous Abscess.—For many years the majority of surgeons would not open a tuberculous abscess unless it was on the point of rupturing. With the advent of antiseptic surgery it was assumed that aseptic incision and drainage would be the proper treatment for these cases; but the results, except in small superficial tuberculous abscesses, have been extremely disappointing. If a large abscess is so treated, pyogenic infection will, in all probability, sooner or later occur, with all its possibilities of disaster. Incision and drainage is, therefore, restricted to small and superficial abscesses.

Treatment of Small Superficial Tuberculous Abscesses.—The surgeon must remember that after one has opened an apparently superficial abscess it is his duty to make an examination to see that there is no channel connecting the abscess with a deep or a distant focus. If he finds such a channel, he may be disposed to follow one of the plans of treatment outlined below and on page 244. It is also his duty to see whether there are sinuses tracking off from the abscess; and if these exist, he must slit them up. If there are loculi in the wall of the abscess, he must stretch their mouths. He must be particularly careful to see that he is not dealing with a *shirt-stud abscess*, in which there is a little opening through the deep fascia connecting the abscess above with the abscess below. In a shirt-stud abscess the deep fascia must be freely incised. After the abscess has emptied itself, its walls must be thoroughly scraped with a curet, and the cavity must be drained with a tube or, preferably, with iodoform gauze. If the skin above a superficial abscess is diseased and discolored, and the abscess is on the eve of spontaneous rupture or has ruptured, the discolored skin must be cut away with scissors. If the discolored skin is allowed to remain, a livid and jagged scar will inevitably result. If it is cut away a healthy scar, not very deforming, will result.

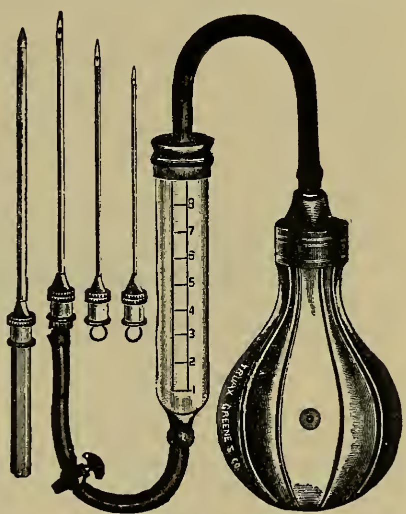

Fig. 104.—Senn's injection syringe.

Treatment of Tuberculous Abscesses of Considerable Size.—*Method* 1. *Aspiration, Irrigation, and the Introduction of Iodoform.*—The operation is carried out with the most scrupulous aseptic care. The trocar is passed through the sound skin; is carried beneath the skin for an inch, as Senn suggests; and is then made to enter into the cavity of the abscess. The stylet is pulled out, and the flow of fluid is aided by very delicate pressure. Occasionally the tube will become blocked by necrosed tissue or plugs of fibrin. It is opened up again by pushing in a wire or forcing through it a stream of sterile fluid. When tuberculous matter ceases to run out of the trocar, a very warm solution of boric acid is thrown in in order to wash the abscess walls. This can be injected with a fountain syringe or with the special apparatus of Senn (Fig. 104). Enough of it is allowed to enter to overdistend the abscess-cavity, as Mr. Callender long ago advised. The fluid is then allowed to pass out; fresh fluid is passed in; and this procedure is repeated, perhaps again and again, until entirely clear fluid flows out. When this takes place, an emulsion of iodoform is thrown in by Senn's syringe. A 10 per cent. emulsion in glycerin is as satisfactory

as the more elaborate formulas. Verneuil used to employ iodoform and ether; but this is painful, is more liable to cause iodoform-poisoning, and sometimes induces gaseous distention and ruptures the wall of the abscess. In order to prevent the danger of iodoform-poisoning the surgeon should not introduce at one time more than 8 dr. of the emulsion, if dealing with an adult; or more than 4 dr., if dealing with a child. After the emulsion has been inserted into the abscess-cavity the wound in the skin is sealed with a bit of gauze and iodoform collodion. Gauze is fluffed up and laid on the skin above the abscess, and the walls of the cavity are then forced toward each other by applying a roller bandage. The part is put at complete rest, and it is usually necessary to put the patient in bed. Sometimes, although very seldom, one injection will produce a cure; but usually, after one or two weeks, it will be observed that the cavity has to some extent filled again. A second operation is then performed; and, if improvement is really taking place, it will be found that the fluid is not nearly so thin as it was at the first operation. It is needless to persist in this method after six or seven attempts have failed to cure. If the abscess has thick and uncollapsed walls it is not fitted for treatment by aspiration and injection.

Method 2. *Incision, Cleansing, and Suture.*—If, owing to the considerable size or the rather rigid walls of the abscess, one believes that the aspiration method would be useless; or if the aspiration method has been tried and has failed, one may adopt the following plan. It should not, however, be employed if the walls are *very* thick and rigid. An incision is made at the most

Fig. 105.—Barker's sharp-edged irrigating curet ("Keen's Surgery").

dependent part of the abscess. The walls are scraped carefully with Barker's sharp-edged irrigating curet (Fig. 105), and are rubbed smooth with bits of gauze. The part is freely irrigated with hot boric acid solution, and pressure is applied to arrest bleeding. Iodoform emulsion is introduced; the skin is sutured; dressings, compresses, and bandages are applied, and complete rest is secured. This operation may cure an abscess, or it may be necessary to repeat the procedure two or three or many weeks afterward.

Method 3. *Incision and Removal of the Primary Focus of Tuberculosis.*—If the surgeon does not wish to use the iodoform treatment, or if it has failed, and if he finds that the primary seat of disease may be attacked and removed, an operation should be undertaken to get rid of Volkmann's membrane in the last-formed abscess and also to remove the primary tuberculous focus. An incision is made, when possible, that will lay open not only the last-formed abscess, but the primary lesion. Tuberculous tissue is thoroughly removed by Barker's spoon and by rubbing with gauze or, perhaps, by scissors and forceps. Any focus of bone disease is curetted and touched with pure carbolic acid, and loose fragments of bone are removed. The part is irrigated with a hot solution of boric acid; bleeding is arrested by pressure, and the wound is nearly, but not quite, closed, drainage being inserted at the most appropriate spot. Dressings, compresses, and bandages are then applied. In this operation the entire tuberculous area has been removed and the raw surfaces have been forced into contact, and there is scarcely more danger of secondary pyogenic infection than there is in any ordinary wound.

General Treatment.—It is never to be lost sight of that in every case of

tuberculous abscess the general treatment of tuberculosis must be rigorously pursued (see page 230). In the treatment of a cold abscess give nutritious food, cod-liver oil, quinin, iron, and the mineral acids. Removal to the mountains or the seaside is often indicated, life in the open air is imperative, and mechanical appliances may be needed for diseases of the bones and joints.

Tuberculous Abscess of Bone.—Make an incision to bare the bone. Open the abscess with the trephine, the gouge, or the chisel; curet the interior of the wall of the cavity with a sharp spoon and rub it with bits of gauze; cut away the edges of the bone with rongeur forceps; irrigate the cavity with hot normal salt solution, dry its walls with gauze, and paint the cavity with pure carbolic acid; pack with iodoform gauze and apply antiseptic dressings. It is better not to employ an Esmarch apparatus. Bleeding will not be severe, and when no apparatus is used to prevent bleeding it is possible to see and thus be sure that all the diseased bone has been removed.

Tuberculous Abscess of Lymphatic Glands.—In non-exposed portions of the body the capsule of the gland should be incised and dissected or scraped away and the cavity swabbed out with pure carbolic acid or iodin and packed with iodoform gauze, but drainage should not be prolonged. If the abscess is allowed to burst, it will cause an ugly scar; therefore, in exposed portions of the body, as the neck, special effort should be made to prevent a scar by incising early before the skin is involved. When only a little caseated matter exists and the skin is not discolored, prepare the parts antiseptically, incise, rub the interior with gauze, inject iodoform emulsion, and suture the wound. It used to be a custom in such cases to carry a silk thread by means of a needle through the skin, through the gland, and out at its lowest point, the part being then dressed with gauze. In three days the thread was removed and a firm compress was applied. The plan is not satisfactory and incision is to be preferred. When the gland is almost entirely broken down and the skin above it is becoming purple and thin, insert a hypodermatic needle through sound skin into the abscess, draw off the fluid tuberculous matter, and inject iodoform emulsion. This procedure is to be repeated when the fluid again accumulates. By this means we can sometimes effect a cure in a week or so. When an abscess breaks or is on the point of breaking, cut away all purple skin, curet the abscess walls (the abscess having become a tuberculous ulcer), remove the remains of gland and capsule, swab the cavity with pure carbolic acid, and dress with iodoform and antiseptic gauze.

Tuberculous glands, if not cured by general treatment, ought to be extirpated. They should certainly be extirpated before they caseate and form an abscess. If an abscess does form it is treated as directed above, and after healing takes place the diseased glands may be extirpated. If sinuses exist they are curetted and touched with iodin or carbolic acid. After healing, the glands are extirpated. When sinuses exist there is always mixed infection.

Tuberculous Abscess of a Rib.—This lesion requires incision of the soft parts and resection of the diseased bone. The tuberculous area is thoroughly curetted, rubbed with pure carbolic acid, and packed with iodoform gauze.

Tuberculous Mediastinal Abscess.—In tuberculous abscess of the mediastinum aspiration and injection of iodoform may prove efficient. In some cases it will be necessary to open and drain.

Tuberculous Abscess of the Mammary Gland.—Many operators simply incise, curet, pack with iodoform gauze, and dress antiseptically. It is wiser to remove the entire gland and to clear out the axilla, as in an operation for cancer, in order to prevent both recurrence and dissemination.

Large Tuberculous Abscesses.—In view of the facts that these abscesses may cause no trouble for years and that an operation may be fatal, some eminent surgeons are opposed to an operation unless the abscess is moving toward

inevitable rupture or is disturbing the function of organs by pressure. Most practitioners believe, however, and I agree with them, that this mass of tuberculous matter is a source of danger through being a depot of infective organisms which may overwhelm the system, and that death will seldom result from an operation performed by one who employs with intelligence strict antisepsis. In no other cases is attention to every detail more important, as a mixed infection may easily take place, and will probably mean death. As W. Watson Cheyne points out, over 70 per cent. of cases of spinal abscess treated by aseptic methods recover completely and without any real illness after such an operation. The recoveries from the old let-alone method will be infinitely less than this, and cases cured by operation usually remain well. The surgeon must always remember that the wall of the abscess and not the fluid in the cavity is the real seat of disease, and this wall must be actually removed or completely sterilized if operation is to be safe. To simply open, drain, and leave the wall to Nature to get rid of as she can is fraught with the gravest peril.

Psoas Abscess.—Some of these cases can be treated by aspiration and injection (see page 243), others by incision and subsequent suture (see page 244), others by the radical operation set forth on page 244.

Treves's operation for psoas abscess is described on page 695.

An operation occasionally performed for psoas abscess consists in an incision in the groin, an incision in the back, removal of carious vertebræ, thorough cleansing of the abscess wall, and through-and-through tubular drainage. It has been found, however, that this operation is uncertain and dangerous. It is not advisable to remove carious vertebræ unless the carious parts are loose, and through-and-through tubular drainage is rarely used unless mixed infection already exists. When a large abscess breaks spontaneously it should be widely opened at once, scraped and irrigated, rubbed with gauze, and packed with iodoform gauze. If secondary pyogenic infection of a large tuberculous abscess does occur the patient will develop septic fever and will probably die (*q. v.*).

Dorsal abscess and **lumbar abscess** are treated after the same plan as psoas abscess. One incision only is usually necessary unless the fluid has traveled to a distant point.

A **postpharyngeal abscess** must not be opened through the mouth. To open it in this manner puts the patient in danger of suffocation by fluid running into the larynx during or after the operation. Further, mixed infection of the abscess area will be certain to ensue. Septic pneumonia will be apt to arise from inhaled infected particles, and profound gastro-intestinal disturbance will be liable to develop because of the inevitable swallowing of purulent, putrid, and tuberculous masses. Incise the neck and open into the abscess by Hilton's method, going through the sternocleidomastoid muscle or behind it. Rub the wall of the abscess with bits of gauze, remove any loose bone, irrigate with hot normal salt solution, inject iodoform emulsion, insert a tube or pack with iodoform gauze.

Tuberculosis of the skin may arise from inoculation with material derived from a bovine or human source. It is frequently found that some other member of the family labors under tuberculous disease or that some family predecessor, direct or collateral, suffered from it. Stelwagon ("Diseases of the Skin") includes all cases under five heads: (1) tuberculosis ulcerosa; (2) tuberculosis disseminata; (3) tuberculosis verrucosa; (4) scrofuloderma; (5) lupus vulgaris.

Tuberculosis Ulcerosa.—The disease arises at a mucous outlet and is usually secondary to internal tuberculous disease. Small miliary tubercles form which caseate and are converted into ulcers. An ulcer is shallow,

round or oval in outline, with soft edges, the floor being composed of sluggish or edematous granulations covered with a crust. The discharge is scanty and seropurulent. In some cases there is but one ulcer; in others there are two or several, and the fusion of ulcers produces a serpiginous outline. The ulcers do not tend to heal, but gradually and steadily advance. Such ulcers are met with about the mouth, the genital organs, and the anus.

Tuberculosis Disseminata.—This occurs only in children; it is acute in onset and widespread. One type is polymorphic: spots, papules, pustules, and crusted ulcers existing, and lymphatic glands being enlarged. Another type arises after an attack of an exanthematous fever and presents "a rough resemblance to flat lupus tubercles, to sluggish acne papules, and to lichen scrofulosum" (Stelwagon, "Diseases of the Skin").

Tuberculosis Verrucosa.—*Anatomical tubercle*, the *verruca necrogenica* of Wilks, is due to local inoculation with tuberculous matter. It may be met with in surgeons, the makers of postmortems, leather workers, and butchers, usually upon the backs of the hand and fingers. It consists of a red mass of granulation tissue having the appearance of a group of inflamed warts. Pustules often form.

Scrofulodermata or Tuberculous Gummata.—By "scrofulodermata" we mean chronic inflammations of the skin, the granulation-tissue product of which caseates, mixed infection occurs, and small abscesses, sinuses, or ulcers form. A *tuberculous ulcer* has a floor of a pale color, and has no granulations at all, or is covered with large, pale, edematous granulations. The discharge is thin and scanty. The ulcer is surrounded by a considerable zone of purple, tender, and undermined skin, which is apt to slough. When healing occurs, the skin puckers and usually inverts.

Lupus begins usually before the age of twenty-five, but is met with often in individuals in middle life. It is most common upon the face, especially the nose. It is a very chronic and extremely destructive disease. Three forms are recognized: (1) *lupus vulgaris*, in which pink nodules appear that after a time ulcerate and then cicatrize partly or completely. These nodules resemble jelly in appearance; (2) *lupus exedens*, in which ulceration is very great, and (3) *lupus hypertrophicus*, in which large nodules or tubercles arise. Lupus may appear as a pimple, as a group of pimples, or as nodules of a larger size. The ulcer arises from desquamation, and is surrounded by inflammatory products which, by progressively breaking down, add to the size of the raw surface. The ulcer is usually superficial, is irregular in outline, the edges are soft and neither sharp nor undermined, the sore gives origin to a small amount of thin discharge, the parts about are of a yellowish-red color, the edges are solid and puckered and scar-like and there is no pain. The sore is often crusted, the crusts being thin and of a brown or black color; it may be progressing at one point and healing at another; it is slow in advancing, but often proves hideously destructive. The scars left by healing are firm and corrugated, but are apt to break down. Clinically, it is separated from a rodent ulcer by several points. The rodent ulcer is deep, its edges are everted, and the parts about filled with visible vessels. It is not crusted, has not a puckered edge, its edges and base are hard, and it rarely shows any tendency to healing. Many victims of lupus live twenty or thirty years and die without the development of pulmonary tuberculosis. It is estimated that one-third of those who die show signs of pulmonary tuberculosis. Lupus patients exhibit a strong focal reaction to tuberculin and also show von Pirquet's reaction.

Tuberculosis of Subcutaneous Connective Tissue.—In this form of tuberculosis tuberculous nodules form and break down (tuberculous abscesses). In the deeper tissues these abscesses are usually associated with bone, joint, or lymphatic gland disease (see Cold Abscess, page 236).

Tuberculosis of the Mammary Gland.—(See page 245.)

Tuberculosis of Blood-vessels.—It is certain that bacilli in the blood or in tuberculous emboli may establish intravascular tuberculosis.

Tuberculous Meningitis.—(See page 801.)

Tuberculosis of nerves is excessively rare. Tuberculous neuritis may arise in the course of general tuberculosis. A nerve lying in a tuberculous area may itself become tuberculous. It rarely does so, however. In fact, nerves resist infections though in the midst of them, and for this reason have been called the "aristocrats of the body."

Pulmonary Tuberculosis.—In adults the lungs are more commonly affected than any other structure. The lung affection may be primary or may be secondary to some distant tuberculous process. Pulmonary tuberculosis belongs to the province of the physician and requires no description here.

Tuberculosis of the pleura is not uncommon. Tuberculous pleurisy may be acute or chronic. In some instances mixed infection takes place and suppuration occurs. The tuberculosis may be primary, but is usually secondary to pulmonary tuberculosis, and may be due to direct extension or to rupture of an area of pulmonary softening. A primary pleurisy not due to traumatism is very apt to be tuberculous. In many cases of tuberculous pleurisy there are tubercles present and in some cases there are none.

Tuberculosis of the Alimentary Canal.—A tuberculous ulcer of the lip occasionally arises, and may be mistaken for a cancer or a chancre. A tuberculous ulcer of the tongue is commonly associated with other foci of disease. Such ulcers are separated from cancer by their soft bases and edges and by the rarity of glandular enlargements, and from syphilitic processes by the therapeutic test. Confirmation of the diagnosis is obtained by cultivations and inoculations. Tubercle may affect the pharynx, palate, tonsils, and, very rarely, the stomach.

Gastric Tuberculosis.—It is thought that the acid gastric juice must protect the stomach from tubercle, because tubercle bacilli are frequently introduced into the stomach, but the organisms very rarely lodge and multiply in the stomach wall. Furthermore, bacilli when introduced into the stomach are retained but a short time and the stomach walls contain few lymph-follicles (Barchasch, in "Beit. Z. klin. d. Tuberculose," vii, Part III, 1907). It may be assumed that gastric catarrh and motor impairment are predisposing causes. Gastric tuberculosis may be primary, but is usually secondary to pulmonary tuberculosis, infected sputum having been repeatedly swallowed ("Jour. Am. Med. Assoc.," Dec. 28, 1907). Gastric tuberculosis may cause cicatricial stenosis of the pylorus, ulcer (of which I reported an instance), a tumor-like thickening, solitary tubercle, and miliary tuberculosis (Barchasch, Loc. cit.).

Intestinal tuberculosis may follow pulmonary tuberculosis, but it may arise primarily in the mucous membrane of the bowel or result from tuberculous peritonitis. Intestinal tuberculosis causes diarrhea and fever, may resemble appendicitis, and may cause abscess and perforation. True tuberculous disease of the appendix occasionally occurs. Tuberculosis of the cecum is by no means as rare as we used to believe (see page 1014). Fistula in ano is frequently tuberculous, and when it is, the lungs are very often involved, the pulmonary lesion being usually primary.

Tuberculosis of the Liver.—Tuberculous disease of the liver causes cold abscess or cirrhosis. Typical cirrhosis without tubercles may arise, the bacilli being present in the tissues. Many cases of supposed alcoholic cirrhosis are probably tuberculous. The hepatic cirrhosis which may arise during peritoneal tuberculosis is tuberculous.

Peritoneal tuberculosis (see page 1027) may be primary, infection having taken place by way of the blood, may be part of a diffused process, or may follow

intestinal tuberculosis, the serous and mucous coats of the bowel having been at some point in contact or a follicular ulcer having perforated (Abbe). The germ may have entered by the Fallopian tube. Tuberculous peritonitis may be due to ovarian or Fallopian tuberculosis, or to ulceration of a tuberculous appendix. In some cases a caseating tuberculous gland furnishes the causative bacilli. Peritoneal tuberculosis usually causes ascites, tympany, and tumor-like formations composed of adherent bunches of bowel or omentum or distended mesenteric glands (see page 1027).

Tuberculosis of the Pancreas.—Tuberculous sclerosis of this organ has been induced experimentally by Carnot.

Tuberculosis of the spleen may occur with tubercles or as a sclerosis.

The **heart muscle** is rarely attacked by tuberculosis. In fact, valvular lesions of the left side of the heart actually protect the individual from pulmonary tuberculosis. Non-tuberculous endocarditis may arise in the course of a tuberculous process elsewhere. Tuberculous endocarditis does *very rarely* occur.

The **endocardium** may be inflamed and covered with fibrous exudate as a result of the toxins from some distant point of tuberculosis.

The **pericardium** may be attacked with primary tuberculosis, or the process may be secondary to pleural tuberculosis. There may or may not be tuberculosis.

Tuberculosis of the brain induces meningitis and hydrocephalus (see page 801).

Tuberculosis of the membranes of the spinal cord is seen alone or in association with tuberculous inflammation of the brain.

Tuberculous disease of fascia is common; in fact, fascia is peculiarly prone to infection. Fascia may be attacked primarily, and when it is, the disease is apt to spread rapidly and widely and to produce most disastrous results. The elder Senn regards tuberculosis of the intermuscular septa of the thigh as a very grave condition, which, if extensive, demands amputation of the limb. Secondary tuberculosis of fascia is far more common than the primary form, the original focus of disease being in bone, joint, tendon-sheath, or lymph-gland.

Tuberculosis of muscle is rare. Instances of primary tuberculosis have been reported. Secondary tuberculosis is more common, but even this condition is rare, muscle seeming to have a high degree of resistance.

Tuberculous disease of bone (see page 494) is very common in youth, and a sprain or a contusion, which is oftener slight than severe, may precede any signs of the disease. The injury establishes a point of least resistance, and in the damaged area the bacilli are depsoited and multiply, or a latent area of tuberculosis is roused into activity by the traumatism. The organisms may be deposited directly from the lymph or blood, or may arrive in an embolus from a distant tuberculous focus (lung or lymph-gland), which embolus is caught in a terminal artery in the end of a long bone and causes a wedge-shaped infarction.

Tuberculous osteomyelitis, as a rule, begins just beneath the articular cartilage or in the epiphysis. There may be one focus, several foci, or many foci in the same bone. The products of the tuberculous inflammation constitute tuberculous nodules which destroy the medullary tissue and hence cut off the nutrition of adjacent bone. Bone trabeculæ are destroyed, and tuberculous granulations take their place, and here and there small dead portions of bone trabeculæ lie as sequestra among the granulations. In some bones, for instance, the vertebræ and the bones of the carpus and tarsus, the tuberculous process spreads widely; in some it tends to remain localized. Tuberculous granulations may be absorbed, may be encapsuled, may be

replaced by fibrous tissue, or may caseate (see page 214). When an osseous tuberculous focus spreads the bone enlarges and becomes spindle shaped, as is seen in a phalanx the seat of tuberculous osteomyelitis, the condition known as *spina ventosa.*

Tuberculous disease of the joints (see page 618) is called *white swelling* and also *pulpy degeneration* of the synovial membrane. Joints are especially liable to tuberculosis in youth, although the wrist and shoulder not infrequently suffer in adult life. Joint-tuberculosis is often preceded by an injury. The tuberculous process in rare cases begins in the synovial membrane. Primary synovial tuberculosis is most often met with in the knee-joint. Usually the disease begins in the end of a bone, dry caries resulting, necrosis ensuing, or an abscess forming, which may break into the joint.

Poncet's rheumatism or tuberculous articular rheumatism is a condition in which toxic joint inflammation is evidence of latent tuberculous infection perhaps at some distant point, it being often impossible to demonstrate the bacillus in the joint fluid or tubercles at the autopsy (see page 619).

Tuberculosis of lymphatic glands is known as *tuberculous adenitis.* It is the most typical lesion of scrofula. Tuberculous adenitis is most frequent between the third and fifteenth years. A person not of the tuberculous type may acquire tuberculosis of the glands, but the disease is unquestionably of much greater frequency in those who are recognized as predisposed to tuberculosis. Tuberculous glands may get well, may even calcify, but usually caseate if let alone. Long after healing they may break down and soften (*residual abscess of Paget*). They very frequently suppurate because of mixed infection. Though at first a local disease, tuberculous glands may prove to be a dangerous focus of infection, furnishing bacteria which are carried by blood or lymph to distant organs or throughout the entire system. Glandular enlargement is in rare instances widely diffused, but it is far more commonly localized. Enlargement of the cervical glands is most common. Tuberculous disease of the mesenteric gland is known as *tabes mesenterica.* Tuberculosis of lymph-glands may be due either to bovine bacilli or to human bacilli.

Tuberculosis of the cervical lymph-glands is a very common condition. It is most common in children over two years of age and is often seen in young adults. It is rare in children under two and in persons of middle age. In the majority of cases infection takes place from the tonsils, pharynx, or posterior part of the oral cavity, and in these cases the first glands to enlarge are those just below the parotid salivary gland. In a number of cases enlargement begins in the submaxillary or submental glands, and in these cases infection originates from the teeth, mouth, or face (Dowd, in "Surgery, Gynecology, and Obstetrics," March, 1909). A tuberculous lesion of the scalp may be followed by tuberculosis of the parotid lymph-glands. Cervical adenitis may be unilateral or bilateral and is a very chronic condition. It is predisposed to by enlargement of the tonsils, adenoids, and nasopharyngeal catarrh. In 30 per cent. of cases the bacilli of bovine tuberculosis may be found (Dowd, Ibid.). The enlargements usually arise insidiously, but sometimes (after whooping-cough, measles, or scarlet fever) they come on more rapidly. When first observed the enlargements are small, round, firm, isolated, painless, and somewhat movable. As they enlarge they fuse into an irregular swelling which may be quite tender and is always anchored to surrounding parts. As the glands caseate the mass softens, the skin over it becomes adherent and red, and finally breaks open. Cold abscess may form or mixed infection with pus cocci may take place.

Cervical lymphadenitis may be confused with lymphadenoma. The former, as a rule, first appears in the submaxillary triangle; the latter, in the occipital or sternomastoid glands. The mass in the former is more tender, softer, and

less movable than in the latter. Tuberculous glands weld together, they are apt to remain localized for a considerable time, and they tend to soften. The younger the patient, the greater the probability of softening. In adults there is comparatively slight tendency to softening. Tuberculous adenitis may be accompanied by other tuberculous manifestations. Lymphadenoma from the start affects many glands; it may arise simultaneously in several regions, although in some cases there is a distinct beginning in one region. Lymphadenoma shows very little tendency to suppurate, and does not break down except late in the course of the disease, and is accompanied by great debility and anemia. Tuberculin tests may aid in the diagnosis, but a difficulty is that Hodgkin's disease and tuberculosis may coexist. Malignant gland-tumors infiltrate adjacent glands and other structures, binding skin, muscles, and glands into one hard, firm mass.

Tuberculous cervical adenitis is in most instances a reasonably curable condition. In children under two or three years of age, however, it is a dangerous condition and one apt to be associated with severe pulmonary, osseous, or other complications. Some cases of adenitis can be cured by open-air treatment, food, medicine, tuberculin, and hygienic care. In many, however, operation is indicated in addition to such treatment, and these operations are usually successful if thoroughly performed when the disease is localized and softening has not occurred. When possible operation should be performed when the patient is at the seaside, or, at least, the patient should convalesce there if circumstances permit. Thorough extirpation is the proper operative treatment and any diseased condition of scalp, face, mouth, tonsil, or nasopharynx is to be corrected. My belief is that about 75 per cent. of cases are permanently cured by thorough operation. If a patient is well five years after operation the cure may be regarded as permanent. Cured cases seldom die subsequently of any tuberculous lesion.

It is not uncommon after removal of infected glands and healing of the wound to have several or numerous small, hard nodules form beneath the skin in the area operated upon. Dowd extirpated some of these nodules and found they were not tuberculous, but were fibrous. I have been able to confirm Dowd's statement in several of my own patients.

Medical treatment is not nearly so valuable as surgical treatment in this form of tuberculosis. If medical treatment alone is relied on, many of these cases develop pulmonary tuberculosis. Attridge, quoting Demme and Dowd ("Surgery, Gynecology, and Obstetrics," Dec., 1908), sets the number which develop it when medical treatment is relied on at 21 per cent., and the number developing other distant tuberculous lesions at 8.2 per cent.—a total of 29.2 per cent., and these figures do not include bone infections and late infections of the lymph-nodes. Even in cases supposed to have been cured by medical means it will be found that most of them react to tuberculin, showing that lesions are latent rather than cured. Wohlgemuth shows that complete removal cures 75 per cent. of cases; curetting and drainage cures 63 per cent.; general treatment, 24 per cent. (Attridge, Ibid.). In a series of 100 cases operated upon by Dowd, pulmonary tuberculosis arose in but 1 case and bone tuberculosis in 3 cases. If miliary tuberculosis exists, if the patient is much exhausted, if the infection is not definitely localized, or if an internal organ is the seat of active tuberculosis, operation is not indicated.

Death seldom follows operation. The mortality without operation is probably 10 per cent. Complete extirpation of the involved group of glands is practised when the disease is well localized. If it is not well localized I follow Attridge's plan (Ibid.) and wait until it becomes so, treating the patient in the interval by open-air life, nourishing food, medicine, tuberculin, and the *x*-rays. If softening occurs, the area should be incised and curetted and the exposed sur-

face should be treated by repeated applications of tincture of iodin. When healing occurs, extirpation is to be performed. If sinus formation exists, mixed infection has occurred or will occur and the sinuses must be curetted and treated with iodin until they heal, when the glands may be extirpated. I do not believe in a bilateral extirpation at one séance. The operation even on one side is prolonged and bloody and is all the patient is fit to stand. If both sides of the neck are involved, an interval of several weeks should be insisted on before the other side is attacked.

In chronic cases of cervical lymphadenitis it is invariably necessary to search for intra-oral and nasopharyngeal disease, and if such disease exists it must be treated before the glands are removed. After operation rigid open-air life is insisted on.

Tuberculosis of tendon-sheaths (*tuberculous tenosynovitis*) is discussed on page 722.

Tuberculosis of the Kidney.—(See page 1290.)

Tuberculosis of adrenals may cause sclerosis.

Tuberculosis may attack the **Fallopian tubes, ovaries,** or **uterus.**

Tuberculosis of the urethra, prostate gland, seminal vesicles, and **bladder** is considered in a section on Regional Surgery.

Tuberculosis of the Testicle (see page 1393).—This disease is not rare. It is sometimes primary, but is usually preceded by tuberculosis of the kidney, bladder, or prostate. But one testicle is affected in the beginning, but the other gland is apt to be attacked later. The tuberculous mass softens, becomes adherent to the scrotum, and breaks or bursts, exposing the damaged testicle (*fungus of the testicle*). The cord is apt to be involved in tuberculosis of the testicle.

Typhobacillosis.—This condition was described by Landouzy in 1883. It is a toxemia in which the localization of lesions is very much deferred and is preceded by a prolonged typhoid or septic stage (Matas, "Southern Med. Jour.," Oct., 1911). Bacilli of tubercle are widely distributed throughout the body, but for a long time there are no tubercles formed, and all of the symptoms are due to bacillary poison. Matas describes the condition as "a continued fever with remissions and enlargement of the spleen, without signs of visceral localization" (Ibid.). It strongly resembles typhoid, but the pulse is more frequent, the temperature is less regular, there are no spots, and no intestinal or bronchial symptoms pointing to typhoid. Few of these cases die early. Most of them make an incomplete recovery after several weeks, and in periods varying from weeks to months develop evident localized tuberculosis.

Acute Miliary Tuberculosis.—In this condition an organ, several organs, or the entire body is infected with tubercle bacilli which have caused the formation of multitudes of tubercles. The symptoms for a time resemble typhoid, but in a short time an organ or organs present evidences of disease. Death occurs in from three weeks to three months.

XIV. RACHITIS, OR RICKETS

Rickets was known by the people and named by them long before any medical man had written of it. It first appeared in the London bills of mortality in 1634. Glisson, in 1650, wrote the first description of it and renamed it rachitis, because of the commonly resulting spinal curvature. Rickets is a chronic disorder of nutrition arising during the early years of life (the first two or three) as a result of insufficient or of improper diet, aided and abetted in many cases by bad hygienic surroundings. A deficiency of fat and phosphate in the food

or the use of a diet which, by inducing gastro-intestinal catarrh, prevents assimilation causes rickets. It is characterized by incomplete osteogenesis and other nutritive failures. The disease is not common in nursing children unless breast-feeding has been unduly prolonged, and children fed upon artificial food are particularly apt to develop it. Holt says such diet is very deficient in fat and often in proteins, and contains an excess of carbohydrates ("Diseases of Infancy and Childhood"). Sir J. Bland-Sutton made some valuable experiments to indicate the injury done animals by denying them natural diet. He fed lion cubs in the London Zoological Gardens on raw horse meat only and the animals developed rickets. The rickety animals rapidly recovered on feeding them with milk and powdered bones mixed with cod-liver oil. The disease is essentially a city malady, "being principally seen in children living in crowded tenements where the effects of improper food are most strikingly shown; yet even here the disease is rare in those who get a plentiful supply of good breast-milk" (Holt, Ibid.). Rickets must not be regarded as a bone disease. It is true the bones are affected, but so are various structures and organs, all of the disorders being due to an underlying nutritive defect. Some maintain that lactic acid or some other toxic material produced in the intestinal canal causes bone inflammation, but most observers do not believe the bone changes are inflammatory. Children are very seldom born with rickets, but develop it later, the period of greatest liability being between the seventh month and the fifteenth month. So-called congenital rickets is usually sporadic cretinism. A child with rickets may become scorbutic (*scurvy rickets*). Some regard rickets as the result of an infection. Glisson, in the seventeenth century, thought it was infectious. Some observers claim to have found bacteria in rickety bone and in the cerebrospinal fluid of rickety children (Mirculi, Sorgente). Others think it results from thymus atrophy. Some blame syphilis, some malaria, some the thyroid gland, some the nervous system. Some believe that disease of the parathyroids alters calcium metabolism—perhaps two much calcium being cast out, perhaps too little being taken in or assimilated.

Whatever may be the cause of rickets, the essential condition in the bones is an insufficient deposit of mineral matter in the new bone cells. The new bone is soft and vascular and bone lamellæ toward the medullary canal are actually absorbed. There is excessive proliferation of cartilage which results in enlargement. The proliferating and imperfectly ossified cells cause enlargements at the ends of long bones and at the sternal ends of the ribs, and various bones bend and are distorted. The parietal bones bulge, the fontanels remain long open; there may be unossified gaps in the occipital bone, membrane only filling them (*craniotabes*). There may be pigeon-breast, bent long bones, curved spine, and distorted pelvis. The bones later may become firmly ossified in deformity. In rickets the spleen and liver are enlarged and the thymus is atrophied.

Evidences of Rickets.—Rickets is apt to arise in the spring, but may begin any time of the year. In some few cases it begins with fever. The condition is one of general ill-health; the child is ill-nourished, pallid, flabby; it has a tumid belly and suffers from attacks of diarrhea and sick stomach; it is disinclined for exertion and has a capricious appetite; it is liable to night-sweats; enlarged glands are often noted, the teeth appear behind time, and the fontanels close late. In health the posterior fontanel closes in the second month and the anterior fontanel in the eighteenth month. In rickets the anterior fontanel is often open when the child is three years of age. The sutures are often open at the end of the first year. The head is square in shape, the cranial bones are thick, and areas of thickening known as bosses appear over the parietal bones. The head is large and the forehead bulges. The long bones become much curved, the upper part of the chest sinks in, curvature of the spine appears, and

the pelvis is distorted. The ligaments are relaxed and lengthened and the joints are wobbly. The muscles are feeble and ill-developed. Infantile convulsions are common. Nocturnal restlessness and night terrors are the rule. Laryngismus stridulus and tetany may occur. Swelling appears in the articular heads of long bones, by the side of the epiphyseal cartilages, and in the sternal ends of the ribs, forming in the latter case *rachitic beads*. The lesions of rickets are due to imperfect ossification of the animal matter which is prepared for bone formation, and the soft bones gradually bend. The swellings at the articular heads are due to pressure forcing out the soft bone into rings. Rachitic children rarely grow to full size, and the disease is responsible for many dwarfs. Most cases recover without distinct deformity, but the time lost during the period when active development should have gone on cannot be made up, and some slight deficiency is sure to remain. Bow-legs, knock-knees, and spinal curvatures are usually rachitic in origin. The disease may be associated with scurvy, inherited syphilis, or tuberculosis. In appearance the rickety child is pot-bellied, pale and anemic, and usually fat and flabby, though occasionally thin. The spleen may be enlarged. There is great liability to enlargement of the tonsils, gastro-intestinal catarrh, and bronchial catarrh. The blood is deficient in red corpuscles and hemoglobin, and sometimes there is leukocytosis. The disease lasts for many months and is usually recovered from. It does not directly produce death, but is a powerful indirect cause of infant mortality because it lessens resistance and predisposes to many diseases. It is almost always afebrile, rarely congenital, and in unusual cases, known as late rickets, develops between the fifth and tenth year. The so-called acute rickets is practically always scurvy (Holt). The victims of rachitis are very liable to fracture the bones from slight force and green-stick fractures are particularly prone to occur (Fig. 106). After fracture of a rickety bone union is usually delayed.

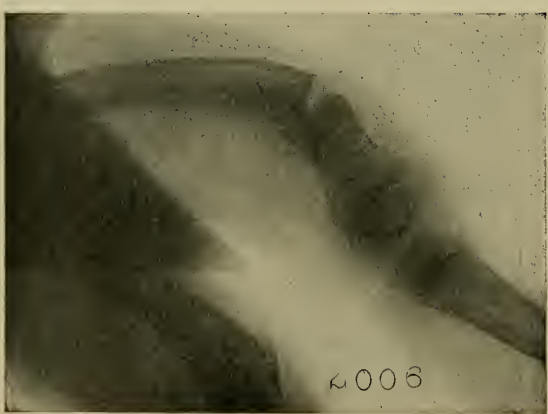

Fig. 106.—Fracture of femur in rickets.

The **treatment** consists in having the child live as much as possible in the open air and sunshine. Salt-water baths are useful. Sea air is very beneficial. Fresh food (milk, cream, and meat-juice) should be ordered. Cod-liver oil, syrup of the iodid of iron, arsenic, and some form of phosphorus are to be administered. It is absolutely necessary to improve the primary assimilation. Slight deformities of the extremities require no special treatment unless they increase. If the deformity is marked or is increasing, use braces; employ massage, manipulation, and faradism. By the time the child is three years of age the bones are usually so firm that the pressure of a brace cannot cure the deformity, though the real test of brace efficiency is the degree of elasticity present in the bones, as determined by the surgeon's hands. After the age of three braces are commonly useless. Pronounced established deformities of the extremities are usually treated surgically. Kyphosis is treated by making the patient lie upon a hard bed without a pillow. The child sits up a few hours each day, the shoulders being held back and support applied to the body. In

bad cases, during the time the child is erect it should wear a brace or plaster-of-Paris jacket. Daily manipulation, the child lying prone, is helpful. Friction and electricity to the spinal muscles do good.

Scorbutus (Scurvy).—Many ancient writers described symptoms which must have been due to scurvy. For instance, Pliny, speaking of the army of Germanicus when near the Rhine, describes a condition of illness characterized by sore gums, falling out of teeth, and weakness of the legs. Voyagers in the fifteenth century noted symptoms which we now know were caused by scurvy. In Vasco de Gama's voyage around the Cape of Good Hope more than half of his crew perished of what was certainly scurvy. It seems to have been first specifically described early in the sixteenth century. A most graphic picture of scurvy as it used to occur at sea will be found in "A Voyage Around the World in 1740 by Lord Anson," compiled by the Rev. R. Walter, chaplain of the "Centurion." Scurvy is rare to-day in adults, but was at one time very common among those who took long voyages, or who engaged in campaigns, or were the victims of sieges, and was quite common even in cities. Poupart describes it as he saw it in the St. Louis Hospital of Paris early in the eighteenth century. Of recent years it is very uncommon, and has occurred chiefly among voyagers in the Arctic regions or those who were beleaguered. It can occur in any part of the world, on land or sea. Some years ago I saw several cases in the Philadelphia almshouse. It is important to remember that though scurvy is rare in adults, it is by no means uncommon in ill-nourished infants.

Scurvy is a constitutional malady due to the consumption of improper diet, and especially to the employment of a diet characterized by the absence of vegetables.

The use of salt meat as a staple article seems to favor the production of the disease, but scurvy can occur when there was not a salty diet, and increase of sodium chlorid in the blood is not characteristic of scurvy, but occurs in various forms of anemia. Garrod considered absence of potassium salts to be the real cause. The diminution of potassium salts is supposed to be responsible for diminished alkalinity of the blood, but we know that diminished alkalinity is common in all forms of secondary anemia. Absence of variety in diet, bad water, poorly ventilated quarters, and insufficient exercise favor the development of the disease. Some believe that an organic poison derived from tainted food is responsible (Torup). A bacterial origin has been suggested by Berthenson, Babès, and others. Certain studies made in the Transvaal suggest the bacterial origin of scurvy. Myer Coplans ("Lancet," June 18, 1904) states that it occurred in those getting excellent rations and began as inflammation of the gums, the constitutional symptoms following. If the gum condition is early recognized and cured simply by cleanliness and antiseptics, that is, by pure local treatment, constitutional trouble does not develop. Goadly ("Brit. Med. Jour.," 1910) showed that the mouth of a scurvy patient is acid to litmus, and even though there is no dental caries, in most cases there is early inflammation of the gums. Hewetson examined 400 South African males, varying in age from fifteen to thirty-five. He found 134 with scorbutic gums, although they seemed in good health ("Transvaal Medical Journal," April, 1911).

The effect of great depression of spirits in predisposing to scurvy and in aggravating cases of scurvy has often been commented on. During the siege of Breda in 1625 scurvy was rife. Bad news rapidly increased the number of cases. Good news checked it. Anson made a similar observation.

Scurvy begins with sore gums, weakness, drowsiness, muscular pains, and great susceptibility to cold. The skin is pallid or dirty white, and is occasionally mottled and often peels off. The patient is breathless on the slightest exertion. The pulse is excessively weak and slow. There is no fever unless a com-

plication arises. The gums are often tender and inflamed from the start, but in some cases they are not. After two or three weeks in all cases usually the gums are found to be tender, painful and swollen, and bleeding at frequent intervals; the breath becomes offensive, the teeth loosen and even drop out; subcutaneous hemorrhages take place, giving rise to petechiæ or extensive extravasations; the vision becomes dim; the urine becomes scanty and of low specific gravity; cutaneous vesicles form, rupture, and give rise to bleeding ulcers, and ulcers likewise arise from breaking down of blood extravasation; hemorrhages take place into and between the muscles, and in severe cases beneath the periosteum and into joints, and blood may flow from the nose, lungs, kidneys, stomach, and intestines. Deep hemorrhages are palpable as hard lumps. Bleeding at an epiphyseal line may separate the epiphysis from the shaft. If an inflammation or ulceration arises at any point, fever is observed. In many cases blood-clotting is retarded. Wright maintains that there is diminished alkalinity of blood and that scurvy is really acid intoxication. Other observers dispute this. The examination of corpuscles and hemoglobin gives a picture identical with second-

Fig. 107.—The gums in scurvy.

ary anemia. As a rule the red cells number from 3,000,000 to 4,000,000 per c.mm., but may fall to 1,000,000 or even less. Hemoglobin loss is more marked than corpuscular diminution, hence the color-index is low. There is usually an increase in leukocytes. It was observed by DeHaven, who commanded the Grinnell expedition in search of Sir John Franklin, that scurvy causes old and soundly healed wounds to ulcerate. The same observation was made years before in Lord Anson's voyage. A sailor of the "Centurion" had been wounded fifty years before at the battle of the Boyne. He developed scurvy and the old wound opened. In another case an old and soundly united fracture gave way and felt like a fresh break. Most cases of scurvy get well under proper treatment, but complete recovery is not attained for a long time. Sudden death is liable to occur if any exertion is made. The lightest exercise may be fatal. Even moving a man while he is lying down may cause death. Many cases while quiet and recumbent feel well, eat well, sleep, make no complaint of pain, and yet even slight movement may cause death. Nansen is said to attribute the loss of the gallant Scott and his companions in the Antarctic to

scurvy, the effort necessary to climb a glacier being, in his opinion, the cause of death.

Prevention and Treatment.—Captain Cook succeeded in preventing scurvy among his sailors by providing plenty of fresh water; guarding them against fatigue, wet, and extremes of heat and cold; attending to cleanliness and ventilation, and stimulating cheerfulness. This great navigator lost no men from scurvy. After the time of Captain Cook, the British Admiralty, acting on the suggestions of Lind and Blane, provided ships with lime-juice or lemon-juice with the most beneficial results in preventing the disease. As a matter of fact, lime-juice was suggested by John Woodall long before the time of Lind and Blane. Woodall died in 1643. Until comparatively recent years sailors of the United States Navy were accustomed to refer to sailors of the British Navy as "lime-juicers." Scurvy is prevented at the present time by employing a proper diet and by maintaining cleanliness and hygienic conditions.

The following agents are believed to be especially useful as preventives: fresh meat, lemon-juice, cider, vinegar, milk, eggs, onions, cranberries, cabbages, pickles, potatoes, and lime-juice. When the disease develops, give vinegar, lemon-juice, onions, scraped apples, cider, nitrate or citrate of potassium, whisky or brandy, and plenty of nourishing food. Lind used, with great success in many cases, 4½ oz. of lemon-juice or lime-juice and 2 oz. of sugar in a pint of Malaga wine. This was taken during each twenty-four hours. In twenty-four hours improvement would be manifest. Antiseptic mouth-washes are necessary and strychnin is a valuable stimulant to the circulation. Sleep must be secured and ulcers are treated by antiseptic dressings and compression.

Infantile scurvy or **Barlow's disease** may exist alone or with rickets (*scurvy rickets*). It occurs most often in the children of the well-to-do, those who have been brought up on artificial foods, in fact, only children who are fed on artificial foods get it. Sterilized milk, condensed milk, or other artificial food may be responsible. It occurs most frequently between the eighth and eighteenth months of life. It is noted that the child has lost its appetite, is losing weight, has lost the use of its legs, lies quiet with the thighs flexed and abducted, cries when touched and when it fears it is going to be touched (Grasty, in "Amer. Jour. Obstet.," 1910). The child is anemic, suffers from gastro-intestinal disorders, spongy and bleeding gums if teeth have erupted, weakness of the legs, general muscular tenderness, night-sweats, and often febrile attacks (Rotch), bleeding from the nose, bleeding beneath the skin (blue spots), bloody urine and stools, bleeding beneath the periosteum, into joints, viscera, or muscles. In some cases hematuria is the first and perhaps the only symptom (J. Lovett Morse, "Jour. Am. Med. Assoc.," Dec. 17, 1904). A subperiosteal hemorrhage is very dense to palpation, is tender, is fusiform in outline, and does not fluctuate. It is sometimes mistaken for sarcoma. In 1 case seen by the author a hemorrhage beneath the periosteum of the femur was mistaken for a sarcoma. The limb attacked is flexed and the child will not move it. In another case hemorrhage into the knee-joint was thought to be inflammatory effusion from traumatism. Separation of an epiphysis may result from hemorrhage between it and the bone. Infantile scurvy is often unrecognized. If promptly treated, recovery is the rule, otherwise death may occur from exhaustion.

Treatment.—Keep the child quiet in bed and give liberal amounts of fresh and raw cows' milk and beef-juice from raw meat. Administer orange-juice, grape-juice, scraped apples, and tonics. To children over one year of age give potatoes. Antiseptic mouth-washes are necessary.

XV. CONTUSIONS AND WOUNDS

Contusions.—A contusion or bruise is a subcutaneous laceration due to the application of blunt force, the skin above it being uninjured or damaged without a surface-breach and blood being effused. Punches, kicks, blows from a blackjack, etc., cause contusions. In intra-abdominal contusions the skin of the abdomen is frequently not damaged. In contusions of structures overlying a bone the skin suffers with the deeper structures. If a large vessel is ruptured hemorrhage is profuse and much blood gathers in the tissue. If only small vessels suffer hemorrhage is moderate. An *ecchymosis* is diffuse hemorrhage over a large area, the blood lying in the spaces of the subcutaneous or submucous areolar tissue. A very small ecchymosis is known as a *petechia;* a very large ecchymosis is called a *suffusion* or *extravasation*. A *hematoma* is a blood-tumor or a circumscribed hemorrhage, the blood lying in a distinct cavity in the tissue. In extremely severe contusions tissue vitality may be destroyed or so seriously impaired that gangrene follows. Suppuration rarely occurs, but occasionally does so, and is most apt to in a drunkard or a person of debilitated constitution. When hemorrhage arises in the tissues after a contusing force it soon ceases unless a very considerable vessel is ruptured. The arrest of hemorrhage is brought about by the resistance of the tissues, the contraction and retraction of the vessels, coagulation of blood, and in some cases of severe injury coagulation is favored by syncope. Blood in the tissues, as a rule, soon coagulates, the fluid elements being absorbed and the red corpuscles breaking up and setting free pigment, which pigment may be carried away from the seat of injury or may crystallize and remain there as hematoidin. In some cases inflammation occurs about the extravasated blood, a capsule of fibrous tissue being formed, and the blood being slowly absorbed or the fluid elements remaining unabsorbed (*blood-cyst*), or the blood becoming thicker and thicker, finally calcifying. Blood in serous sacs (joints, pleura, pericardium) coagulates very slowly. As blood is being absorbed it undergoes chemical changes and color changes ensue, the part being at first red and then becoming purple, black, green, lemon, and citron. The stain following a contusion is most marked in the most dependent area. After a bruise of the periosteum a blood-clot forms, much tissue-induration occurs, and a hard edge can be detected by palpation at the margin of the clot.

Symptoms.—The symptoms are tenderness, swelling, and numbness, followed by some aching pain or a feeling of soreness. The pain rarely persists beyond the first twenty-four hours. Cutaneous discoloration appears quickly in superficial contusions, but only after days in deep ones. In some regions—the scalp, for instance—it can scarcely be detected; in others, as in the eyelid and vulva, discoloration is early, widespread, and marked. Discoloration and swelling are very marked in regions where loose cellular tissue abounds (eyelids, prepuce, scrotum). The discoloration is at first red, and becomes successively purple, black, green, lemon, and citron. The swelling is primarily due to blood, and is added to by inflammatory exudation. In a more severe contusion a hematoma may form. A recent hematoma fluctuates, but gradually, because of cell-proliferation, the edge becomes hard, but the center continues to fluctuate. The mass gradually grows smaller and finally disappears. A subperiosteal hematoma of the scalp may be mistaken for depressed fracture of the skull. Any form of hematoma of the scalp may be mistaken for an abscess, but differs from it in the absence of inflammatory signs. It occasionally, though rarely, suppurates. In a case in which suppuration occurs an abrasion, which may be very minute, often exists on the skin. In any severe contusion there is considerable and possibly grave, or even fatal, shock.

Treatment.—In a severe injury bring about reaction from the shock. Local treatment consists in rest, elevation, and compression to arrest bleeding, antagonize inflammation, and control swelling. Cold is useful early in most cases, but it is not suited to very severe contusions nor to contusions in the debilitated or aged, as in such cases it may cause gangrene. In very severe contusions employ heat and stimulation. When inflammation is subsiding after a contusion, compression and inunctions of ichthyol should be employed. If the amount of blood is very large, massage must not be used because it may cause embolism or fat-embolism. Massage and passive motion are imperatively needed after contusion of a joint. If a distinct cavity exists, aspiration or incision lessens the danger of fat-embolism. A contusion should never be incised unless the amount of blood is large and a distinct cavity exists, or hemorrhage continues, or infection takes place, or a lump remains for some weeks, or gangrene is threatened. For persistent bleeding freely lay open the contused area, turn out clots, ligate vessels, insert drainage-strands or a tube, and close the wound. If gangrene is feared, make incisions and apply heat to the part. If a slough forms, employ antiseptic fomentations. The constitutional treatment for contusion, after the patient has reacted from shock, is the same as that for inflammation. (See Abdomen, etc.)

Wounds.—A wound is a breach of surface continuity effected by a sudden mechanical force. Wounds are divided into open and subcutaneous, septic and aseptic, incised, contused, lacerated, punctured, gunshot, stab, and poisoned wounds.

The **local phenomena of wounds** are pain, hemorrhage, loss of function, and gaping or retraction of edges.

Pain is due to the injury of nerves, and it varies according to the situation and the nature of the injury. It is influenced by temperament, excitement, and preoccupation. It may not be felt at all at the time of injury. At first it is usually acute, becoming later dull and aching. In an aseptic wound the pain usually remains slight, but in an infected wound it always becomes severe.

The nature and amount of *hemorrhage* vary with the state of the system, the vascularity of the part, and the variety of injury.

Loss of function depends on the situation and extent of the injury.

Gaping or *retraction of edges* is due to tissue elasticity, and varies according to the tissues injured and the direction, nature, and extent of the wound.

The **constitutional condition** after a severe injury is a state known as *shock*.

Shock.—The name "shock" was introduced in 1795 by James Latta to designate the condition ensuing upon severe injury. (See G. C. Kinnaman, in "Annals of Surg.," Dec., 1903.) Shock is a depression of the vital powers arising from an injury or a profound emotion acting on the nerve-centers. No theory of shock is entirely satisfactory. Most observers state that there is exhaustion or inhibition of the vasomotor mechanism. Exhaustion is gradually induced; inhibition is suddenly produced. It is supposed that by overstimulation of sensory nerves violent impressions are conveyed to the nerve-centers, the vasomotor center is exhausted or inhibited, vasoconstrictor power is lost, the peripheral arteries and capillaries are palsied and are depleted or nearly emptied of blood, and the blood is largely transferred to the veins. The blood-pressure is lowered, the cardiac action is impaired, the respiratory action is impeded, and quantities of dark-colored blood gather in the somatic veins, but especially in the veins of the splanchnic area. (See the masterly study of "Surgical Shock," by Crile.) Although this theory finds wide acceptance, some able investigators do not accept it. In shock the abdominal veins are greatly distended and the other veins of the body may also be overfull, the

arteries contain less blood than normal, and an insufficient amount of blood is sent to the heart and to the vital centers in the brain. In other words, in shock there is a deficiency in the circulating blood. The term *collapse* is used by some to designate a severe condition of shock, and is employed by others as a name for a condition produced by functional depression of the vasomotor center the result of mental disturbance, cardiac failure, respiratory failure, or vasomotor insufficiency, rather than of physical injury. Crile regards collapse as inhibition of the vasomotor center, in contrast to shock, which is exhaustion of the center. As a matter of fact, shock and collapse are often both present. That the bombardment of the nerve-centers by a tumult of peripheral impressions causes shock is shown by the fact that if the nerves from a part are thoroughly cocainized so that they will not transmit sensation, operation upon the part produces practically no shock. Crile calls such cocainization the introduction of a *physiological block*. Again, Crile insists that in shock there are demonstrable changes in the brain cells. The changes consist in shrinking of nuclei and dissipation of the granular matter of the protoplasm. Such changes mean that the cells involuntarily discharged nerve force many times, were caused to discharge by impressions brought to them, and by the discharges were exhausted of certain necessary chemical materials. Shock may be slight and transient, it may be severe and prolonged, it is usually sudden in onset, but may come on gradually, and it may even produce almost instant death. I agree with Bloodgood that even a violent injury does not of necessity at once produce it. Every now and then we see a man with a crushed limb who does not exhibit shock, the condition gradually coming on from pain, terror, etc., and being aggravated perhaps by hemorrhage. During an operation if shock arises it is apt to do so gradually, but this is not always the case, for sometimes it comes on with great suddenness, for instance, when traction is made upon the pedicle of the spleen, when the bone of the thigh is sawed through, or when there is a burst of blood from a large vessel. Sudden death from shock is probably due to reflex stimulation of the pneumogastric nuclei and arrest of cardiac action. It is known as *death by inhibition*. Shock is more severe in women than in men, in the nervous and sanguine than in the lymphatic, in those weakened by suffering than in those who are strangers to illness. It is predisposed in disease of the kidneys, diabetes, chronic cardiac disease, and alcoholism. Fear is probably a great factor in shock. Injuries of nerves, of brain, of the intrathoracic viscera, of the intra-abdominal viscera, of the urethra, or of the testicle produce extreme shock. Anything which extracts the body-heat favors the development of shock (exposure to cold air, insufficient covering, chilling the body by solutions or wet towels). In cerebral concussion there is shock plus other conditions. Sudden and profuse hemorrhage greatly aggravates shock. Prolonged anesthetization causes shock. Great shock may occur after the removal of a large tumor or a quantity of fluid from the abdomen. In such a case shock is brought about by the sudden removal of pressure and the consequent rapid distention of intra-abdominal veins. Exposure of tissue and vital parts to air aggravates shock. Crile lays down as the most important causes of shock: fear, pain, and traction.

The influences which cause cells to exhaust themselves by discharge are recognized by the nerve-cells as meaning or suggesting harm to the organism. Such influences cause impulses to escape. Such influences are called by Crile *nocuous* or *noci influences*. Fear itself can cause shock, and fear is a factor even when shock is apparently due to pain or traction. Fear, then, is the ever-existing factor in shock causation. It is often a conscious fear. It may be subconscious fear.

Crile maintains that an individual may be anesthetized by ether or chloroform and feel no pain, and yet noci influences may cause shock. The influences

then act by suggesting painful or harmful things to the nerve-cells, that is, by causing subconscious fear. Crile calls such automatic association *philogenetic association.*

The **symptoms** of ordinary shock (*torpid* or *apathetic shock*) are subnormal temperature; weakness of heart action; irregular, small, weak, rapid, and compressible pulse; cold, pallid, bloodless, and often clammy or profusely perspiring skin; shallow, irregular, and often gasping respiration. A sphygmomanometer will indicate a notable fall in blood-pressure. Consciousness is usually maintained, but there is an absence of mental originating power, the injured person answering when spoken to, but volunteering no statements and lying with partly closed lids and expressionless countenance in any position in which he may be placed. The answers to questions though apparently intelligent are utterly unreliable. There is great motor weakness. The pupils are dilated and react but slowly to light. The sphincters are relaxed. Pain is slightly or not at all appreciated. Nausea is absent and vomiting may, as in concussion, presage reaction. Gastric regurgitation, after a considerable duration of shock, is not unusual, and is a bad omen. It must impress students of physiology that certain of the well-known signs of shock do not seem to indicate that there are paralysis and dilatation of the peripheral vessels, as the popular theory of shock supposes. The signs which do not co-ordinate with the theory are anemia of the surface, lowered temperature of the surface, and small pulse (Seelig and Lyon, in "Surgery, Gynecology, and Obstetrics," Aug., 1910). Shock is not rarely followed by suppression of urine. Whereas the victim of shock is usually stupid and indifferent, he may become delirious. If delirium arises, the condition is very grave. Travers called shock with delirium *erethistic* or *delirious shock.* As a matter of fact, such a state is not genuine shock, but is either a traumatic or a toxic delirium added to or following upon shock. It is usually due to uremia or sepsis. Delirious shock may arise after a person has been bitten by a poisonous snake. Many years ago Travers described a *secondary* or *delayed form* of shock, which comes on several hours after an injury or violent emotional disturbance. This form of shock is seen not unusually in those who have passed through a railroad accident. It may be a sign of hemorrhage, and is sometimes met with after the administration of ether or chloroform. The statements made by a person who has recovered from a severe shock are always unreliable as to events which occurred while shock existed, and are often doubtful as to the details of the accident. Not unusually the memory of the accident is perverted or even destroyed.

Diagnosis.—Concealed hemorrhage is difficult to differentiate from shock. The former produces impairment of vision (retinal anemia), irregular tossing, frequent yawning, great thirst, nausea, and sometimes convulsions. In shock the hemoglobin is unaltered; in hemorrhage it is enormously reduced (Hare and Martin). In hemorrhage recurrent attacks of syncope are met with. In pure shock such attacks do not occur. In concealed hemorrhage the abdomen may exhibit physical signs of a rapidly increasing collection of fluid. Shock and hemorrhage are often associated. A usual characteristic of shock is rapid onset, which separates it distinctly from exhaustion. It arises at a much earlier period after an injury than does fat-embolism.

The Prevention of Shock in Operations.—Examine the patient with care before operating, giving special attention to the condition of the kidneys. The amount of urine passed and the amount of urea it contains should always de determined when possible. The amount of urea should be estimated from the twenty-four-hour urine. The normal amount of urine in the twenty-four hours is about 50 ounces and the normal amount of urea 2 per cent. Less urea is significant of danger from shock and subsequent kidney complications. If the condition of the patient leads us to fear that there will be dan-

gerous shock, do not purge him severely before operation, and just previous to operation give a rectal injection of hot saline fluid and a hypodermatic injection of $\frac{1}{100}$ gr. of atropin. It is also a good plan in some cases to give a hypodermatic injection of $\frac{1}{6}$ gr. of morphin twenty minutes before operation. It tranquillizes the patient and less ether will be needed to anesthetize him. Examine the patient thoroughly and prepare him carefully beforehand and decide if he should take a general anesthetic at all, and if so, which one. Nitrous oxid diminishes operative shock, Crile says, because cell activity is lessened by deficiency of oxygen.

Many operators believe that ether and chloroform lessen shock. Crile disputes this. He holds that they merely inhibit conscious fear and muscular response to peripheral impressions, but do not save the brain-cells from noci impressions, and hence do not keep cells from exhausting discharges.

It would seem that a drugged brain-cell could not receive influences as acutely and strongly as one untouched by ether or chloroform. I believe that a general anesthetic, given properly and in proper amount, does, to some extent at least, lessen the shock of an operation.

In some cases a local anesthetic should be used, for instance, some cases of typhoid perforation and strangulated hernia. The nerves well above the area of operation should be infiltrated with cocain. This prevents the ascent of peripheral impressions, makes what Crile calls a "physiological block," and so prevents shock. After this infiltration a limb can be amputated below the infiltrated area without pain and without great depression of the vital powers. I have performed a number of amputations most satisfactorily relying for anesthesia purely upon cocainization of the nerves. In these cases there has been very little shock. This is a valuable procedure even when ether is given. I employ it frequently and am satisfied of its great value in preventing shock. The ether prevents conscious fear during the operation, the cocainization of the nerve intercepts harmful impressions in their ascent. Thus is shock prevented. In some few cases in which we fear shock spinal anesthesia is used; in others, scopolamin and morphin. If a general anesthetic is used it must be skilfully given and not a drop is given beyond the amount necessary to maintain thorough anesthesia. Cover every part but the field of operation with hot blankets and put cans of hot water about the patient, or put him on a bed composed of hot-water pipes covered with blankets. Prevent bleeding with the greatest possible care. Operate as rapidly as is consistent with safety and thoroughness. The blood-pressure is of great importance in estimating the degree of shock, and any sudden fall of blood-pressure is ominous. It is a custom with many operators to fix a sphygmomanometer to the arm and have an assistant watch the scale constantly during an operation. If shock develops during an operation hasten on the work, lessen the amount of ether, and apply active treatment. Return the patient to bed as soon as possible and without exposure in cold halls or a windy elevator. Occasionally it becomes necessary to suspend an operation in order to prevent death on the table.

Crile's **anoci association operation** is founded on the prevention of shock by the exclusion as far as possible of all painful, terrifying, and depressing influences from a patient before, during, and after operation. The patient is not kept for days or even for hours waiting in fear. He is to be reassured, made confident, dominated by his surgeon. He is anesthetized by means of nitrous oxid and nitrogen, ether being added only if necessary. The tissues are infiltrated with a local anesthetic. During the operation all noci impressions are carefully excluded. This method, in the hands of Crile, Bloodgood, and others, has given highly satisfactory results.

Treatment.—In treating ordinary apathetic shock raise the feet and lower the head, unless this position causes cyanosis. At least place the head flat and

the body recumbent. Wrap the patient in hot blankets and surround him with hot bottles, hot bricks, hot-water bags, or cans of hot water. Always wrap a can, a bottle, or a bag in flannel or some other material to avoid burning the patient. Ordinary stimulants seem of little or no value and drugs given by the stomach are not absorbed. Salt solution may be thrown into a vein (*intravenous infusion*), may be given by the rectum (*proctoclysis*), or subcutaneously (*hypodermoclysis*). Intravenous infusion does good, but, unfortunately, the benefit is very temporary except in cases associated with hemorrhage. In hemorrhage it should always be given, and it should be given mixed with adrenalin chlorid (1 teaspoonful of the 1 : 1000 solution of adrenalin chlorid is added to 1 liter of salt solution). The operation of intravenous infusion is described on page 465. The custom of giving salt solution in a vein has become so common that resident physicians are apt to resort to it as a routine. It is to be remembered that if given rapidly or in too great quantity it may gather in the chambers of a dilated right heart and arrest a heart so weakened that it has almost reached its limit of function. I am satisfied that the rapid administration of salt solution intravenously is responsible for some deaths. Crile maintains that the only way "to increase and sustain the blood-pressure when the vasomotor center is exhausted" is to "create a peripheral resistance either by a drug acting on the blood-vessels themselves or by mechanical pressure."[1] In order to accomplish this he uses adrenalin chlorid. Because of the rapidity with which this drug is oxidized he gives it intravenously, slowly and continuously from a buret, using a solution of a strength of from 1 : 50,000 to 1 : 100,000 in salt solution. The rate of flow should be "controlled by a screw-cock attached to the rubber tube." Crile also places the patient in a rubber suit and distends the suit by means of an air pump and thus obtains equable pressure upon the cutaneous surface and an increase of peripheral vascular resistance. The difficulty with giving the solution in a vein is, the drug first comes in contact with "the vessels having the least power of influencing blood-pressure," and before a notable rise can be affected by arterial action "it is necessary that the solution should pass through the right heart, the lungs on its way to the aorta, then finally affecting the coronary arteries" (Crile, in "Am. Jour. Med. Sciences," Jan., 1909). The best way to use adrenalin solution in severe shock is to introduce it as Crile now advises, that is, into the arterial system and toward the heart. Occasionally, by this means, resuscitation from apparent death may be accomplished. Crile calls this method *centripetal arterial transfusion*. It is applied as follows ("Am. Jour. Med. Sciences," April, 1909):

"In human resuscitation the technic is as follows: The patient in the prone posture is subjected at once to rapid rhythmic pressure upon the chest, with one hand on each side of the sternum. This pressure produces artificial respiration and a moderate artificial circulation. A cannula is inserted toward the heart into an artery. Normal saline, Ringer's, or Locke's solution, or, in their absence, sterile water, or, in extremity, even tap water, is infused by means of a funnel and rubber tubing. But as soon as the flow has begun the rubber tubing near the cannula is pierced with the needle of a hypodermatic syringe loaded with 1 : 1000 adrenalin chlorid and 15 to 30 min. are at once injected. Repeat the injection in a minute if needed. Synchronously with the injection of the adrenalin the rhythmic pressure upon the thorax is brought to a maximum. The resulting artificial circulation distributes the adrenalin that spreads its stimulating contact with the arteries, bringing a wave of powerful contractions and producing a rising arterial, hence coronary, pressure. When the coronary pressure rises to, say, 40 mm. or more, the heart is likely to spring into action. The first result of such action is to spread still further the blood-pressure-raising adrenalin, causing a further and vigorous rise in blood-pres-

[1] George Crile, in "Boston Med. and Surg. Jour.," March 5, 1903.

sure, possibly even doubling the normal. The excessively high pressure is most favorable to the resuscitation of tissue, especially of the central nervous system (Stewart). Just as soon as the heart-beat is established the cannula should be withdrawn, first, because it is no longer needed, and second, because the rising blood-pressure will drive a torrent of blood into the tube and funnel. Unless there has been hemorrhage, the only object in the use of saline infusion is to serve as a means of introducing the adrenalin into the arterial circulation toward the heart. Bandaging the extremities and abdomen tightly over masses of cotton is very useful."

In prolonged shock direct transfusion of blood should be employed (see page 463). The use of hot and stimulating rectal enemata is important. The

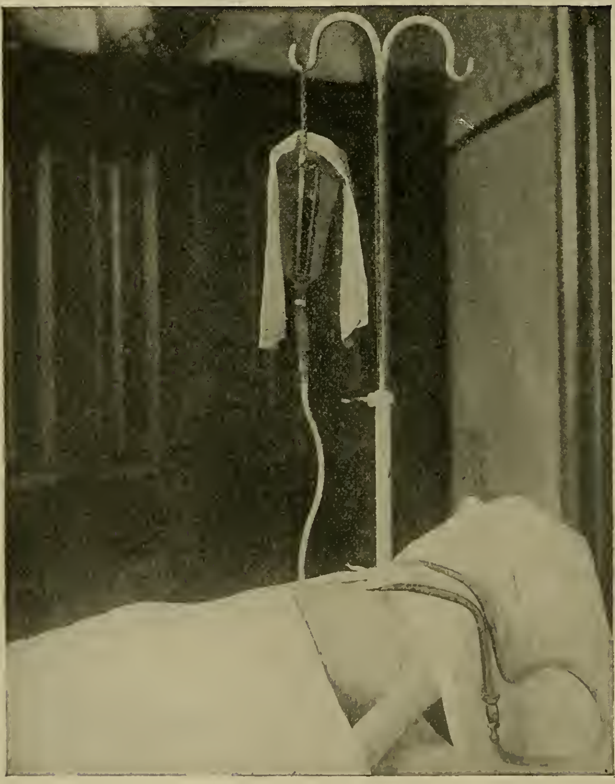

Fig. 108.—Subcutaneous saline infusion (Senn).

rectum may absorb fluids when the stomach refuses to do so. Enemata of hot normal salt solution are beneficial (*proctoclysis*). The tube is carried as high as possible and the injection is introduced so as to distend the colon. *Hypodermoclysis* is given as follows: Insert an aspirator tube into the cellular tissue of the loin, scapular region, or under the mamma, cleansing the part first. The tube is attached to a fountain syringe, which is filled with warm normal salt solution, and is hung at a height of 2 or 3 feet above the bed (Fig. 108). In an hour's time a pint or more of fluid will enter the tissue and be absorbed. It is the custom to give hypodermatic injections of ether, brandy, strychnin, digitalis or atropin, or inhalations of amyl nitrite. Crile has demonstrated experimentally that strychnin is perfectly futile in pure shock and may actually aggravate the condition. In collapse it is of some value. We believe this

statement is true clinically. Strychnin goads a heart to increased action when that organ has not sufficient blood passing into it to enable it to firmly and strongly contract. The use of strychnin in shock has been compared by Hare to beating a dying horse to make it pull. I believe that atropin is of great benefit in shock, especially if the skin is very moist. This drug, according to my colleague, Prof. Hobart A Hare, is a sedative to the vagus; but what makes it particularly valuable is that it acts upon the vasomotor system, combats the dilatation of the blood-vessels, maintains vascular tone, opposes stagnation of blood in any vessels, and increases the amount of moving blood. If the skin is very moist, atropin is particularly indicated. Senn recommends the hypodermatic injection of sterile camphorated oil, a syringeful every fifteen minutes, until reaction begins. Inhalation of oxygen is often of much service, and artificial respiration may be necessary. Opiates are contra-indicated in shock. Mustard plasters should be placed over the heart, spine, and shins. A turpentine enema is useful. An enema of hot coffee and whisky is valuable. In severe cases of shock, bandage the extremities. Bandaging for the relief of shock is called *autotransfusion.* This procedure increases peripheral resistance and enables the body to utilize to the best advantage the small amount of circulating blood, and sends most of it to the brain, where it will maintain the activity of the vital centers and keep up circulation and respiration. For this purpose ordinary muslin bandages may be used, or gauze bandages, or the bandages of Esmarch. Crile's rubber suit accomplishes the object more satisfactorily than does bandaging the extremities. Abdominal massage helps drive out the imprisoned blood, and after massage sets free the abdominal blood apply a compress and binder. In serious cases artificial respiration and stimulation of the diaphragm with a galvanic current may be used. If shock comes on during an operation, the operation must be hurried or even abandoned, and proper treatment must be instituted at once. The anesthetist should give very little ether when shock becomes at all evident. Should we operate during shock? We should only do so when death without instant operation is inevitable. We must operate, if it is necessary to do so, to arrest hemorrhage, to relieve strangulated hernia, intestinal obstruction, obstruction of the air-passages, compound fractures of the skull, extravasated urine, or intraperitoneal extravasations from ruptured viscera. If hemorrhage can be temporarily controlled by pressure or a clamp, so much the better, and the permanent arrest can be effected after the reaction from shock. It is not wise, in the author's opinion, to amputate during shock. A tourniquet or Esmarch bandage should be applied, and attempts be made to bring about reaction, and when reaction is obtained the amputation should be performed. It is only just to say that some eminent surgeons oppose this rule. Roswell Park says that "shock is often alleviated by the prompt removal of mutilated limbs which, when still adherent to the trunk, seem to perpetuate the condition." The same teacher believes in operating at once upon severe compound fractures.[1] After every operation keep careful watch upon the amount of urine passed, see to it that the patient takes sufficient fluid, and if the urine becomes scanty put a hot-water bag to each loin, give diuretics by the mouth, secure cutaneous activity, give saline purgatives, and administer hot saline enemata. If the condition is not soon benefited, the custom is to infuse hot saline fluid into a vein. I am doubtful if intravenous infusion of saline fluid is beneficial in suppression, and I even fear it may do harm (see the studies of Widal, Marie and Crouzon, Merklen, and others). Rössle ("Centralbl. f. Chir.," 1907, xxxiv) says that in certain cardiac and renal conditions salt solution damages the capillaries and does actual harm. In urinary suppression following acci-

[1] Park's "Surgery by American Authors."

dent or surgical operation (*postoperative suppression* or *anuria*) the condition is so dreadfully grave that it is justifiable to expose each kidney and split the capsule in order to relieve tension and in the hope of thus abating congestion. In fact, I believe this should always be done. In a case in which there had been total suppression for three days I did this operation. During the next thirty-six hours the patient passed 12 oz. of urine, but died of complications. *Post-operative suppression of urine* is almost invariably fatal. Delayed shock is treated in the same manner as apathetic shock if hemorrhage can be excluded. If hemorrhage is the cause, the bleeding must be arrested, and blood be transfused, or saline fluid be infused into a vein. If delirious shock is due to sepsis, the treatment is that of sepsis. If it is a nervous delirium, give morphin and other sedatives. If due to uremia, the treatment is obvious.

Fat-embolism.—(See page 191.)

Fever.—(See Fevers, page 128.)

Treatment of Wounds.—All wounds, other than those made by the surgeon, are regarded as infected. The rules for treating such wounds are: (1) arrest hemorrhage; (2) bring about reaction; (3) remove foreign bodies; (4) asepticize; (5) drain, coaptate the edges, and dress; and (6) secure rest to the part and combat overaction of the tissues. Constitutionally, allay pain, secure sleep, maintain the nutrition, and treat inflammatory conditions.

Arrest of Hemorrhage.—To arrest hemorrhage the bleeding point must be controlled by an Esmarch band or digital pressure until ready to be grasped with forceps; it is then caught up and tied with catgut or aseptic silk. Slight hemorrhage ceases spontaneously on exposure of the bleeding point to air, and moderate hemorrhage ceases permanently after the temporary application of a clamp. An injured vessel when not of the smallest size must be ligated, even if it has ceased to bleed. Capillary oozing is checked by hot water and compression. If a large artery is divided in a limb, apply a tourniquet before ligating. (See Wounds of Vessels.)

Bringing About of Reaction.—(See Shock.)

Removal of Foreign Bodies.—Remove all foreign bodies visible to the eye (splinters, bits of glass, portions of clothing, gun-wadding, grains of dirt, etc.) by forceps and a stream of corrosive sublimate solution, sterile water, or normal salt solution. In a lacerated or contused wound portions of tissue injured beyond repair should be regarded as foreign bodies and be removed with scissors.

Cleaning the Wound.[1]—To clean the wound shave the surrounding area, if it is hairy; scrub the surface about the wound with ethereal soap, green soap, or castile soap; wash with water, scrub with alcohol, and then with corrosive sublimate solution (1 : 1000). An accidental wound is infected, and must be well washed out with an antiseptic solution. In every wound in which we have reason to suspect tetanus infection a preventive dose of antitoxin should be given. We have particular occasion to apprehend tetanus if the wound is contaminated with feces, street dirt, stable dust, or stable refuse, or if it was infected with a toy pistol such as boys use to celebrate the Fourth of July. A clean wound made by the surgeon need not be irrigated; in fact, irrigation with an antiseptic fluid leads to necrosis of tissue, causes a profuse flow of serum, and necessitates drainage. If clots have gathered in a wound they must be removed, as their presence will prevent accurate coaptation of the edges. In an infected wound they are washed out by a stream of corrosive sublimate solution. In a clean wound they are washed out by hot salt solution. If dirt is ground into a wound, as is often seen in crushes, pour sweet oil into the wound, rub it into the tissues, and scrub the wound with ethereal soap. The oil entangles the dirt, and the soap and water remove both oil and dirt. After the rough cleansing irrigate with corrosive sublimate solution. In

[1] The use of iodin as a germicide is discussed on page 68.

some cases, especially in bone injuries, it is necessary to scrape the wound with a curet. If a fissure of the skull is infected, enlarge the fissure with a chisel in order to clean it. In a badly infected wound one of the most valuable agents for use in producing disinfection is pure carbolic acid. After cleaning the wound, it is necessary in certain regions to examine in order to determine if tendons or considerable nerves have been cut. If such structures have been divided, they must be sutured with fine silk, chromic gut, or kangaroo-tendon.

Drainage, Closure, and Dressing.—Superficial wounds require no special drainage, as some wound-fluid will find exit between the stitches and the rest will be absorbed. A large or deep wound requires free drainage for at least twenty-four hours by means of a tube, strands of horsehair, silk or catgut, or bits of iodoform gauze. An infected wound must be drained invariably. Good drainage may, to a considerable extent, compensate for imperfect antisepsis. If capillary drains are employed, apply a moist dressing. Otherwise the strands dry and fail to act as drains. Approximate the edges with interrupted sutures of silk or silkworm-gut if the wound is deep and considerable tension is inevitable. Catgut is used for superficial wounds and for those where tension is slight. If there is decided tension, silver wire may be used. In very deep wounds buried sutures must be used. These sutures may consist of absorbable material (kangaroo-tendon or catgut) or unabsorbable material (silver wire) or very fine silk. Of late I have been following the Johns Hopkins custom and have closed all clean wounds with sutures of very fine iron dyed silk passed by small and very sharp sewing needles. By the use of these fine sutures a minimum amount of tissue necrosis occurs; the risk of infection is greatly lessened, and the resulting scar is the smallest that can be obtained. As is well known, tight sutures cause tissue necrosis and hence predispose to infection. It is impossible to tie the fine black silk very tight, because if we do so it breaks. It requires considerable practice to learn to tie the sutures without breaking. This fine silk can be buried without fear, as it never causes a sinus, and it is used for layer sutures with perfect confidence. I learned this plan from Dr. Harvey Cushing, and am much pleased with it. If the wound is infected, dress with warm, moist antiseptic gauze. If it is not infected, dress with dry sterile gauze. The custom once was to cover even dry gauze with a rubber-dam to diffuse the fluids, but we now prefer to omit the rubber-dam and use plentiful dressings. A dry dressing absorbs wound-fluids quickly and is less likely to become infected. Change the dressings in twenty-four hours or sooner if they become soaked with discharge. Dressings are changed for cause, but not according to scheduled time. They must, of course, be changed when they become soaked with wound-fluid, and soaking may occur in a few hours, but may not occur for days. As long as the temperature remains normal and the wound free from pain, if the dressing is not wet with discharge, it can be left in place unless removal is necessary to take out a drainage-tube. If pus forms, open the wound at once. Many surgeons sprinkle wounds before approximation and wound surfaces after approximation with a drying powder. These powders are of great use in infected wounds, but are not necessary in clean wounds. Among the substances employed are salicylic acid, boric acid, calomel, acetanilid, aristol, iodoform, subiodid of bismuth, and glutol. In large wounds which cannot be approximated it is occasionally advisable to skin-graft by Thiersch's method. A small wound which cannot be sutured is dusted with an antiseptic powder and dressed. A granulating wound is dressed as is a healing ulcer. In recent infected wounds rest associated with Bier's treatment comprise the means of local treatment. Incision is usually required. In later infections or severe infections the wound must be opened widely and drained.

A sloughing wound is opened, is dusted with iodoform or acetanilid, and is dressed with hot antiseptic fomentations.

Rest.—Severe wounds require the confinement of the patient to bed. Bandages, splints, etc., are used to secure rest. In a closed wound rest need not be protracted, in fact, our former custom was to insist upon it for too long a period. The slight irritation of moderate motion stimulates repair. We no longer feel it necessary to keep laparotomy cases in bed for three full weeks, but we get them up in from seven to ten days. By doing this we secure just as firm a cicatrix, greatly lessen the annoyance from constipation and flatulence, and diminish notably the number of cases of postoperative pneumonia and phlebitis. I do not, however, advocate getting such patients up in twenty-

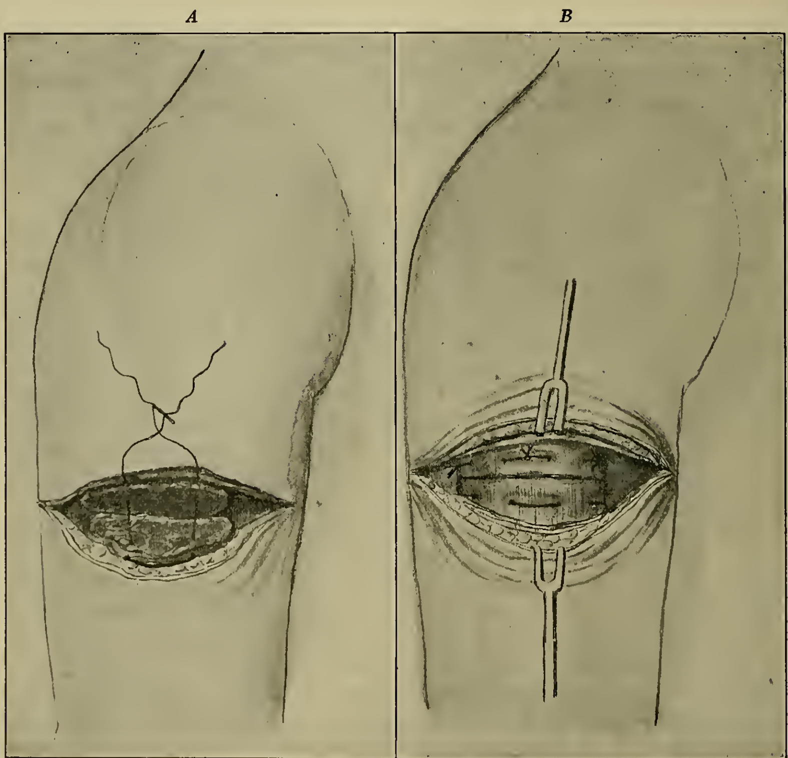

Fig. 109.—Muscle suture: *A*, Transverse wound of biceps muscle, showing marked retraction of muscle-ends and mattress suture in place; *B*, muscle suture completed (Senn).

four to thirty-six hours, as is advised by some surgeons. A patient with an infected wound or an open drainage wound should be confined to bed. The methods of combating inflammation have previously been set forth.

Constitutional Treatment.—Bring about reaction from depression, but prevent undue reaction. Feed the patient well, stimulate him if necessary, attend to the bowels and bladder, secure sleep, and allay pain. Watch for complications, namely, inflammation, suppuration, gangrene, tetanus, erysipelas, suppression of urine, and pneumonia. Observe the temperature closely; it may be a danger-signal of urgent importance.

Incised Wounds.—An incised wound is a clean *cut* inflicted by an edged instrument. Only a thin film of tissue is so devitalized that it must die. These wounds have the best possible chance of union by first intention.

The pain may be very severe; but if the instrument is sharp and used quickly it may be trivial. The pain is less severe than that caused by some other varieties of wounds. The acute pain does not last long, and is followed by smarting. The hemorrhage is profuse, varying, of course, with the region cut. Bleeding from the scalp is violent, because there are numerous vessels which lie in fibrous tissue and cannot retract nor contract. The edges of incised wounds retract because of tissue elasticity, and the wound "gapes." If the skin or fasciæ are divided at a right angle to the muscle beneath, there is wide gaping. If the cut is parallel to the muscle-fibers, the gaping is slight.

When the skin is violently pulled upon, it tends to split in a certain line. Langer and Kocher speak of this as the line of cleavage, and point out the direction of these lines in various situations. A cut across the line of cleavage is followed by wide gaping. A cut in the direction of the line of cleavage produces slight gaping, and is followed by a trivial scar.

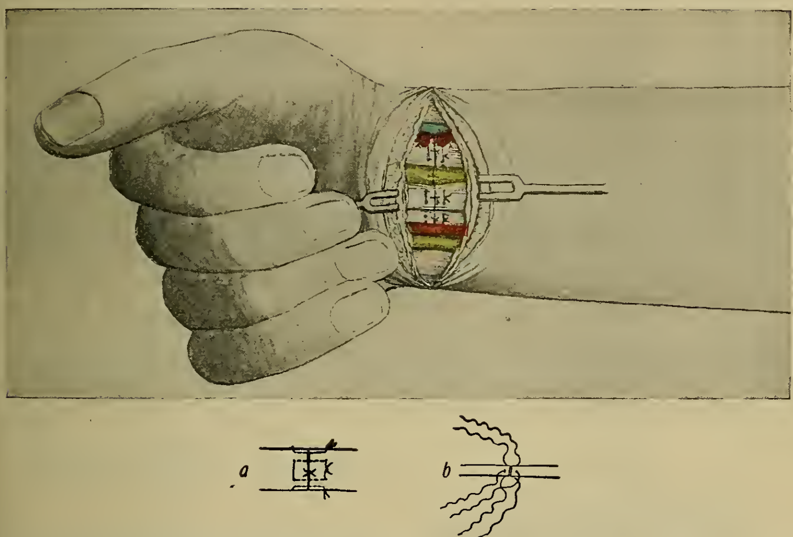

Fig. 110.—Suturing of tendons and nerves in incised wounds: *a*, Primary tendon suture; *b*, primary nerve suture (Senn).

When a muscle is cut across the wound edges widely separate. When a tendon is completely cut across extensive separation occurs.

An incised wound can be thoroughly inspected, all divided structures can be identified, foreign bodies can be easily removed, and disinfection can be satisfactorily carried out.

Treatment.—According to general principles. Arrest hemorrhage, asepticize, etc.

Examine the wound carefully to see if a nerve, a tendon, or a muscle is divided, and if such injury is discovered, suture at once (Figs. 109 and 110). If the wound is extensive or deep, it may be necessary to use buried sutures in order to keep the sides of the wound in contact. If the surface of a wound is approximated, but the depths are not, the dead space or cavity becomes filled with fluid, and infection almost certainly occurs. If buried sutures have not been used, such a cavity must be obliterated by the judicious application of pressure upon the surface. This is secured by the adaptation of a mass of loose or fluffed-up gauze, and the firm application of a bandage or binder. An

incised wound is usually closed with interrupted sutures (Figs. 111 and 112). In adjusting the sutures, see that the edges of the wound are not inverted, but are neatly approximated with raw edge to raw edge. Tie the stitches firmly but not tightly. If a stitch is tied too tightly it will make a ridge, as shown

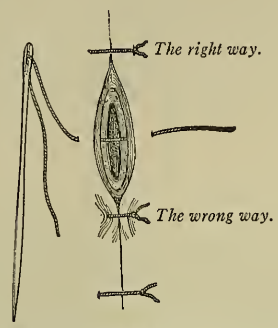

Fig. 111.—The interrupted suture (after Bryant).

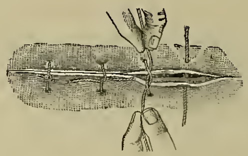

Fig. 112.—Tying an interrupted suture. The knot is placed to the *side* of the wound as shown in Fig. 109.

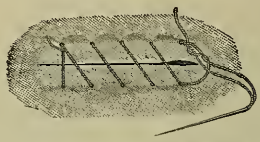

Fig. 113.—Continuous suture.

in Fig. 111, and undue tightness is sure to cause necrosis, and is often productive of a stitch-abscess. As previously stated, I usually close wounds with sutures of very fine black silk. This will break if we try to tie it tightly, and as it never causes a sinus when retained in the tissues it can be used for buried

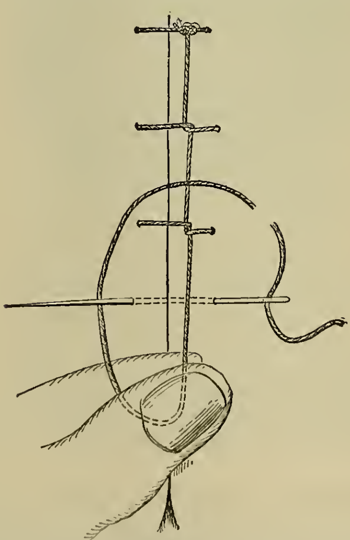

Fig. 114.—Ford's suture: A square knot, a single knot, a double or friction knot, and the first method of passing the needle to tie a single knot immediately.

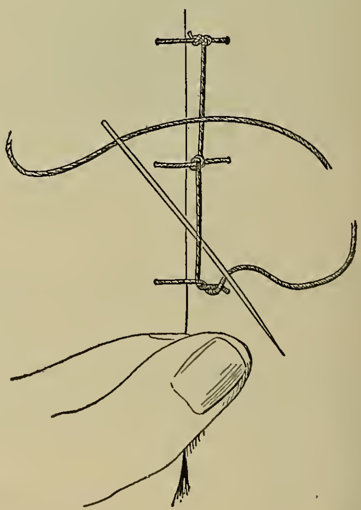

Fig. 115.—Ford's suture: Showing two square knots, a single knot, and the method of completing a square knot.

sutures as well as for the skin. A silk suture and catgut suture should be tied with the reef knot; a suture of silkworm-gut may be tied with either a surgeon's knot or a reef knot. If a wound is on the face, particular care must be employed in closing it, in order to limit the amount of disfigurement. Fine silk sutures are passed with a small sharp needle or a subcuticular stitch is used.

In a clean wound stitches may, as a rule, be removed in from six to eight days. In a large wound one-half the stitches are removed at one sitting, and in a day or two the rest are removed. Stitches are promptly removed if they begin to cut out or if infection occurs.

The old continued suture is rarely used for skin-wounds at the present time. This suture is employed to suture the dura after division, to suture the two layers of pleura together before an abscess of the lung is opened, to suture the peritoneum after laparotomy, and to suture the mucous membrane after certain operations upon the stomach. The continuous suture is shown in Fig. 113. A continuous suture knotted after each emergence was devised by Ford. It is very useful in suturing the parietal peritoneum (Figs. 114 and 115.)

Halsted's subcuticular stitch (Fig. 116) makes a most perfect closure of the skin-wound, and is followed by the smallest possible scar. In closing a deep wound the muscles and fasciæ are sutured in layers by buried sutures before the subcuticular stitch is inserted. It is only used in wounds which are almost certainly clean (as those made by the surgeon), and in wounds which do not require drainage. The suture material should be of silver wire caught upon a curved Hagedorn needle or silkworm-gut carried by a long, straight, round needle. The suture is passed through the corium on each side of the wound, as shown in Fig. 116. The curved needle must be held in the bite of a needle-holder. When the suture has been passed the ends are pulled upon, and the skin-wound closes neatly.

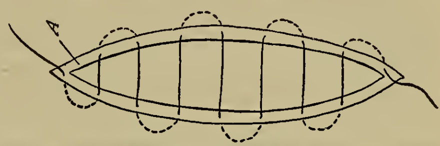

Fig. 116.—Halsted's subcuticular suture: *A* is the true skin.

Halsted's suture does not penetrate the cuticle; hence, in passing it the white staphylococcus is not carried through stitch-holes and into the wound, an accident which might be followed by infection of a stitch hole or even of the wound. When it is desired to withdraw this suture, take one end in the bite of the forceps, cut it off short with scissors, catch the free end with forceps, and pull steadily upon it.

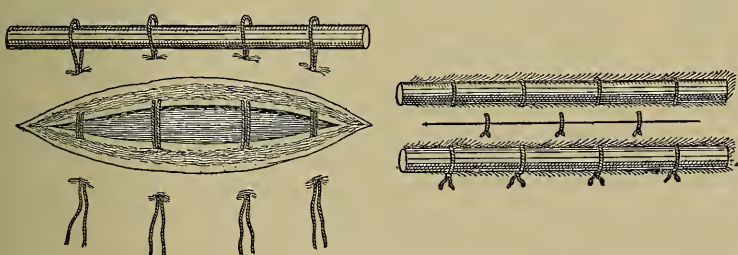

Fig. 117.—The quilled suture.

In very deep wounds or wounds in which there is much tension after approximation the quilled suture (Fig. 117) or the button suture (Fig. 118) may be used. The twisted suture or hare-lip suture is shown in Fig. 119.

Problems of drainage, dressing, etc., are discussed on pages 76, 77, and 78.

If infection occurs, the wound becomes swollen, tender, painful and discolored, and the temperature of the patient soon becomes elevated. In such a condition cut the stitches, disinfect, and drain.

Wounds of Mucous Membranes.—If the surgeon intends to inflict a wound upon a mucous surface, he should see to it that the patient's general condition is good. Thorough asepsis is impossible, and a good result depends

largely upon the vital resistance of the tissues. Before operating, irrigate the part frequently with boric acid, peroxid of hydrogen, or normal salt solution. When ready to sew up the wound be sure that all irritant fluids are removed (saliva in the mouth, etc.). Cleanse the wound with hot normal salt solution. The stitches must include submucous tissue as well as the mucous membrane, and consist of silver wire, catgut, silk, chromic catgut, or silkworm-gut. After sewing up a wound in the mouth wash the oral cavity at frequent intervals with salt solution, and follow each washing with an insufflation of iodoform.

In accidental wounds irrigate with salt solution, dust with iodoform, and close as directed above. Corrosive sublimate is so irritant that it does harm when applied to a mucous membrane.

Contused and Lacerated Wounds.—A contused wound results from a blow or a squeeze which bruises and crushes the tissues and splits or ruptures the skin. It is a common injury when force is applied to tissues over a bone. The blow of a blackjack upon the scalp may cause either a contusion or a contused wound. A contused wound is irregular in outline, has jagged edges, and is surrounded by a broad zone of contusion. The worst form of contused wound is a crush of an extremity produced by being run over. The skin is often widely separated from the tissues beneath.

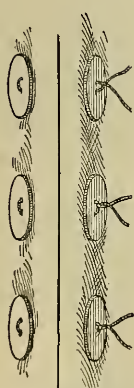

Fig. 118.—Button suture.

A lacerated wound results from tearing apart of the tissues. It, too, is irregular and jagged, and is accompanied by more or less contusion. A *brush-burn* is a contused-lacerated wound due to friction. Both lacerated and contused wounds contain masses of partly detached and damaged tissue, the vitality of which is endangered. Nerve-trunks, muscles, and great vessels may be torn across. Hence, such wounds are apt to slough, frequently suppurate, and are occasionally followed by cellulitis or even by gangrene. There is more danger of tetanus than in incised wounds. A wound especially apt to be followed by tetanus is made by the toy pistol. In contused and lacerated wounds the edges are discolored and cold to the touch, and there is little primary hemorrhage unless a cerebral sinus is opened or a great vessel is torn. There is considerable danger of secondary hemorrhage if large vessels have been bruised. In wounds of this nature the pain is often slight, but it may be violent. Shock is very severe.

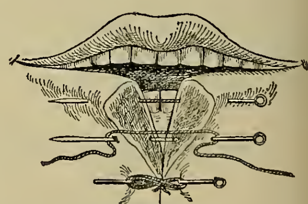

Fig. 119.—The twisted suture.

Avulsion of a limb is a dreadful form of lacerated wound. The thumb or a finger may be torn off or the arm may be wrenched from the body with or without the scapula. In such cases the wound is large, jagged, and irregular, long strings of muscle or tendon hang from the gap, the wound edges are cold, but the bleeding is trivial. The shock is, of course, profound.

Avulsion of the scalp may be produced when the hair is caught in machinery. The American Indian inflicts this injury when he scalps a conquered foe. In some cases of avulsion of the scalp the periosteum is removed with the flap; in most it is not. The flap usually consists of skin and aponeurosis. In this form of laceration there is severe bleeding.

Treatment.—The surgeon brings about reaction and endeavors to asepticize the wound and skin about it (see page 266), arrests hemorrhage, and ligates any visible damaged vessel whether it bleeds or not. Hopelessly damaged tissue should be cut away, doubtful tissue being retained. In some cases amputation

is necessary. If we apprehend tetanus, give an injection of antitetanic serum as a preventive. Secure thorough drainage, in some situations making counter-openings if necessary. Tube-drainage may be necessary or iodoform gauze in strands may be used. Contused wounds and lacerated wounds, except when on the face, are seldom closed by sutures. They are rarely closed, because the damage is so great and the blood-supply so interfered with that primary union will not occur. In the face the blood-supply is so good that primary union may be obtained in part or entirely, and it is worth while to try to obtain it. Cold must not be applied to a region of lowered vitality because it might cause gangrene. Heat is useful. Hence, it is advisable, even from the start, to dress with hot antiseptic fomentations, and this mode of dressing becomes imperative if sloughing begins. An excellent fomentation is made by soaking the gauze in a hot solution of acetate of aluminum, using 1 fluidram of a $7\frac{1}{2}$ per cent. solution to an ounce of water (Waterhouse, "British Med. Jour.," July 9, 1910). Of course, the part must be kept at rest. After healing has advanced the occasional application of an 8 per cent. ointment of scarlet red greatly stimulates cicatrization.

If suppuration occurs, the surgeon sees to it that the pus has free exit, and if necessary secures free exit by making incisions. Bier's treatment and rest are useful for infections.

After avulsion of a limb the patient is reacted from shock, large vessels are sought for and tied, damaged tissue is cut away, the wound is drained by gauze and is *partly* approximated by sutures. After avulsion of the scalp bleeding vessels are carefully ligated. A portion of the scalp may be torn away, but a pedicle may connect it with the balance of this structure. In such a case cleanse the parts thoroughly and suture the flap in place (W. T. Bivings, "Phila. Med. Jour.," June 7, 1902). If the portion of scalp is entirely separated, adopt Gussenbauer's suggestion when possible and graft pieces of the avulsed scalp. In any case the ulcer resulting from avulsion must be repeatedly grafted. Abbe obtained healing in a case after four years by the use of 12,000 grafts.

Punctured wounds are made with pointed instruments, as needles, splinters, etc. The depth of a punctured wound greatly exceeds its surface area. After the withdrawal of the instrument inflicting the injury the wound partly closes at points, blood and wound-fluid cannot find exit, and if, as is probably the case, bacteria were deposited in the tissues, infection by pus organisms is very likely to occur, and if it does occur suppuration spreads widely. There is also danger of infection by tetanus bacilli. Such a wound may involve an important blood-vessel, and in such a case profound hemorrhage may occur; otherwise hemorrhage is slight. A great cavity of the body may be penetrated or an important organ may be wounded. Large-sized foreign bodies may be driven into the tissues or a portion of the instrument may break off and lodge. Pain is rarely severe unless a considerable nerve has been damaged. If both a large vein and artery are punctured, varicose-aneurysm or aneurysmal-varix may arise.

Treatment.—When possible, inspect the instrument which did the damage to see if a piece has been broken off. If there is severe hemorrhage, enlarge the wound and tie the bleeding vessels. In a puncture not made by the surgeon the wound must be regarded as infected. If a wound is made by a dirty instrument through skin known to be unclean, it is proper that the skin about the puncture be sterilized, that the wound be enlarged, that foreign bodies be removed, that the wound be irrigated with an antiseptic solution or be painted with pure carbolic acid, and be drained with a tube, a strip of gauze, or a piece of rubber tissue. Such treatment, though painful, and appearing unnecessarily severe or even cruel to the sufferer from a trivial puncture, is neces-

sary, and may save the patient from serious illness or from death. Every deep puncture inflicted by an instrument not surgically clean, and every puncture inflicted by a nail, a splinter, a meat-hook, a rusty pin, a tooth of a cat or dog, etc., must be regarded as grossly infected and must be treated by incision, sterilization, drainage, hot antiseptic fomentations, and rest. If the puncture is superficial and is made with a smooth-pointed instrument like a needle, when the instrument was not grossly infected the parts may be dressed with hot antiseptic fomentations, but they should be inspected daily for evidence of infection, and at the first sign of trouble an incision must be made. If a foreign body is retained in the tissue it must be removed.

Pure carbolic acid is a most efficient agent to sterilize a punctured wound.

If an important cavity of the body has been invaded by a puncture exploratory incision is necessary (see Brain, Thorax, Abdomen). In punctures with contaminated instruments the antitetanic serum finds a valuable place as a preventive of tetanus.

Stab-wounds were formerly considered with punctured wounds, but Senn wisely placed them in a class by themselves. Stab-wounds are inflicted by penetrating the tissues with a pointed or narrow instrument—for instance, a dagger, a knife, the blades of scissors, a bayonet, or a sword. Such wounds are narrow and very deep. A stab-wound may cause rapid death by penetration of a large blood-vessel. Some great cavity of the body may be penetrated and internal hemorrhage will then occur. The body may be transfixed by a sword or bayonet. Bone is rarely injured unless the skull is penetrated or the chest entered. In stab-wounds there is usually great hemorrhage and shock.

Treatment.—Whenever possible, look at the instrument which did the damage and see if a piece is broken off. If no great cavity is entered, treat by general rules: arrest bleeding, react from shock, etc. The treatment of penetrating wounds of the abdomen, thorax, and cranium is discussed in the special sections.

Arrow-wounds might be considered under the head of punctured wounds or stab-wounds. When hostilities with the red men were frequent and before mercenary traders had fitted out the savages with rifles, arrow-wounds were common among the men of the frontier. They are now very rare. Military surgeons still encounter them, especially in some parts of Africa and in the Philippine Islands. An arrow-wound may be a trivial puncture of the skin, a deep wound of the soft parts with or without bone injury, a penetration of a joint, or of one of the body cavities. The skull cavity may be entered by an arrow. In some of these cases there is a puncture of the bone without the formation of fissures, but usually when bone is punctured there is fissure formation, splintering, or depression. A large blood-vessel may be divided by an arrow and violent bleeding result or fatal concealed hemorrhage may take place from a wounded viscus. Some tribes poison arrows. It is said that the Piutes were the only tribe of North American Indians which did this.

Some tribes in South America use curare, others use snake-poison, others used decomposed meat. In Northern Nigeria some form of strophanthus plays a part in nearly all the poisons used (Allan C. Parsons, in "Brit. Med. Jour.," Jan. 23, 1909). The same author points out that the poison used is generally complex and contains also various animal and vegetable ingredients, particularly decomposed organic matter, plant juice containing strychnin, and soil contaminated with tetanus organisms.

Treatment.—An arrow is always septic and should be extracted. Sometimes when it has been buried deeply in a part it should be pushed across and extracted through a counteropening after the protruding shaft has been cut off. An arrow-head cannot be pulled out by the shaft. The barbs on the head catch and prevent extraction and the neck of the shaft is apt to break. The

tissues should be freely divided down to the head of the arrow and on each side of it, when it can usually be withdrawn by forceps. If imbedded in bone, the head must be gently rocked from side to side to loosen it, every care being taken to avoid breaking a stone or bending an iron arrow head. If an arrow has penetrated the abdomen, a laparotomy should be performed. If it has entered a joint, the joint should be freely opened. If it has entered the chest, one or more ribs will require resection. If it has entered the skull, trephining is indicated. Any bleeding vessels are to be caught and tied. The track of the arrow should be carefully disinfected and drainage should be secured. It is particularly important to remove a poisoned arrow at once. After removing a poisoned arrow, if the nature of the poison is known, proper treatment should be applied to antidote the poison. The French Colonial surgeons fill wounds inflicted by poisoned arrows with tannic acid. The same custom is followed by English surgeons in West Africa (Allan C. Parsons, in "Brit. Med. Jour.," Jan. 23, 1909).

Gunshot-wounds are contused or contused-lacerated wounds inflicted by materials projected by explosives. A bit of rock or a crowbar hurled by dynamite inflicts a gunshot-wound, as does a shell-fragment, a pistol-ball, small birdshot, a rifle bullet, pieces of a hand grenade, a flying cap, a piece of wadding, grains of powder, a buckshot, a fragment of metal broken off a shell, grapeshot and canister, or a cannon-ball. Injuries by shell-fragments, portions of a bursted boiler, pieces of masonry or wood, are either lacerated or punctured wounds, and need no special consideration here. In this article we treat of injuries caused by bullets and shot, that is, by missiles propelled from firearms.

Firearms are instruments by means of which missiles are projected to a distance by the expanding gases of burning gunpowder. There are many different sorts of firearms. Artillery includes various sizes of guns upon supports, from the great 12-inch guns of a battleship, which fire shells weighing 850 pounds, to machine-guns, which fire ordinary rifle bullets. Field artillery uses little but shrapnel-shells. Such a shell is a case of steel, cylindroconoidal in shape, containing a number of bullets and a charge of explosive, the shell exploding by means of a time-fuse. Canister is an iron casing containing bullets unassociated with an explosive discharge within the casing. The canister breaks when fired, and the balls separate over a large area. It is used only at close range—that is, 300 or 400 yards.

Among small arms may be mentioned muskets, revolvers, shotguns, and rifles. Wounds from the old-time musket ball are now never met with except in warfare against barbarous tribes. The musket has a smooth bore and fires round bullets of soft lead. This round, soft bullet, being large, moving with comparative slowness, and flattening easily, is very liable to glance, to deform, and to lodge. When a musket is fired at close range and the bullet strikes the tissue at a right angle, it produces a punched-out entrance wound. If the velocity is low or the impact is not at a right angle to the tissues, the entrance wound may "be formed of triangular flaps," the corners of which are inverted.[1] The entrance wound is surrounded by a bruised area. The track of the bullet is larger than the bullet, and is so badly contused and lacerated that some tissue is devitalized; and the shaft of a bone, if struck, is likely to be splintered. If the ball emerges, the wound of exit is larger than the bullet, and forms triangular and everted flaps. Healing by first intention seldom occurs in such wounds. The old smooth-bore musket, firing a round bullet, has been displaced by the rifle propelling a conical projectile.

In the firearms of civilians, as a rule, the bullets are made of lead, hardened and shaped by compression or hardened by an admixture with tin. The conical or cylindroconoidal rifle bullet has much greater velocity and pene-

[1] "Wounds in War," by Surgeon Col. W. F. Stevenson.

trating power than the round bullet. Hence, it is more liable to penetrate and less likely to deflect and to lodge. The tissues in the track of this bullet are less devitalized than in the track of the round bullet. The cutaneous surface is not so much contused. The wound of entrance is about the size of the bullet, and is punched out or inverted; and the wound of exit is larger than that of entrance and is often everted. The bones are more seriously comminuted than by the round bullet, and osseous fragments may be driven widely into the tissues. In fact, "an explosive effect" may occur at close range. Delorme lays it down as a rule that comminution of bone makes the wound of exit larger; and he asserts that a wound of exit larger in diameter than the thumb means comminution of bone.

Gunshot-wounds Seen in Civil Life.—Wounds are occasionally inflicted by the sporting rifle or the shotgun, and frequently by blank cartridges; but the vast majority of such wounds seen by the civilian surgeon are inflicted by the revolver.

Fig. 120.—Lodged shot.

Wounds from the Sporting Rifle.—In the sporting rifle a large charge of powder is employed. Some sporting rifle bullets have no hard jackets. Others have an incomplete hard jacket. In a bullet with a partial hard jacket the "nose" of the bullet is exposed and soft. The bullets are usually larger than those used in the military rifle. Such bullets deform in the tissues, and inflict dreadful, tearing wounds. If a bullet of a sporting rifle strikes a limb, amputation may be required. If it strikes the head or trunk, it will almost certainly produce a fatal wound.

Wounds from the Shotgun.—The degree of injury is in direct relation to the adjacency of the wounded individual to the gun, when the discharge takes place, to the size and number of the shot, and to the charge of powder. Single shot may bruise the surface and fail to enter the tissues or may enter the tissues.

When many shot enter together they strike as a solid body. Single shot are usually deflected from vessels and nerves, and seldom lodge in bone, but, rather, flatten on the bone surface. Even a single shot lodged in the eyeball is apt to produce violent inflammation which may destroy the eye. Numerous shot entering together at close range produce extensive contusions of the surface and fearful lacerations of the tissues, and often inflict irreparable damage. Bone may be fractured and bits of clothing or other foreign bodies may be carried into the wound with the shot. At close range toes or fingers may be blown off, an eye may be blown out, or portions of tendon or muscle may be shot away. At close range dreadful subcutaneous lacerations are caused by the gases. Primary hemorrhage is seldom severe because the wound is lacerated; but secondary hemorrhage is to be feared, and serious infection usually follows such injuries. Buckshot at close range inflict grave or dreadful wounds. The United States Army is supplied with a cartridge for use in riots. This cartridge contains two shot, each about the size of a buckshot.

The Treatment of Shotgun Wounds.—If the shot be scattered and lodged it is seldom necessary to remove them. As a rule, such cases require only cleansing of the skin and aseptic dressings. If shot lodge in a joint, they impair function; if in the face, they produce deformity. In both of these cases removal is necessary. When a shot lodges in the eye it usually, but not always, causes blindness. If the eye is gravely damaged it must be enucleated. In serious lacerations produced by shot at close range the hopelessly damaged tissue must be cut away, hemorrhage must be arrested, foreign bodies must be removed (though no protracted search is either necessary or desirable to remove grains of shot), the wound must be disinfected as well as possible, and free drainage must be employed. It is wise to give a prophylactic dose of antitetanic serum.

Blank-cartridge Injuries.—These injuries can occur only at close range. They consist of burns and lacerations, frequently a wad or a bit of clothing lodge in the tissues, and tetanus is a not unusual sequence. The explosive used in the toy pistol is a fulminate, and bits of the envelope of the explosive may be driven quite deep into the tissues. There is considerable danger of tetanus after injuries inflicted by the toy pistol. What in the United States is called "Fourth of July tetanus" is tetanus following such an injury, the small boy being prone to employ a toy pistol to contribute noise to the celebration of the nation's birthday (see page 203).

Blank-cartridge wounds and toy-pistol wounds are treated by cleansing the skin, enlarging the wound, removing foreign bodies, disinfecting, and draining. A prophylactic dose of antitetanus serum should always be given.

Wounds Inflicted by the Revolver Bullet.—The revolver varies in caliber from .22 to .45. Whereas it is true that certain military revolvers of the automatic type fire a hard-jacketed rifle bullet, the revolvers of civil life propel cylindroconoidal unjacketed bullets at a velocity of about 700 feet a second. A revolver bullet of the civilian's weapon never produces an explosive effect. It is liable to deform in the tissues, is often deflected from bone or tendon, and is very apt to lodge. The shape of the bullet, the velocity with which it is propelled and with which it rotates, and its hardness make it unlikely that at any near range the bullet will merely contuse, and not enter, the skin. Unless striking at an angle to the perpendicular, it will almost always enter. In some cases, however, a pistol bullet, like a spent rifle bullet, may fail to enter the tissues. It then grazes the surface and inflicts a brush burn or simply contuses the part. Sometimes it perforates, more often it lodges. Whereas it may be deflected, it comparatively seldom is; and it often deforms, though it does not do so to anything like the degree that the soft, round bullet does. If a bullet enters the tissues, a cavity, or an organ, and lodges there, it causes a

penetrating wound. If it enters and emerges it causes a *perforating wound.* The bullet may not enter alone, but may carry with it bits of clothing or other foreign bodies, though this complication is much rarer in injury with the conical bullet than with the round ball. On one occasion I removed a piece of coat from the interior of the lung, to which it had been carried by a pistol bullet. In another instance I removed a piece of shirt from the interior of the abdomen, to which it had been carried by a similar bullet. A revolver bullet may break bone, though it is not nearly so liable to do so as a rifle bullet.

In studying a gunshot-wound one must consider the *wound of entrance,* the *tissue track,* and, if the bullet has emerged, the *wound of exit.* It is usually stated that if a revolver bullet fired from a distance of 10 feet or more from the person struck hits the skin at a right angle, it makes a wound of entrance that is smaller than the bullet because the skin is elastic. It is a certain fact that one cannot assert from a mere inspection of the wound of entrance what size bullet a man was struck with. A .22 often leaves a most trivial opening. Careful separation of the margins enables us to measure a wound of entrance, and if this is done it will be found that a wound of entrance is never smaller than the bullet. (See Wm. S. Wadsworth, in "International Clinics," Vol. IV, Twentieth Series.) The shape of the wound is somewhat, but not regularly, circular, because a certain amount of tissue is destroyed. The margins are also somewhat depressed. It has a punched-out look, and the edges, as Draper tells us, are frayed in appearance ("Text-book of Legal Medicine"). The edges of the wound look thickened and are contused, this discoloration being noted for a distance of 1 inch or even 2 inches from the margin of the wound. The skin surface is distinctly blackened; but unless the weapon were fired at very close range this is not due to burning, but rather to staining with a mixture of burnt gunpowder and the grease of the outer surface of the bullet. The appearance of the wound of entrance will be very different if the bullet strikes the surface at an acute instead of a right angle. Then the wound will not be round, but oval or, perhaps, linear. When a bullet is fired very near to the surface of the body the hair of the skin will be burned, there will be some staining with gunpowder around the wound, and powder-grains will be found lodged in the skin. The burning is due to hot gases and with the gases come powder-grains. Whether the weapon inflicting the wound was close or distant there is bruising of the skin, but when the powder is found in the tissues or on the surface and when the surface is scorched the weapon must have been close at the time of discharge. Hot gases singe hairs, clothing, or the skin itself. The nearer the skin the weapon was held the more severe the burning. Wordsworth says, "all gas phenomena require very close range, usually within 18 inches." What is called the smudge is due to "the débris and smoke from the powder" and takes place at a range of less than 18 inches (Wadsworth, in "International Clinics," Vol. IV, Thirtieth Series). The absence of embedded powder, however, does not *prove* that the shot was not close, because the weapon employed might have been one using smokeless powder. When smokeless powder was used the burn is the same as from black powder, the smudge is apt to be of an orange color, tattooing is rarer, and when it does occur shows fewer grains. If the smokeless powder contains graphite it produces a smudge. If the weapon were fired at close range the skin may have been burnt by burning gases or the clothing may have been burnt and the skin scorched by the burning clothing. Staining of the skin with powder can be washed off, but when the skin has been burnt it is dry like parchment. When unexploded powder-grains are lodged in the skin the resulting condition is spoken of as *tattooing,* and this always means a very close shot. Powder-grains may cause severe wounds. It has been held by some that powder-grains are *never* found in the skin unless the bullet has been fired from a distance of less than 3 feet, but this is too arbitrary

a statement to make in a court of law. In any medicolegal case experiments should be made with a weapon and ammunition similar to those used in inflicting the wound in order to determine the real facts of the case. Draper ("Text-book of Legal Medicine") makes the following important statement relating to burns of the skin: "If the weapon is held in the hand in the ordinary way, hammer and sight on the barrel directed upward, the wound in the skin will show, immediately above its orifice, a brand or scorching caused by a slight recoil in the act of firing. The location of this brand will change as the position of the hammer is changed. If the weapon is held in a vise and fired this relation of the brand to the wound is obliterated. This observation, first made and published by Dr. D. B. N. Fish in 1883, supplies an accurate index of the position in which the pistol is held in firing." Wadsworth is of the opinion that the "flip" is usually but not always toward the hammer side. It is modified "by the grip on the handle at the instant of discharge." If the muzzle of a pistol is pressed lightly against the skin gases enter with the bullet and "burst the skin outward, giving a large ragged wound, which is not a wound of entrance, though always called so, but a wound of exit of the gas" (Wadsworth, in "International Clinics," Vol. IV, Thirtieth Series). If the muzzle is held firmly against the surface the gases cause a horrible wound under the skin. This condition is not the same thing as the explosive effect of a bullet. In passing through the tissues the revolver bullet makes a contused-lacerated wound, and we may find along this wound powder-grains (if the bullet has been fired at close range) and portions of clothing, pieces of the bullet itself, or perhaps of bone. A bullet may pass directly through both walls of the skull, traversing the brain in its passage. It may pass through a wall of the skull and lodge within the cavity of the cranium. In some cases it makes an opening of entrance that is smallest on the external surface of the bone and largest on the inner table. In other cases it makes extensive comminuted fractures. When a bullet tracks its way through a muscle it makes a jagged, contused, lacerated wound. It does the same in the brain. In both cases the track of the bullet is larger than the bullet, and the tissue for a considerable distance wide of the track is contused or actually destroyed. In passing through an aponeurosis or a serous membrane the bullet may make a round orifice or a slit-like tear. Of course, the nature of the wound in the tissues will be greatly affected if the bullet is deformed by having struck bone, or if it carries bits of bone along with it. The deflection of a bullet from an aponeurosis, fascia, or bone so alters its course that the missile becomes very difficult to locate and remove. In some cases a bullet has entered near the front of the body and passed around the wall of the chest until it has almost reached its point of entrance, or else has lodged or emerged at some point of this course—in either case constituting what is known as a *contour wound*. Contour wounds are not infrequently seen upon the head. For instance, a bullet may strike the frontal region, pass around under the scalp, and lodge in or emerge from the occipital region.

When the bullet does not lodge, but emerges from the body, the wound of exit must be studied. If an undeformed bullet passes straight through the body it makes a wound of exit that is somewhat larger than the bullet. It has a torn-out appearance, but without distinct destruction of tissue, and exhibits an irregular outline and eversion of the edges. The margins of such a wound are bruised, but are never scorched and never show powder-grains. If a bullet has been deformed by hitting bone, or if it has driven bone before it, a very large lacerated wound of exit may be formed. It is important to remember that the presence of a number of wounds on the surface of the body does not in itself prove that a number of different bullets have been fired, for in certain circumstances one bullet may make several wounds. A few years ago I saw

a case in which a bullet had penetrated the right hand and the right thigh, and had lodged in the left thigh. There were three wounds of entrance and two wounds of exit. Many very extraordinary cases of this sort have been reported.

Symptoms of a Gunshot-wound.—Hemorrhage is often considerable, but ceases spontaneously unless a large vessel has been divided. If hemorrhage is profuse the constitutional symptoms of hemorrhage exist (see page 436). These symptoms are of great importance in abdominal wounds. A pistol ball seldom causes severe primary hemorrhage, because it will not often penetrate a large artery. It is apt to push aside a vessel and secondary hemorrhage is not unusual. Even if a large vessel is wounded and a succession of violent hemorrhages occur, a man may live for several days. Secondary hemorrhage may follow a gunshot-wound because of contusion of vessels or of infection.

Pain is often not noticed at first. The injured individual, if greatly preoccupied or excited, may not know that he has been struck by a bullet. There may be only a feeling of numbness, but usually there is a dull or stinging pain. If a large nerve has been injured there may be violent pain. Even trivial gunshot-wounds frequently produce profound shock, and yet it may happen that severe wounds may be accompanied by but slight shock. In most gunshot-wounds of the brain, abdomen, and spinal cord the shock is very great.

General Considerations as to Treatment.—The dangers are shock, hemorrhage, and infection. Bullets are not aseptic when they enter a part, but a bullet usually carries few bacteria, and if infection is not inserted in the track of the ball the wound will in most instances heal kindly. A stationary bullet, when there is no infection, is usually let alone. "The fate of a wounded man is in the hands of the surgeon who first attends him" (Nussbaum). . The danger of a wound depends upon the size and velocity of the bullet, the part struck, "and the degree of asepsis observed during the first examination and dressing" (De Nancrede). The rules of treatment are: bring about reaction, arrest hemorrhage, preserve asepsis, and, in some cases, remove the ball. Always notice if a wound of exit exists. It is a good plan, when endeavoring to determine the extent of injury, to put the parts in the position they were in when the injury was inflicted. We should try to ascertain the size and nature of the weapon, and the range at which it was fired. Examine the clothing to see if any fragments are missing and could have been carried in. Such fragments render sepsis almost inevitable. The surgeon must not feel it his duty to probe in all cases. In many cases it is better not to probe at all. Never probe when there is a wound of entrance and a wound of exit. Explore for and remove the ball when there is infection or when sure that it has carried with it foreign bodies; or when its presence at the point of lodgment interferes with repair; or when it is in or near a vital region (as the brain). We must locate the ball when it is necessary to know its position in order to determine the question of amputation or resection. If the wound is large enough the finger is the best probe. The x-rays render the use of the probe seldom necessary.

Fluhrer's aluminum probe is a valuable instrument (Fig. 121). It is employed especially in brain-wounds, and is allowed to sink into the track of the ball by the influence of gravity after the part has been placed in a proper position. If a lead bullet is deeply embedded it is possible to distinguish the hard projectile from a bone by inserting the asepticized stem of a clay pipe, a bit of pine wood, or *Nélaton's porcelain-headed probe* (Fig. 122). On any one of these appliances lead will make a black mark. No such test can be applied to a military bullet, for this has a hard metal jacket, and will not make a black mark on a white substance.

Though Nélaton's probe will not show the difference between a hard-jacketed projectile and bone, it is a valuable instrument to follow the track of any bullet wound. The porcelain head ought to be larger than it is usually made; in fact, it should be nearly the size of the bullet (Senn) (Fig. 123).

In passing a probe use no more force than in passing a catheter.

The *induction balance* of Graham Bell has been employed to determine the situation of a bullet. The bullet may be located by *Girdner's telephonic probe.* In order to construct this instrument take a telephone receiver, fasten one of the wires to a metal plate and the other one to a metallic probe. Moisten a portion of the patient's body and place the metal plate in contact with it. The surgeon places the receiver to his ear and inserts the probe into the wound.

Fig. 121.—Fluhrer's aluminum gravitation probe (natural size, except the length, which is 12 inches).

Fig. 122.—Nélaton's bullet-probe.

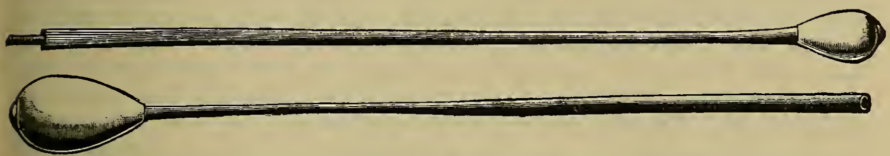

Fig. 123.—Senn's bullet-probe.

If the probe strikes metal, a click is heard with distinctness. A bullet may be located by *Lilienthal's probe.* This apparatus consists of a mouth-piece, two insulated copper wires, and a probe. The mouth-piece is composed of two plates, one of copper and one of zinc, which are applied to the sides of the tongue. An insulated wire runs from each plate and into the metal probe. The tip of the probe is composed of two or four pieces of metal, is separated from the shank by a washer of rubber, and is attached to the wires. The operator closes the teeth upon the mouth-piece and inserts the probe into the wound. If the probe touches the bullet a distinct and continuous metallic taste is appreciable.

The best means of discovering a bullet is to use the *fluoroscope* or take a *skiagraph.* In order to locate it accurately view it through a series of squares,

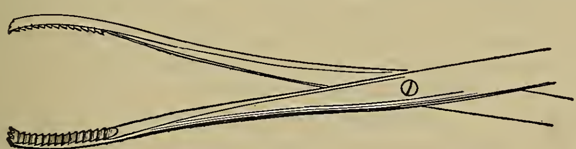

Fig. 124.—Bullet-forceps.

insert guide-pins, or, better than either of these plans, employ Sweet's apparatus. Bullets are readily seen by the fluoroscope in the superficial soft parts, and are discovered in deeper structures (bone, abdomen, lung, brain, etc.) by taking skiagraphs.

In extracting the ball use very strong forceps (Fig. 124). The old American bullet-forceps is useless for the extraction of the hard-jacketed ball, as the points will not penetrate and the instrument will not hold.

If hemorrhage is severe in a gunshot-wound, enlarge the wound, find the

bleeding vessel, and tie it. Before handling a gunshot-wound asepticize the parts about it and irrigate the wound with hot sterile salt solution. In some situations a wound should be drained with a short tube or a bit of iodoform gauze; in other regions this is unnecessary. The dressing should be antiseptic. Primary union rarely takes place after a wound inflicted by a pistol-ball or an ordinary rifle-ball, because of the inevitable necrosis of damaged tissue in the track of the ball, but in some cases it can be obtained. Primary union is frequent after injury by the small hard-jacketed modern army projectile. Healing begins in the depths of the wound and extends toward the wound of entrance, or, if there be also a wound of exit, toward both. Radical operations may be demanded: laparatomy, trephining, rib-resection, joint-resection, or amputation.

Excision may be required when there is great comminution. *Amputation* is sometimes demanded because of severe injury to the soft parts (as by a shell-fragment), great splintering of a bone, grievous injury of a joint, damage to the chief vessels or nerves, or the destruction of a considerable part of a limb. Perform a primary amputation if possible, and make the flaps through tissue that will not slough. In civil practice, with careful antisepsis, more questionable tissue can be admitted into a flap than in military practice, where transportation will become necessary and antisepsis may be imperfect or wanting. It has been shown in recent years that even when a large joint has been perforated by a small hard-jacketed projectile, amputation or resection is rarely required if the wound was treated aseptically from the beginning, but this is scarcely true of the revolver bullet.

Wounds by Grenades.—In the Russo-Japanese War grenades were largely used at close range. At close range they are much more destructive than rifle bullets because they explode and hurl fragments all about. The grenade may be cast by the hand, but it can be projected to a much greater distance "when fixed to and fired from the muzzle of a rifle by the discharge of a small blank cartridge" (Lt.-Col. Borden, in "Keen's Surgery," vol. vi). Grenade fragments produce nasty lacerated and usually infected wounds.

Wounds by Cannon-balls.—A solid shot was apt to kill a man instantly, tear off a limb or lacerate it extensively. Strange cases have been reported in which balls weighing 5 and 6 pounds were embedded in the tissues. In some cases of injury by spent balls the bone is destroyed and the muscles disorganized while the skin is intact. At the present time the projectiles usually fired in war by cannon are shells. A shell is a metal case containing an explosive charge and perhaps also bullets.

Wounds by Shells.—Sometimes a shell fails to explode and may then produce fearful mutilation or tear off a limb. Bursting shells may cause "injury by their concussion-blast, their flame may produce extensive burns, and their fumes may be overpowering. Actual wounds are inflicted by the fragments and by splinters, to which has been communicated the nature of missiles" ("Naval Surgery," by Surgeon-General Stokes, in "American Practice of Surgery"). The fragments vary in size, one man may be struck by many of them, wounds may be deep or superficial, may be horrible pulpifications, grave lacerations, or slight tears. Fragments are usually embedded, but may not be deep. Fractures are common. All shell wounds suppurate.

An ordinary shell contains only an exploding charge and injury is inflicted by the fragments of the exploded shell. Some shells explode by a time-fuse, others by percussion when the shell strikes a hard substance. The shrapnel shell is filled with bullets.

Wounds in War Inflicted by Rifle-bullets.—During the last few years frequent and notable improvements have been made in the military rifle. The range and rapidity of firing have been vastly increased, the velocity of the

projectile and its penetrating power have been enormously added to, and the trajectory has been decidedly lowered. Hence, the zone dangerous to an enemy has been lengthened. In order to accomplish these things changes have been made in the gun, the explosive, and the projectile. It is a far cry from the old Brown Bess, of song and story, to the modern Lee-Enfield of the British Army, or the Springfield of the United States Army. All modern military rifles are of small caliber, that is, less than .35 inch. The Springfield rifles of the days of the war between the States had a caliber of .45 inch. The old Springfield projected a bullet at an initial or muzzle velocity of 1300 feet a second; whereas the modern rifle sends a projectile on its way with an initial velocity of 2700 feet a second, the bullet rotating on its long axis more than 2500 times during the first second of translation. At a range of 1000 yards it will penetrate nearly 13 inches of pine wood. At a range of 100 yards it "will penetrate a steel plate .3843 inch thick" (Borden, in "Keen's Surgery," vol. vi). Up to 5000 yards a modern rifle can inflict a fatal wound, and it can be used point-blank at a range of from 500 to over 700 yards. With the present gun of the United States Army the point-blank zone of danger is about 718 yards. A bullet from a modern military rifle, even after having struck some solid, hard body, may grievously injure a man by ricochet. With a magazine rifle, at 2500 yards, from 5 to 10 per cent. of the balls will ricochet from turf. At 3000 yards they will bury in turf, but may ricochet from very hard ground. The United States Army now uses a magazine Springfield that weighs less than 9 pounds. The barrel is 24 inches in length and the diameter of the bore is .30 inch. The rifling makes one complete turn in every 10 inches. With this weapon, by magazine fire, 25 aimed shots may be fired in a minute; and when used as a single-loader, 23 aimed shots (Surgeon-General O'Reilly, U. S. A., in "Keen's Surgery," vol. iv).

Old-fashioned Black Gunpowder as Compared with Smokeless Powder.—There are many different varieties of smokeless powder, but each is essentially a nitro-powder. Among these smokeless powders are melenite, used by the French; lyddite, employed by the British; and shimose, adopted by the Japanese. The United States forces use cellulose nitrate in perforated cylindrical, amber-colored grains. Nitro-powder is very nearly smokeless because all the products of its combustion are gases. Of the products of the combustion of black gunpowder, 57 per cent. by weight settle out from the atmosphere in solid form on cooling.

There are great advantages in the use of smokeless powder. It is much more powerful than black gunpowder; hence, a smaller charge can be employed. The modern Springfield requires a charge of 47 gr.; and at the time of the discharge the pressure in the chamber is about 49,000 pounds to the square inch. Smokeless powder gives the bullet a greater velocity, causes less recoil, and fouls the barrel infinitely less than black powder; and the absence of smoke maintains a clearer atmosphere for observation, and also furnishes no sign of location which might prove of advantage to the enemy.

Projectiles.—The bullet of a modern rifle is conical, has a lead core, and is hardened by being covered with a mantle or jacket of copper, steel, or nickel, or of alloys of copper and nickel, or of copper, nickel, and zinc. The hard jacket is absolutely essential, because the speed of the projectile is so great that no soft bullet would take the rifling. Fragments would be torn off from the bullet in the gun, and the grooves of the gun would soon be filled with metal, the gun becoming useless. The projectile of a modern Springfield rifle is elongated and pointed. The air-resistance is least in a bullet of this shape. The core is composed of lead hardened with tin, and its jacket is of nickel and copper.

The military surgeon deals with wounds inflicted by these small, dense,

(Adapted, with modifications, from Spencer's " Gunshot Wounds" and Stevenson's "Wounds in War.")

hard, conical projectiles, impelled with great velocity, and carried long distances. The old bullet was liable to lodge, was often deflected in the tissues, was flattened out on meeting with resistant structures, such as bone or cartilage, and, after flattening, became larger, tearing and lacerating the soft parts and comminuting the bone. The modern projectile is likely to penetrate, is rarely deflected, and is so hard that its shape is often but little altered on meeting with resistant structures. Hence, it was thought that the new bullet would prove more humane than the old projectile and inflict wounds that would be more easily treated, because the bullet would be unapt to lodge and extensive damage would seldom be inflicted. This view has proved, to a great extent, correct.

With the modern rifle of small caliber and the hard projectile propelled by smokeless powder the range has been notably increased, the trajectory of the bullet's flight has been greatly lowered, and the danger-zone to an enemy has been correspondingly lengthened.

1 2

Fig. 125.—1, Krag-Jorgensen; 2, new Springfield.

Mechanics of Projectiles.—If a moving bullet were acted upon by no force but propulsion, it would continue to move in the direction that it was pursuing when it left the muzzle of the gun and its course would be a straight line, but it is acted upon by other forces. Even in a vacuum its course would not be a straight, but a curved line, because gravitation would draw it toward the earth. Under ordinary circumstances the air also resists its forward progress.

A moving bullet is urged onward by the force of the exploding powder. This onward movement is called the *motion of translation.* The rate of forward movement is the *velocity,* and this is expressed in feet per second. Air-resistance causes the velocity to lessen rapidly, and the farther away from the gun the projectile is, the greater is its loss of velocity. For instance, on leaving the muzzle of the Lee-Enfield rifle a bullet has a velocity of 2060 feet a second (*muzzle velocity* or *initial velocity*); at 700 yards it has a velocity of 1039 feet a second; at 2000 yards, 571 feet a second; at 3000 yards, 369 feet a second ("Gunshot-wounds," by Major C. G. Spencer). The muzzle velocity of the

bullet of the United States Army Springfield is 2700 feet a second. The velocity of a bullet at any particular portion of its flight is called *remaining velocity.*

A bullet fired from a rifle rotates on its long axis. This rotation is called *spin* or the *movement* of *rotation,* and is in the direction of the groove of the rifling. It is this motion that keeps the point of the bullet toward the front and prevents rotation on its short axis, which would be responsible for increased air-resistance, diminished striking force, and lessened range. If a cylindro-conoidal bullet were fired from a smooth bore, it would rotate on its short axis at even as short a range as 9 yards, and would strike a target in its length (Stevenson's "Wounds in War").

The diminution in the transverse diameter of bullets has necessitated an increase in length in order to maintain their weight and sectional density. (*Sectional density* is the weight divided by the area of the cross-section.) The increase in length makes an increased rapidity of rotation indispensable. The higher the pitch of the rifling, the more rapid the rate of rotation imparted to the bullet. The Minié rifle had a complete turn in 78 inches. The United States Army Springfield has a complete turn in 10 inches. The velocity of spin as the bullet leaves the barrel of a Springfield is about 2500 times a second. The velocity of rotation changes as the velocity of translation changes; and when translation ceases, because the energy of propulsion has expended itself, rotation also ceases. "But when the motion of translation is suddenly and completely arrested by contact with an obstacle, then, if the bullet is not broken up, the motion of rotation continues until its energy is expended" ("Wounds in War," by Surgeon-General W. F. Stevenson, C. B., A. M. S.). A rifle-bullet in its flight deviates a little laterally, and in the direction of the groove of the rifling. In the United States Army rifle the groove of the rifling is toward the right when the gun is held with the butt toward the shoulder; hence, the deviation of the bullet is toward the right. This lateral deviation is called *drift.*

Influence of Gravity and Air-resistance.—We have previously stated that, even if moving in a vacuum, the line of flight of a bullet (the *trajectory*) would be a curved and not a straight line, because of the influence of gravity, which pulls the bullet toward the earth. The bullet would fall 16 feet the first second, 48 feet the second second, 80 feet the third second, and so on. A bullet moving forward in a vacuum would advance through equal distances in equal periods of time, and, as gravity would draw it toward the earth with increasing rapidity, the trajectory would be a parabola (Fig. 126, line A–E–F–G).

Air-resistance strongly retards the advance of a bullet and causes it to rapidly lose its velocity, and a bullet fired in air does not advance through equal distances in equal periods of time. Because of air-resistance a bullet falls to the earth sooner than it would under the influence of gravity alone. Hence, the trajectory of a bullet in air is not a true parabola, but the line of descent is much nearer to the vertical than would be the case in a vacuum (Fig. 126, line A–*e*–*f*–*g*).

Air-resistance depends upon the velocity of the bullet, the cross-section area of the bullet, the shape of the head of the bullet, the atmospheric density, and the steadiness of flight ("Gunshot-wounds," by Major C. G. Spencer). Air-resistance is least in the bullet that tapers rapidly. A bullet begins to lose its steadiness of flight about 1000 yards from the muzzle of the rifle.

The Danger Zone.—Owing to the fact that the trajectory is a curved line elevation must be given to rifles except at point-blank range, and the degree of elevation must be increased according to the range. Point-blank range for a Springfield is up to 718 yards. By this term is meant that when a gun is aimed horizontally the entire course of the bullet up to 718 yards is dangerous for infantry. For longer ranges the rifle must be elevated and the bullet "shot into the air." Sighted at 2000 yards the Snider sent a bullet 866 feet above the line

of sight; the Martini-Henry sighted at the same range, 357 feet; the Lee-Enfield at the same range, 194 feet. It becomes evident that when a rifle is elevated the bullet rises far above a man's head, and continues to rise to what is known as the *culminating point*, when it begins to descend. It does not become dangerous

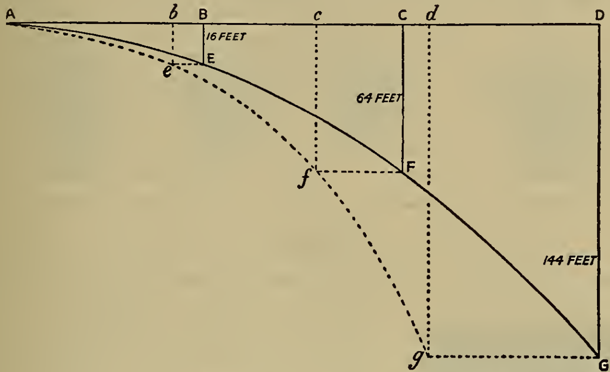

Fig. 126.—Trajectories in vacuo and in air (Stevenson).

to men until it gets near to the earth. The point at which it becomes dangerous to cavalry is called *"the point of first catch for cavalry"* (Fig. 127). The point at which it becomes dangerous for infantry is called *"the point of first catch for infantry"* (Fig. 127). The *dangerous zone* (Fig. 127) is from the point of first

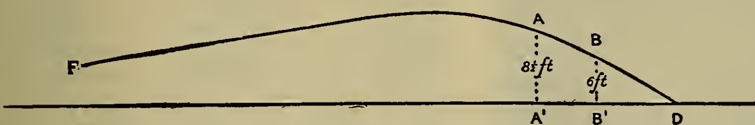

Fig. 127.—Trajectory, showing dangerous zones: A–B–D, Trajectory of bullet; D, point of termination of the bullet's flight; A–B, point of first catch for cavalry; B, point of first catch for infantry; A′–D, dangerous zone for cavalry; B′–D, dangerous zone for infantry (Spencer).

catch to the termination of the bullet's flight, because anywhere in this zone men may be struck, but between the point of first catch and the man firing the gun soldiers are perfectly safe. The point of first catch for cavalry is about 8½ feet and for infantry about 6 feet above the ground.

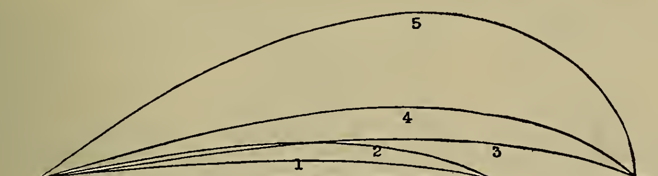

Fig. 128.—Trajectories of bullets from certain rifles: 1, Trajectory of Lee-Enfield at 1500 yards, action-point, 81 feet; 2, trajectory of Martini-Henry at 1500 yards, action-point, 178 feet; 3, trajectory of Lee-Enfield at 2000 yards, action-point, 194 feet; 4, trajectory of Martini-Henry at 2000 yards, action-point, 357 feet; 5, trajectory of Snider at 2000 yards, action-point, 866 feet; horizontal scale, $\frac{1}{24000}$ (1 inch = 2000 feet); vertical scale $\frac{1}{12000}$ (1 inch = 1000 feet). Vertical measurements are represented on twice as large a scale as horizontal measurements (Spencer).

The more nearly vertical the line of the bullet's descent, the shorter is the danger zone; the less vertical the line of descent, the longer is the danger zone. The higher the culminating point of the trajectory, the more vertical is the line of descent, hence the shorter is the danger zone; the lower the

culminating point, the flatter is the trajectory, and the less vertical the line of descent, hence the longer the danger zone. The chief object of improvements in rifles is to lower the trajectory (that is, make it less curved) and thus lengthen the danger zone, render marksmanship more accurate, and insure velocity.

Power of the Bullet to Wound.—According to Spencer ("Gunshot-wounds"), this depends upon its energy and the ease with which its energy is converted into work on striking. Energy is largely a matter of range. At short range energy is enormous, but it rapidly diminishes as the range is increased. At 3000 yards energy is only about one-sixteenth of what it is at 300 yards. The ease with which a bullet converts energy into work depends upon (see Spencer (Ibid.): (1) The area of the cross-section of the bullet. The larger the bullet, the worse the wound. (2) The deformation of the bullet. Such deformation enlarges the area. A bullet that expands on striking is said to "*mushroom.*" The modern bullet seldom deforms much unless its jacket has been more or less torn off; and it inflicts, as a rule, a much less grave injury than does the soft bullet. It has been found that this very humanity of the bullet is at times regarded as an objection. The bullet lacks "stopping power" unless it strikes a vital part or a large bone, and a wounded man may continue to fight and charge. Civilized men will usually stop when hit, but savages very often will not. Hence, in warfare with barbarous people, it was until recently the custom to modify the bullet. A portion of the soft bullet at the apex of the projectile was left exposed, and such a bullet was said to be uncovered or to have a "*soft nose.*" It was called a *Dumdum* bullet, because such missiles were first made at Dumdum, the ordnance factory near Calcutta. When a Dumdum bullet strikes, it spreads and expands, or "mushrooms," and inflicts an extensive and dreadful wound, which stops the most ferocious savage or the most fanatical tribesman. These expanding or deformable bullets are often wrongly called "explosive bullets." They have been forbidden by The Hague Convention, although Stevenson and some other surgeons maintain that they are more humane than were the bullets of the Snider or the Martini-Henry rifle. The present weapon of the United States Army will produce wounds "which will resemble the wounds made by the 'deformable' bullets whose use is forbidden in civilized warfare" (Borden, in "Keen's Surgery," vol. vi).

Fig. 129.—Mauser bullet-wound of chest: *a*, Wound of entrance; *b*, point where bullet was extracted (Major Charles F. Kieffer, U. S. A.).

The Resistance Encountered.—If energy is great (as at close range) and a very resistant tissue is struck (bone), dreadful injury may be inflicted, but if a tissue with little resistance is struck but little damage may be done. At a long range the energy of the bullet is so lessened that the danger to resistant tissue will be much less; whereas injury of soft parts may be much the same as at closer range.

The Nature of the Wounds Inflicted by the Small Projectile.—The effect of lessening the size of the bullet is to decrease its wounding power, because, other things being equal, the larger the bullet, the greater its wounding power. In many instances the modern bullet will make a clear track, without lacera-

tion or comminution. It was thought, as has been stated, that this projectile would prove humane, that it would kill comparatively few, and that the wounded would receive injuries which would incapacitate them, but from which most of them would subsequently recover. Recent wars have indicated that at a range of over 1500 yards the bullet, as a rule, penetrates cleanly,

Fig. 130.—Deformation of leaden bullets (natural size) (Seydel).

making a wound that heals by first intention. Sir Frederick Treves expressed his experience by saying, "the Mauser bullet is a very merciful one."

Very many studies have been made of the action of the modern bullet, and numerous experiments have been carried out—firing through boxes filled with wet sand, firing into thick oak, firing at cadavers at fixed distances with reduced charges, and firing at corpses and at live horses with service charges.

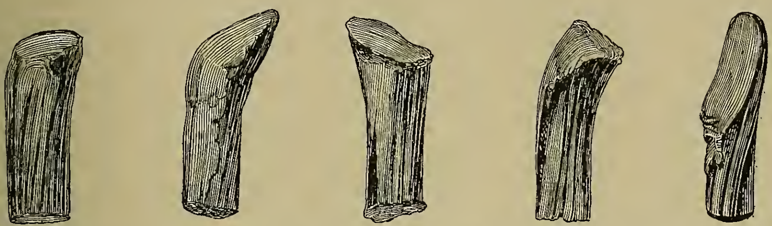

Fig. 131.—Deformation of small-caliber jacketed bullets (after Bruns).

De Nancrede, some years ago, wisely cautioned us to remember that experiments upon the cadaver, employing reduced charges and standing at fixed distances, are uncertain in their provings. "The difference," he said, "between the velocity of rotation and the angle of incidence with reduced charges at fixed distances and service charges at actual distances is marked. The tension of living muscle and fascia, as compared with dead tissues, and the physical

Fig. 132.—1, Empty Krag jacket removed from thigh after penetrating 6 inches at 340 yards; 2, 3, 4, 5, lodged Krag bullets removed from wounds after deflection from frozen ground. Ranges from 50 to 300 yards.

change of semiliquid fat of adipose tissue and medulla to a more solid condition by the loss of animal heat, influence the results" (Ibid., "Gunshot-wounds," Roswell Park's "Surgery by American Authors").

All the theoretical conclusions derived from experiment and the observations made on the occasional victims of suicide or homicide have been put to the test of war in recent years; and we now draw our deductions from a study of the

wounds in the Chitral Expedition, the Greco-Turkish War, the Spanish-American War, the South African War, the taking of Pekin, and the Russo-Japanese War. (Reports from the Balkan War are not as yet accurate or comprehensive.) Preconceived opinions have, to a great extent, at least been confirmed. It has been found that the wounds are usually non-infected and are apt to heal by first intention unless inflicted by ricochet, which deforms the bullet. At a range of 1500 yards or more the wounds are commonly clear tracts, without much splintering of bone or laceration of tissues. The wound of entrance is extremely small and could be overlooked by a careless observer. It is usually circular, it may be triangular. The bullet is far less liable to lodge in the body than was the older bullet. If it perforates, the wound of exit is usually small, and may be either round or a slit. The wound of exit is large if the injury was inflicted at close range, or if bone was splintered and fragments were driven along with the bullet.

Theoretically, the projectile does not flatten, but it has been found that in many instances it does flatten a little (Fig. 131). Its coat is apt to be torn off when it strikes hard bone at a distance of less than 1800 yards. Treves has pointed out that if a bullet smashes a bone and lodges, the shell, as a rule, peels off from the core. Then the bullet may be distorted or broken into fragments. When a hard-jacketed bullet is "traveling over 2000 feet per second" it "will hold together" and penetrate any human structure "without breaking up, but as the velocity drops, there comes a point when the resistance is too great for the momentum of the bullet to overcome quickly, and then the bullet piles up on itself, just as it does when it strikes a very hard object, and the lead crowds to the front part of the bullet till the nose of the jacket bursts. When this happens the wounds are very serious and have given rise to rumors of the use of 'dumdum' or soft-nose bullets or of explosive bullets" (Wadsworth, in "International Clinics," Vol. IV, Twentieth Series). At long range the bullet may lodge, or it may also do so if it hits a man after bounding from a stone, hard ground, or a piece of metal. It may lodge in compact bone. In Cuba 10 per cent. of the wounded suffered from lodged bullets. In the Russo-Japanese War less than 10 per cent. of the wounded suffered from lodged bullets.

It is seldom that bits of clothing are carried in with the bullet, but sometimes they are, and some fabrics are more liable to be carried in than others. Threads are not unusually carried in on the roughened areas cut into the bullet by the gooves of the rifling. If the bullet ricochets from stony ground, bits of stone may enter the tissues.

Blood-vessels are likely to be cut and not pushed aside, as was often the case with the old-time bullets. Cases of arterial contusion and subsequent secondary hemorrhage are, however, occasionally met with. If a large vessel is struck and cut, primary hemorrhage is profuse and may prove rapidly fatal. The modern bullet is seldom deflected in the tissues, but, as a rule, it passes straight ahead. The skin is usually split by it. Fascia and muscle are likely to be much damaged, but in a transverse wound of muscle the fibers may be separated rather than destroyed.

Although under most circumstances this bullet is humane, it has been found that in some instances it pulpifies structure for a considerable distance around the track of the ball, producing what is known as an *explosive effect.* The cause of this condition has been much debated, though it never means that the bullet has exploded. Some think that it is always due to comminution of bone and the blowing of bone-fragments ahead of and around the ball. Most believe that the sudden impact against the tissues engenders waves of force, which cause explosive and distant damage. Certain it is that an explosive effect causes horrible and often irreparable injury.

Explosive effects are most frequently seen at close range, when the velocity

of translation and the frequency of rotation are most marked. Such injuries were seen in the marines killed at Guantanamo, in persons killed during the Milan riots, and in many instances in South Africa, China, and Manchuria.

A pistol-bullet has no explosive action at all; and the old-time large, soft bullet possessed it only at a very close range. The modern projectile is apt to produce explosive effects up to 500 yards, but it does not invariably do so. Up to 1300 yards it is liable to produce them in the skull and brain; and at this distance a single bullet may entirely destroy the cranium. Explosive effects may at times occur at longer distances upon the liver, spleen, kidneys and lungs, and upon hollow viscera containing fluid. At a distance of 500 yards or less a bone will usually be shattered into many fragments; whereas, at a range of 1500 or 2000 yards the bone will, as a rule, be cleanly perforated, usually without comminution.

It is often extraordinary how little trouble follows a wound by a modern projectile and how quickly healing occurs. This is due to the facts that the tissue is cleanly perforated, that foreign bodies are seldom carried in, and that the wound rarely becomes infected. This freedom from infection is not due to the bullet being sterile. It is not sterile, and when the gun is fired the bullet does not heat sufficiently to certainly destroy bacteria. The bullet is carried in a dirty belt or pouch, is handled by dirty hands, and is not clean when put into the rifle, but its sides may be scraped cleaner by the rifling and the burning powder may disinfect it in part. The point, however, contains bacteria on its surface. They are few in number; are readily scattered in the tissues; and, in most instances, are overcome by tissue resistance. The clean track of the bullet which is usual in wounds inflicted at ordinary fighting ranges impairs tissue resistance much less than a badly contused and lacerated wound. In some observed cases there have been almost no symptoms after perforation of the lung. In others, none after perforation of the abdomen, a joint, or the skull. The bullet when it has become stationary seldom does harm, unless lodged in the brain. It is obvious that in most conflicts the modern rifle has proved to be humane and that its humanity is largely a matter of range. At a range of 1500 yards or over modern rifles (except the Springfield) are humane weapons.

What used to be called a *wind contusion* is a severe and often a dreadful injury. The skin being unbroken, bones may be broken, viscera ruptured, tissues torn asunder. The older surgeons believed that such an injury was produced by the wind pressure, a projectile passing close to, but not touching the surface. We know now that they result from a projectile's glancing along the surface, the elasticity of the skin saving it from immediate destruction, although in many instances it sloughs later.

A bullet in striking never gets hot enough to burn a part. It is needless to say that bullets are never deliberately poisoned.

Symptoms.—*Pain* is seldom severe in wounds of the soft parts, but violent, immediate pain is felt when a bone or a nerve is injured; the pain is usually stinging or burning, but is seldom of long duration, except in bone injuries, spinal cord injuries, and nerve injuries. Sometimes a man does not know he has been struck. It is common to have anesthesia or numbness and loss of muscle-function about the wound for several hours or days.

Shock is very variable. In some cases it is scarcely noticeable, in others it is overwhelming. It is most marked in wounds of bone, the spine, the abdomen, and the brain. It is greatly aggravated by hemorrhage. Hemorrhage is great if a large vessel is struck. If the vessel is in a limb it is seldom that much blood escapes externally, but a large hemorrhage occurs in the tissues. Such cases reach the hospital for treatment, and are spoken of as "traumatic aneurysm." They were quite common in South Africa. Secondary hemor-

rhage is uncommon. When it does occur it is usually a result of infection, but it may arise, as in a soft-bullet injury, from contusion of a vessel. De Nancrede reports secondary hemorrhage, in the absence of infection, from contusion of the brachial artery. If a great vessel is divided in the chest or abdomen, the patient rapidly bleeds to death on the field, and seldom reaches the hospital at all. A military bullet may cause arteriovenous aneurysm. Makins, De Nancrede, and others have reported cases. De Nancrede saw one arteriovenous aneurysm of the subclavian, two of the femoral, and one of the external iliac from Mauser bullet wounds.

Primary infection is rare. The bullet wound tends to remain uninfected unless bits of clothing or other foreign bodies have been carried in, unless the bullet was deformed, unless the wound was at close range, or unless unnecessary and uncleanly probing was practised. If suppuration occurs, it is apt to remain localized. Pyemia and true septicemia are rare. In the Russo-Japanese War suppuration seems to have been common. In the Japanese hospitals at least 60 per cent. of wounds of the soft parts by undeformed bullets suppurated. At most in only one case out of ten does the bullet lodge. (Report on Russo-Japanese War, by Maj. Chas. Lynch, Medical Department, General Staff, U. S. A.) It is stated that among the Russians suppuration occurred in 30 per cent. of the cases. More wounds suppurated in winter than in summer. The Russians used a larger bullet than the Japanese, and the wound inflicted by the Russian bullet was far more liable to suppurate than was that produced by the Japanese projectile. Practically all wounds of bone made by Russian bullets suppurated. (Lynch, Ibid.) The above remarks upon the military projectile do not apply in all particulars to the new bullet adopted by the United States (model of 1906). It is of the same caliber as its predecessor, but it is .17 inch shorter, 70 gr. lighter, and its point is decidedly sharper. The muzzle velocity is 400 yards per second greater. Point-blank range has been extended from 600 to 718.6 yards. Because the new bullet is short and because the center of gravity is toward the base the bullet is easily deflected and is prone to enter the tissues sideways, inflicting a frightful wound, instead of the usual small puncture of the ogival headed bullet of 1903. La Garde has pointed out that even the skin resistance may cause the bullet to turn. Hence it is evident that the bullet of the Springfield now in use is distinctly not a humane weapon; it will inflict horrible injury and will be very apt to kill the victim outright (Lt.-Col. Borden, U. S. A., in "Keen's Surgery," vol. vi). It has not yet been tested in war.

Treatment.—The military surgeon is a specialist, and he must know many things besides the treatment of the sick and injured. He must be a master of hygiene; he must possess executive capacity; he must be able to discipline others and to subject himself to discipline; he must be forceful, self-reliant, and resourceful; he must be acquainted with the laws and regulations of the military establishment; and he must have a special knowledge of gunshot-wounds as received in battle. Even the best qualified civil surgeon is unfit to pass into military service without special instruction. It is for this reason that the United States insists that every man appointed to the Medical Corps of the Army or Navy shall receive special instruction in the Army Medical School or the Naval Medical School before he goes to a regiment or a ship. The wounds received in war are peculiar, and treatment appropriate for a wound inflicted by a revolver bullet is often inappropriate or impossible for a wound inflicted by the projectile of a military rifle.

In civil life the patient has the best of surroundings. Every care can be given him. Numerous skilled assistants are at hand if needed. The problems of the case are entirely surgical, and the case can be dealt with purely according to its surgical necessities. In war there are problems of transportation

which are not presented in civil life, for strategic necessity may compel hurried movement. Accommodations, also, may be bad. Shelter may be imperfect, climate and meteorologic conditions may be most trying. Food may be scanty and inappropriate. Medicines may be scarce. There are sure to be too few assistants. After some engagements in South Africa the British surgeons had to care for numbers of men under difficulties that were appalling, among which were fearful clouds of dust and swarms of flies. In other words, the military surgeon, after a battle, is seldom able to treat his cases purely in accordance with surgical necessities, but his conduct must be influenced by other, often imperative, needs. If there are numerous wounded, he does not have time to do immediate laparotomies. He will lose some cases because he has not done laparotomy, but he would lose many other cases from delay in treating dangerous but remedial conditions were he to make many simpler cases wait until his laparotomies had been performed. He is forced to make the abdominal wounds wait, and after long delay there is seldom any use in opening the abdomen at all.

Again, the wound inflicted by the bullet of a military rifle is very different in nature and in danger from the wound inflicted by a revolver bullet. In the former, if a large vessel is struck, it is usually perforated or divided, and profuse bleeding occurs, either into a cavity or in the tissues. If the bleeding occurs in a cavity the patient usually dies on the field, and does not reach the first dressing-station at all. If it occurs in the tissues a "traumatic aneurysm" forms. In revolver bullet wounds primary hemorrhage is seldom severe. Wounds with revolver bullets are very apt to suppurate. Wounds with the undeformed hard-jacketed projectile that has not ricocheted very commonly escape primary infection.

Wounds that in civil life might require only a resection, may in military practice require amputation. The promise of aseptic healing leads the military surgeon to trust many wounds without operation which in civil life would be operated upon at once, and both surgeons would be right in the different courses pursued by them.

In civil life the rule is absolute to open the abdomen for every case of gunshot-wound entering that cavity. The experience of all military men is that more cases get well under a policy of non-interference than with laparotomy. In military surgery laparotomy can be performed only when there is "*time to do it*"; and, even then, is performed only when there is hemorrhage or else certain evidence or a very strong probability that an organ or viscus has been struck or perforated. On account of the difficulties in the treatment of the wounded in military life, as compared with civil life, military surgery is a pure specialty; and the details of the treatment of wounds in war must be sought for in treatises by military surgeons. The watchwords of the military surgeon are to preserve asepsis and to avoid meddlesome interference.

In handling patients in the field the clothing is cut away (if the wound is under the clothing). If possible, the wound and skin about it are washed with alcohol and painted with iodin (tincture, diluted one-half with alcohol) and then the dressings are applied. If this cannot be done the dressings are applied at once. The dressing should be absorbent and, if possible, antiseptic rather than aseptic gauze. Absorbent cotton should be placed over the gauze, and a bandage of linen should be applied to hold the dressing in place.

In warfare at the present day an attempt is made to limit the death-rate from gunshot-wounds by protecting them from infection at an early period after the accident. Esmarch offered a suggestion which has been adopted in the armies of all civilized countries. Every officer and private soldier carries a package which contains antiseptic dressings, and at the first opportunity after the infliction of a wound, if possible on the field, these dressings are applied by

the soldier, by a comrade (for even the privates are instructed in the application), or by an ambulance man. If not applied on the field, they are applied at the first dressing-station by a surgeon or a hospital steward. The dressing is removed only when there are indications calling for surgical interference. Many wounds heal under this primary dressing. In the United States Army the first-aid package is carried in a metal case to prevent contamination and damage by moisture. The case is hermetically sealed, but can be easily opened. It is carried hooked to the cartridge belt. It contains two bandages, two compresses of absorbent corrosive sublimate gauze, and two No. 3 safety-pins, all wrapped in waxed paper. One compress is stiched to the center of each bandage, and the bandage is so folded that the compress can be opened without touching its inner surface. Each private of the hospital corps and the orderly of each medical officer carries the hermetically sealed tubes—each tube contains 1 gm. of iodin and $1\frac{1}{2}$ gr. of iodid of potassium. By adding 50 c.c. of water or alcohol a proper antiseptic solution is obtained. In injury of limbs amputation is seldom necessary. It is done when the great vessels are injured, when the soft parts are grievously lacerated, when an articular surface is badly comminuted, and perhaps when there is menacing secondary infection. Excision is occasionally performed when there is comminution. As a rule, a wound of an articulation is recovered from by antiseptics and splinting.

Most lodged balls are let alone. If the wound is infected, or is known to contain foreign material other than the bullet, the bullet and all other foreign material must be removed. A bullet in the brain should be removed, though we often wait perhaps for days to let the tissues regain resisting power (De Nancrede). Serious hemorrhage always calls for operation. Tie the vessel in the wound if possible; if not, tie the main trunk above, and if this fails, amputate (De Nancrede). In a chest wound delay for symptoms. In an abdominal wound do not operate except for hemorrhage or for evident visceral injury.

In the foregoing article I have obtained facts from numerous sources. The following books and articles I found particularly serviceable: "Wounds in War," by Surgeon-General W. F. Stevenson, of the British Army; "Gunshot-wounds," by Major C. G. Spencer, of the British Army; "Military Surgery," by Surgeon-General Robert M. O'Reilly, U. S. A., in Vol. IV of "Keen's Surgery"; "Naval Surgery," by Surgeon-General P. M. Rixey, U. S. N., in Vol. IV of "Keen's Surgery"; Treves, in the "British Medical Journal," 1900; Senn, in "The Hispano-American War"; Makin, "Surgical Experiences in South Africa"; "Chirurgie de Guerre," Paris, 1897, by Constans; "Surgical Notes from the Military Hospitals in South Africa," by Dent, in the "British Medical Journal," 1900; "Gunshot-wounds," by Maj. Wm. C. Borden, U. S. A., in the "American Practice of Surgery," by Bryant and Buck, Vol. II; "Delorme's Traite de Chirurgie de Guerre"; "Recent Reports of the Surgeon-General of the U. S. A. and of the Surgeon-General of the U. S. Navy"; the Chitral Campaign," by H. C. Thomson; "Les Projectiles des Armes de Guerre," by Nimier and Laval; "Volumes of the Proceedings of the Associations of Military Surgeons, U. S. A."; Follenfant, in "Archives de Medicine et de Pharmacie Militaire," July, 1906; "Reports of Military Observers in Manchuria during the Russo-Japanese War," by Maj. Charles Lynch, Medical Department, General Staff, U. S. A., 1907; Neate, "The Military Surgeon," 1911; "United States Magazine Rifle," Government Printing Office, Washington, 1909; Borden, in "Keen's Surgery," Vol. VI; Surgeon-General Stokes, U. S. N., in "American Practice of Surgery," 1911; Wadsworth, in "International Clinics," Vol. IV, Twentieth Series. (For gunshot-wounds of special structures, see Bones, Joints, Abdomen, Brain, etc.)

Poisoned wounds are those into which some injurious substance, chemical or bacterial, was introduced. This poison may be microbic and capable

of self-multiplication, or it may be chemical, and hence incapable of multiplication. There are three classes of poisons:[1] (1) mixed infection, as septic wounds, dissection-wounds, and malignant edema; (2) chemical poison, such as snake-bites and insect-stings; and (3) infection with such diseases as rabies, glanders, etc.

Septic or **infected wounds** are those which putrefy, suppurate, or slough. Septic wounds should be opened freely to secure drainage, and hopelessly damaged tissue should be curetted or cut away. The wound should be washed with peroxid of hydrogen and then with corrosive sublimate, dusted with iodoform or orthoform, either drained by a tube or packed with iodoform gauze, and dressed by hot antiseptic fomentations. The part must be kept at rest and internal treatment should be stimulating and supporting. If lymphangitis arises, the skin over the inflamed vessels and glands is to be painted with iodin and smeared with ichthyol, and quinin, iron, and whisky are given internally. The temperature is watched for evidence of general infection or intoxication. The patient must be stimulated freely, nourishing food is given at frequent intervals, pain is allayed by anodynes if necessary, and sleep is secured. In infected wounds of the extremities Bier's treatment is very useful.

Dissection-wounds are simple examples of infected wounds, and they present nothing peculiar except virulence. They affect butchers, cooks, surgeons who cut themselves while operating on infected areas, those who make postmortems, and those who dissect. A dissection-wound inflicted while working on a body injected with chlorid of zinc possesses but few elements of danger unless the health of the student is much broken down. If a wound is simply poisoned by putrefactive organisms, there is rarely serious trouble. Postmortems are peculiarly dangerous when the subject has died of some septic process. When a wound is inflicted while dissecting, wash it under a strong stream of water, squeeze, and suck it to make the blood run, lay it open if it be a puncture, paint it with pure carbolic acid, and dress it with iodoform and hot antiseptic fomentations. Trouble, of course, may follow, but often it is only local, and a small abscess forms. It should be treated by hot antiseptic fomentations and early incision. Occasionally lymphangitis arises, adjacent glands inflame, and constitutional symptoms arise. It is rarely that true septicemia or pyemia arises unless the wound was inflicted while making a postmortem upon a person dead of septicemia or while operating on a septic focus. If glands enlarge and soften, it may be necessary to remove them surgically.

Malignant edema or **gangrenous emphysema** arises most commonly after a puncture. It is due to a specific bacillus which produces great edema. The emphysema which soon arises is due to mixed infection with putrefactive organisms. Pus does not form, but gangrene occurs. The disease is identical with one form of traumatic spreading gangrene (see page 170).

Symptoms.—These are identical with those of traumatic spreading gangrene with emphysema.

There is a rapidly spreading edema, followed by gaseous distention of the tissues and by gangrenous cellulitis. The zone of edema is at the margin of the emphysema, and the process spreads rapidly. The emphysematous zone crackles when pressed upon. The area of edema is covered with blebs which contain thin, putrid, reddish matter, and the skin becomes mottled. If a wound exists, the discharge will be bloody and foul. If incisions are made, a thin, brown, offensive liquid flows out. High fever rapidly develops, the patient becomes delirious, and often coma arises. In most cases death ensues in from twenty-four to forty-eight hours.

[1] "American Text-Book of Surgery."

Treatment.—If malignant edema affects a limb after a severe injury amputate at once, high up. If it affects some other part or begins in a limb after a trivial injury, make free incisions, employ hot, continuous antiseptic irrigations or the hot antiseptic bath, and stimulate freely (see page 171).

Stings and Bites of Insects and Reptiles: Stings of Bees and Wasps.—A bee's sting consists of two long lances within a sheath with which a poison-bag is connected. The wound is made first by the sheath, the poison then passes in, and the two barbed or twisted lances, moving up and down, deepen the cut. The barbs on the lances make it difficult to rapidly withdraw the sting, which may be broken off and remain in the flesh. Edematous, discolored swelling quickly arises. The pain is severe and burning. Besides bees, hornets, yellow jackets, and other wasps produce painful stings like bee-stings. The sting of a wasp is rarely broken off in the tissues because the beards on the darts are shorter; hence the sting is not so firmly fixed in the flesh, and also because these insects are more rapid and nimble in their actions. Stings of bees and wasps seldom cause any trouble except pain and swelling. In rare cases syncope occurs. Widespread urticaria may develop. Erysipelas or phlebitis may arise. In some unusual cases a bee-sting is fatal; persons have been stung to death by a great number of these insects.

Symptoms.—If general symptoms ensue, they appear rapidly, and consist of great prostration, vomiting, purging, and delirium or unconsciousness. These symptoms may disappear in a short time, or they may end in death from heart-failure. Stings of the mouth may cause edema of the glottis.

Treatment.—To treat a bee-sting, extract the sting with splinter forceps if it has been broken off and is visible in the wound. If it is not visible, squeeze the part lightly in order to expel it, or at least expel the poison. Pressure may be most satisfactorily made by means of the barrel of a key. The poison is counteracted by touching with ammonia or washing the part in ammonia-water, touching with pure carbolic acid, painting with tincture of iodin, or soaking in a strong solution of common salt or carbonate of sodium. The part may be dressed with lead-water and laudanum, a solution of washing-soda, or a solution of common salt. If constitutional symptoms appear, stimulate.

Other Insect-bites and Stings.—If a tick bites a person it clings to the victim. If an attempt is made to pull it off the barb remains in the tissues and an abscess follows. If a little ammonia is dropped on a tick the insect will at once withdraw its barb. A tick bite never causes constitutional symptoms. The mandibles of a *poisonous spider* are terminated by a movable hook which has an opening for the emission of poison. The bite of large spiders is productive of inflammation, swelling, weakness, and even death. The bite of the poisonous spider of New Zealand produces a large white swelling and great prostration; death may ensue, or the victim may remain in a depressed, enfeebled state for weeks or even for months. The *tarantula* is a much-dreaded spider. The scorpion has in its tail a sting. The sting of the *scorpion* produces great prostration, delirium, vomiting, diaphoresis, vertigo, headache, local swelling and burning pain, followed often by fever and suppuration, and occasionally even by gangrene, but it is rarely fatal. *Centipedes* must be of large size to be formidable to man, and the symptoms arising from their stings are usually only local.

Treatment.—To treat the bite of a poisonous spider or sting of a scorpion tie a fillet above the bitten point; make a crucial incision, favor bleeding, and paint the wound with pure carbolic acid or some caustic or antiseptic (if in the wilds, burn with fire or gunpowder); dress antiseptically if possible, and stimulate as constitutional symptoms appear. Slowly loosen the ligature after symptoms disappear. Chloroform stupes and ipecac poultices are recommended; also puncture by a needle and rubbing in a mixture of 3 parts of

alcohol and 1 part of camphor (Bauerjie). Antiscorpion venene is recommended by Todd for scorpion stings.

Myiasis.—When the larvæ of dipterous insects are deposited in the tissues the condition is called myiasis. Certain varieties of flies sting with the ovipositor and lay their eggs in the skin or in the mucous membrane of the nose. The bot-fly may do this, and the larvæ or maggots of bot-flies are called bots. Inflammation arises in the area containing the ova and suppuration may occur. Myiasis is most common in tropical and subtropical countries, but the bluebottle fly may be responsible for the condition in temperate climates.

Treatment.—Incision and application of pure carbolic acid to kill the larvæ. If in the nasal passages inhalation of chloroform may prove fatal to larvæ.

Maggots in Wounds.—In tropical countries especially flies may lay eggs in wounds and maggots form in immense numbers. Larrey saw many such cases. I have seen maggots several times in foul leg ulcers. Antiseptic dressings prevent such an occurrence and antiseptics will destroy larvæ. Iodin is very successful.

Chigger.—The chigger or sand flea is common in the tropics and subtropics. The female when impregnated may enter an abrasion or may pass through "the soft skin, especially in the sole between the toes" or "around the nails" (Madden, in a "System of Surgery," edited by C. C. Choyce).

Inflammation occurs and the body of the flea is recognizable as a small black spot. Suppuration may occur and the flea may be cast out with the pus. Sinuses may arise and persist. There is some danger of erysipelas, tetanus, and gangrene (Ibid.).

Treatment.—Apply a hot solution of bicarbonate of soda for some hours, enlarge the opening with a knife, remove the insect without breaking it up, and dress the part antiseptically (Ibid.).

Fish Stings.—The spines of certain fish inflict a poisoned wound, as they are covered with an irritant material obtained from the skin. The spines of the catfish are known to do this. Certain fish actually inject poison along a spine, the poison coming from a receptacle or bag. These wounds are very painful, are septic, and are apt to be followed by lymphangitis, erysipelas, erysipeloid, gangrene, or general sepsis.

Treatment.—Incise, favor bleeding, swab with pure carbolic acid or iodin, and apply hot antiseptic fomentations.

Snake-bites.—The poisonous snakes of America comprise the copperheads (red vipers or upland moccasins), water moccasins (rice snakes or cottonmouths), harlequin snakes (coral snakes), and rattlesnakes. The cobra of India is the most deadly of reptiles. In some countries great numbers of people and the lower animals are killed by poisonous serpents. In India during 1898, 21,921 persons and at least 80,000 cattle were killed by snakes ("Brit. Med. Jour.," Nov. 25, 1899). The coral snake is found in the southeastern United States, and is common in South Carolina, Georgia, and Florida. It is often discovered in sweet potato fields.

The water moccasin, which is semi-aquatic, infests "the lagoons and sluggish waterways of the southeastern portion of the United States" ("Reptiles of the World," by Raymond L. Ditmars).

The copperhead, which is a variety of mocassin, is found east of the Mississippi River from Florida to Massachusetts, and west of the Mississippi in Texas. In the South it lives on plantations, in the North in or near forests (Ibid.). In practically every part of the United States there dwells some variety of rattlesnake. Fifteen species are catalogued as dwelling within our borders (Ibid.). Some inhabit prairie, some desert, some rocky land, some timber regions, some dwell adjacent to water. The diamond-back rattlesnake is the most poisonous serpent of the United States. A small rattler is not nearly so dangerous to life as a big rattler. Next to a big rattlesnake in poisonous

power comes the water moccasin. Mr. Ditmars characterizes the coral snake as "highly formidable" and the copperhead as "highly venomous." Statistics seem to contradict the belief that the copperhead is very dangerous. Prentiss Willson ("Jour. Am. Med. Assoc.," Aug. 27, 1910) has established 99 instances of persons bitten by copperheads. There were only 5 deaths. It used to be taught that there is no essential difference in the action of venoms of different varieties of snakes, and that the venom of an Indian cobra is practically identical with the venom of an American rattler, any apparent difference in action depending upon difference in toxic power and the different dose of poison introduced. We now know that there are essential differences in venoms (Leonard Rogers, in "Lancet," Feb. 6, 1904). The natural toxic power of the poison varies in different species and also in different members of the same species. Poison injected into a vein may prove almost instantly fatal. The poison is not absorbed by the sound mucous membranes. Poison is harmless when given by the mouth and swallowed, but if directly introduced into the intestines of an animal it is certainly fatal. The pancreatic ferment destroys the toxic power of the venom (R. H. Elliot, in "Brit. Med. Jour.," May 12, 1900). The venom is discharged through the channeled fangs of the reptile, having been forced out by contractions of the muscles of the poison-bag. The coral snake, like the cobra, has short and rigid fangs. Rattlesnakes, cotton-mouths, and copperheads have long and movable fangs. A coral snake bites like a cobra. It grasps the object, sinks in its fangs, and then advances its fangs by chewing, thus inflicting several wounds. In viperine snakes the teeth lie along the back of the mouth and are only erected when the reptile strikes. The maxillary bones of the rattlesnake are very short and move with great freedom at the prefrontal articulation. The fangs are canaliculated, are attached to the maxillary bones, and move with the bones. The poison gland drives the poison into the canals of the fangs. The canal emerges from the front of each fang near the tip. The fangs, when depressed, are carried in a fold of mucous membrane. When the animal is ready to strike the fangs are erected into a vertical position and carried to the front of the mouth. Cope describes the movement used by the rattlesnake in biting. The body springs forward, but never more than two-thirds of the reptile's length, the jaws seize the tissues and then the fangs penetrate and move to and fro as the poison emerges from them. Snake-poison is a thin, greenish-yellow, turbid, sterile fluid, of acid reaction and of a distinctive odor. The two chief poisonous principles are called venom-peptone and venom-globulin (Gustave Langmann, "Medical Record," Sept. 15, 1900).

Symptoms.—Rogers ("Lancet," Feb. 6, 1904) divides poisonous snakes into two classes: the *colubrines* (of which the cobra is an example) and the *viperines*, which are not so poisonous (this class includes rattlesnakes and puff adders). Colubrine venom, according to this observer, causes paralysis of the respiratory center and of the motor end organs of the phrenic nerves, destruction of red blood-corpuscles, lessened coagulability of blood, and death by respiratory paralysis. Viperine venom causes paralysis of the vasomotor center and great destruction of red corpuscles. Some viperine venoms may cause thrombosis, and death from any one of them is due to vasomotor paralysis. The venom of some snakes, Rogers says, contains a mixture of the above-mentioned venoms (among such snakes are the Australian colubrines and the American pit-adders). The mortality from snake-bites varies. The mortality in India from cobra bites is about 25 per cent. (Sir Joseph Fayrer). The mortality in America from rattlesnake bites is about the same. According to Willson the mortality from copperhead bites is only 5 per cent. ("Jour. Am. Med. Assoc.," Aug. 27, 1910). The local symptoms are: pain, soon becoming intense; mottled swelling of the bitten part, which swelling may be enormous, and which is due to edema and extravasation of blood, and assumes a pur-

puric discoloration. The *bite of a cobra* produces inflammation and marked spreading edema. It may be recovered from without symptoms or with trivial symptoms; it may induce profound systemic involvement. The general symptoms begin in a comparatively few minutes. The coagulating power of the blood is lost, and there is great destruction of red corpuscles. The patient is terror-stricken and soon becomes unable to stand because of weakness of the legs. Glossopharyngeal paralysis arises, and talking and swallowing become impossible. There is a profuse flow of saliva, perhaps nausea and vomiting. The patient may be dull mentally, but is not unconscious. The paralysis becomes widespread, and finally the diaphragm and respiratory center become involved, and death occurs from respiratory paralysis. Artificial respiration may prolong life for hours (Sir Joseph Fayrer). Bad cases usually die in three or four hours, but life may last for many hours. A *rattlesnake* bite produces severe pain and mottled swelling from blood extravasation. In some cases there is enormous swelling from edema and blood; the discoloration in such a case is purpuric. The blood of the victim quickly undergoes hemolysis and loses the power of coagulation. It was previously stated that in laboratory experiments it has been shown that viperine poison may produce thrombosis, but it does not do so in man, as it contains a very small amount of the coagulating element (Rogers). Extravasations of blood occur in serous and mucous membranes and in the skin, petechial spots frequently arising upon the cutaneous surface. There may be free bleeding from mucous surfaces and great extravasation beneath the conjunctivæ. These blood extravasations are due, according to Flexner, to destruction of vascular endothelium. General symptoms begin in from a few minutes to several hours. The symptoms are those of profound shock, possibly with delirium, the vasomotor center being exhausted and finally paralyzed. There are usually muscular twitching and convulsions, and finally paralyses are noted in most cases (pharyngeal palsy, paraplegia, and ascending paralysis). There may be complete consciousness, or there may be lethargy, stupor, or coma. Death may occur in about five hours, but, as a rule, it is postponed for a number of hours. If death is deferred for a day or more, profound sepsis comes upon the scene, with glandular enlargement, suppuration, and sometimes gangrene.

Treatment.—Cases of snake-bite must, as a rule, be treated without proper appliances. The elder Gross was accustomed to relate in his lectures how he had seen an army officer blow off his finger by a pistol the moment after it was bitten by a rattlesnake, and thus escape poisoning. If the bite is upon a limb, and it usually is, twist several fillets at different levels above the bite to prevent the dissemination of the poison from the limb throughout the body. If possible the fillets should be elastic, but in an emergency any available material must be used. As soon as fillets have been applied above the bitten area make crucial incisions to the depth of each bite. A rattlesnake bite, a copperhead bite, and a water mocassin bite show but two punctures. A coral snake bite shows several. After incising suck or cup it if possible, and cauterize it with pure nitric acid or by a cautery. There is no danger in sucking the wound, provided there are no abrasions upon the lips, cheeks, or tongue. Before sucking, fill the mouth with a dilute solution of permanganate of potash, to oxidize and thus destroy the poison. An expedient among hunters is to cauterize by pouring a very little gunpowder on the excised area and applying a spark, or by laying a hot ember on the wound. Some surgeons inject in many places about the wound a 10 per cent. watery solution of chlorid of calcium to chemically neutralize the poison. It is taught by others that if a man is bitten by a large and deadly snake, the surgeon, if one is at hand, should at once amputate well above the bite.[1] Wynter Blyth pointed out that permanganate of potassium mixed

[1] Charters James Symonds, in "Heath's Dictionary of Practical Surgery."

with an equal weight of cobra venom renders the venom inert. A number of surgeons have treated snake-bites by injecting in and about the wound a 1 per cent. solution of permanganate of potassium, but this plan is inefficient. Rogers ("Lancet," Feb. 6, 1904) says we should tie fillets around the limb above the bitten part, take a knife and enlarge the wounds, and rub in crystals of permanganate. The fillets are not to be removed suddenly, and they had best be kept on for some time. Remove the highest constricting band first; if no symptoms come on after a time, remove the next, and so on; if symptoms appear, reapply the fillets. Whatever local treatment is employed, stimulants are given. Some give strychnin hypodermatically; others, ether; others, digitalis. Halford, of Australia, advocated the intravenous injection of ammonia (10 min. of strong ammonia in 20 min. of water). Adrenalin as given in shock is indicated if there is a marked fall in blood-pressure, and autotransfusion and external heat are also indicated. If the respiration is failing, artificial respiration and oxygen inhalation are required. Few beliefs are more tenaciously held than that large amounts of whisky or brandy should be given to the victim of snake venom. And yet this belief is false. In a person badly poisoned by snake venom the medullary centers are depressed and threatened with paralysis. Large doses of alcohol increase this tendency and may hasten death. It is well known that if a drunken man is bitten by a large poisonous snake he is practically certain to to die, because the depression produced by alcohol is enormously accentuated by the venom. Moderate doses of whisky or brandy are useful (1 to $1\frac{1}{2}$ ounces every half-hour). The wounds made by the incisions of the surgeon are kept open for a number of days by the insertion of bits of rubber tissue, and warm and moist antiseptic dressings are used. Attempts are being made to obtain a curative serum. Animals can be rendered immune by giving them at first small doses of the poison and gradually increasing the amount administered. It is asserted that the serum of immune animals will cure a person bitten by a venomous snake. Cures have been reported after the use of Calmette's antivenene serum. Antivenene is obtained by immunizing a horse by injecting attenuated venom. The mixture to be attenuated consists of 80 parts of cobra venom and 20 parts of viperine venom. It takes a number of months to obtain strong antivenene. The dose is from 10 to 20 c.c. hypodermatically, repeated if necessary in three or four hours. It seems certain, however, that no single serum can antidote the venom of all varieties of serpents (A. T. F. Macdonald, of Australia), and it has been shown that, though Calmette's antivenene is antagonistic to colubrine venom, it is inert against viperine venom. Again, as Rogers says, it deteriorates quickly in hot climates and is seldom on hand when wanted. The horse can be immunized against rattlesnake venom, and antivenene obtained from the horse may be used against rattlesnake poison.

The **poisonous lizard** (*Gila monster*), of the southwestern United States, can certainly kill small animals, but it is doubted by many that its bite is ever fatal to man. When we recall, however, that small animals which die of the poison present symptoms identical with those produced by serpent venom, we should regard the Gila monster with careful respect.

The lizard bites and hangs on. Each tooth of the lower jaw has a conducting channel for poison and there is a poison gland for each tooth.

The treatment of a bite of the Gila monster is practically the same as for a snake-bite.

Anthrax (**malignant pustule, charbon, wool-sorters' disease, milzbrand,** or **splenic fever**) is a term used by some as synonymous with ordinary carbuncle, but it is not here so employed. It is a specific contagious disease resulting from infection with the bacillus of anthrax. Cattle anthrax has long been known. Virgil refers to it (Ponder, in "Lancet," Nov. 4, 1911).

Pollender showed more than fifty years ago that a rod-shaped organism is present in the blood of animals dying from splenic fever. Duvaine insisted that the organisms caused the disease. Koch proved it in 1876. Animal anthrax is particularly common in the East and in Russia, and is frequently met with in Germany, Italy, and South America. In some regions so many cases arise year after year that the district obtains an evil notoriety. It is stated that in Novgorod, Russia, in four years "56,000 horses, cattle and sheep, and 528 men perished from anthrax" (Frank S. Billings, in "Twentieth Century Practice"). It is a rare disease in the United States. In Philadelphia cases occasionally occur in workers in the woolen mills. The author has seen 5 cases of human anthrax, 4 of which occurred in Philadelphia and 1 in New Jersey. Herbivora are most liable, next omnivora, but carnivora seldom suffer. Anthrax, as met with in man, is a disease contracted in some manner from an animal with splenic fever. It may be contracted by inoculation while working around diseased animals, while handling or tanning their hides, or sorting their hair or wool; brush-makers, spinners, workers in horn and combers, rag sorters, veterinary surgeons, clippers, stockmen, farmers, and butchers may become inoculated. Infection may take place through the hair-follicles of unbroken skin. Menschig reported 2 such cases ("N. Y. Med. Jour.," Nov. 18, 1905). Anthrax may be conveyed by eating infected meat or by drinking infected milk. Flies may carry the poison. Inhalation of poisoned dust may infect the lungs. Catgut ligatures may be contaminated and carry the poison. Blood-stained wools and hides are a particular peril. It is stated that in England 1 out of 7000 leather makers dies of anthrax each year (Ponder, in "Lancet," Nov. 4, 1911). Ponder points out that 40 per cent. of English cases (arising among those working in the hide, skin, and leather industries) are due to Chinese or East Indian goods; that no anthrax has ever been traced to wet salted hides; that infection may arise at wharf, dockyard, or tannery; that the pulmonary form occurs particularly among wool workers; that among those who work with hides, skin, and leather cutaneous anthrax is the common form, and intestinal anthrax is extremely rare.

Fig. 133.—Anthrax. Case in author's wards in Philadelphia Hospital, recovered. Treated by ipecac both externally and internally.

In all probability many slight cases are recovered from without being recognized. This would explain the fact that it is particularly among recent employees that anthrax seems to occur (Mitchell, "Brit. Med. Jour.," April 4, 1911). Many older employees may be immune because they have had the disease. Many attempts have been made to render animals immune (Pasteur, Woolbridge, Hankin). Pasteur's method has been used in France with decided success, but with less success in other countries. Pasteur devised a method for vaccinating animals against anthrax by injecting attenuated cultures beneath the skin. First, a much-attenuated culture is used and later a stronger one. When an animal has been actively immunized, its blood-serum contains pro-

tective materials of a specific nature and may be used therapeutically. The immunity is regarded by some authorities as "a phagocytic immunity" (Jordan's "General Bacteriology"). Certain organisms are antagonistic to anthrax (the streptococcus of erysipelas, the pneumococcus, the Micrococcus prodigiosus, and the Bacillus pyocyaneus).

Forms of Anthrax.—There are two forms of the disease—external and internal. Internal anthrax may be intestinal from eating diseased meat, laryngeal or pulmonary from inhalation of poisoned dust. Intestinal anthrax arises only when the bacilli in the meat contain spores. Koch and others have pointed out that the non-sporulating bacteria are destroyed by the gastric juice. Internal anthrax is quick in progress, and death sometimes takes place within twenty-four hours of the onset of symptoms. It cannot be diagnosticated with certainty unless bacilli are found in the blood.

External anthrax may be *anthrax carbuncle* or *anthrax edema. Anthrax carbuncle* or *malignant pustule* appears on an exposed portion of the body, especially the face, neck, hand, or finger, in 90 per cent. of cases of external anthrax. I have seen one upon the temple and one on the neck. It appears in from twenty-four hours to six days after inoculation, and presents an itching, burning papule with a purple center and a red base; in a few hours the papule becomes a vesicle which contains bloody serum, and the tissues about the papule become swollen, reddened, and indurated. The vesicle bursts and dries, the base of it swells and enlarges, other vesicles appear in circles around it, and there is developed an "anthrax carbuncle," which shows a black or purple elevation with a central depression surrounded by one or more rings of vesicles. The surrounding tissues become purple, and great edema may spread widely, the vesicles grow very large, new vesicles form, and gangrene may occur. Pain is trivial or absent. Lymphatic enlargements occur, but pus does not form. The constitutional symptoms may rapidly follow the local lesion, but may be deferred for a week or more. The patient feels depressed, has obscure aches and pains, and is feverish, but usually keeps about for a short period. In some cases with constitutional symptoms there is no elevated temperature, and such cases are frequently fatal. After a time he is apt to develop rigors, high irregular fevers, sweats, acute fugitive pains, diarrhea, delirium, typhoid exhaustion, dyspnea, cough, and cyanosis. The carbuncle of anthrax is distinguished from ordinary carbuncle by the central depression, the adherent eschar, the absence of pain, tenderness, and suppuration of the first, as contrasted with the elevated center, the multiple foci of suppuration and sloughing, and the more severe pain usual in the second. If anthrax has a visible lesion and the constitutional symptoms are slight or absent, the chance of cure is good. In cases which get well a line of demarcation forms about the pustule and the gangrenous area is rather rapidly cast off, a granulating surface remaining.

Anthrax Edema.—An area of edema surrounds a malignant pustule and often spreads widely, but in cases of external anthrax without a pustule there is edema alone. This lesion occurs in connective tissue, especially loose tissue. It is a spreading, livid edema, with an ill-defined margin. There is no pain and usually no vesication and no fever. In severe cases, however, there is fever, vesicles form, and gangrene may arise. Anthrax edema differs from cellulitis in the absence of pus formation, and from malignant edema by the less disposition to result in gangrene. Two of the cases I have seen were anthrax edema. In Horwitz's case in the Philadelphia Hospital the forearm, arm, and shoulder were enormously edematous. In Keen's case in the Jefferson College Hospital the forearm and arm were edematous.

Bacilli in the Blood in All Forms of Anthrax.—In some cases they are found, in others they are not. To find them is extremely ominous, as most cases with

bacilli-laden blood die. Bacilli are seldom found until thirty-six hours before death (Mitchell, in "Brit. Med. Jour.," April 1, 1911). In fatal cases the blood always contains bacilli.

Prognosis.—When bacilli are found in the blood the prognosis is very bad. Becker knows only of 3 such cases which survived ("Münchener medicinische Wochen.," Jan. 23, 1912). Of Becker's 44 cases which had no bacilli in the blood, 43 recovered. There were 11 with bacilli in the blood and all died. A case which is going to be fatal always shows bacilli in the blood, at least within thirty-six hours of death. Even apparently bad cases with negative blood findings are apt to recover (Becker, Ibid.). During six years the Board of the Bradford woolen industry reported that in 71 cases of anthrax 24 died (15 internal and 9 external). The former estimate of the death-rate from external anthrax was from 25 to 30 per cent. If a lesion is upon the face the prognosis is much worse than if it is upon an extremity, and if upon the upper extremity it is worse than if it is upon the lower. It is claimed that death-rate has been notably reduced by modern treatment, and under serum treatment is said to be but little over 6 per cent. In a series of 15 cases of external anthrax reported by Royer and Holmes there were 3 deaths ("Therapeutic Gazette," Jan., 1908). Eleven of these cases received serum, and of the 11, 2 died.

Pulmonary anthrax and intestinal anthrax have been regarded as invariably fatal, but vastly better results may be looked for hereafter.

Prevention of Human Anthrax.—Spores are the great danger. Unfortunately, there is no known disinfectant for wool which will kill spores and not injure fabric (London letter in "Jour. Am. Med. Assoc.," Feb 17, 1912). Blood-stained wools are the great peril. The blood contains the spores and formalin will not penetrate dried blood. Wet salted hides are entirely safe, and governmental regulation to prevent the importation of any other kind would prevent anthrax among those who work in hide, skin, and leather industries (Ponder, in "Lancet," Nov. 4 1911).

Treatment of External Anthrax.—If a person is wounded by an object suspected of carrying the infection, cauterize the wound by the hot iron or fuming nitric acid. A sufferer from anthrax must be isolated in a well-ventilated room. All dressings are to be burned, all discharges asepticized, and after the removal of the patient the bed-clothes are burned and the room disinfected. If there are no bacilli in the blood a malignant pustule should be entirely excised, and the wound mopped out with pure carbolic acid or burned with the hot iron. If there is an extensive area of edema, it should be freely incised down to the deep fascia at several points. The area about an anthrax edema or an excised pustule should be injected every sixth hour with a 5 per cent. solution of carbolic acid. The wound and the edematous area should be dressed with hot antiseptic fomentations, and, if dealing with an extremity, a splint is applied. Excision should be practised for pustule even when glands are enlarged. When excision cannot be performed make crucial incisions through the lesion, mop the wounds with pure carbolic acid, and inject about and in the pustule carbolic acid (1:20) every six hours until the disease abates or toxic symptoms appear. Dress the part as directed above. In a successful case the adherent eschar is finally separated by the influence of the fomentations. Davaine advised the following plan: Inject the pustule and the tissues about it at many points every eight or ten hours with 1 part of tincture of iodin diluted with 2 parts of water or with a 10 per cent. solution of carbolic acid, or with a 0.1 per cent. solution of corrosive sublimate. Dress with wet antiseptic gauze and apply an ice-bag. Personally I would not use an ice-bag on an area of infection, but would prefer heat. In Keen's very severe case of anthrax edema multiple incisions were made, carbolic acid was injected into sound tissues above the edema, and the part was dressed with hot antiseptic

fomentations. Recovery followed. Constitutional treatment in anthrax edema, malignant pustule, or internal anthrax must be sustaining and stimulating. Maffucci gives carbolic acid internally, and also uses it externally. Davies-Colley uses ipecac locally and gives 5 gr. by the mouth every four hours. Statistics indicate that the serum treatment is of the greatest value. The material is known as Sclavo's serum; it is obtained from the immunized ass, and it was introduced into practice in 1897. It is perfectly harmless and may be given in a vein or subcutaneously. Sclavo injects 40 c.c. in different regions of the wall of the abdomen. Usually the temperature begins to fall in an hour; if improvement is not obvious in twenty-four hours, the dose is repeated. Intravenous injection is reserved for severe cases, the dose being 10 c.c. into a subcutaneous vein of the dorsal surface of the hand. The serum can do no harm and should always be given. If given early, all cases but very severe ones will recover (Legge's Nilray Lectures, "Brit. Med. Jour.," March 18, 1905). Becker ("Münch. med. Woch.," Jan. 23, 1912) has given salvarsan, and he believes it saved the life of a very ill man. The persistence of anthrax infection in a room was well shown in the record of Keen's case. The infection lingered on the floor of the room in which the patient had been operated upon for a long time. Three disinfections were necessary before it became impossible to obtain anthrax bacilli from the contaminated floor. This indicates that such a case should be operated upon in a room not regularly used for operations.

Hydrophobia, Rabies, or Lyssa.—Hydrophobia is a spasmodic and paralytic disease due to inoculation with virus from a rabid animal. Inoculation is nearly always through a wound, but cases occur after the licking of the hand by a diseased dog. The disease does not appear to arise except as the result of inoculation. It is most common in dogs and wolves, but it may develop in cats, horses, goats, foxes, cattle, sheep, and pigs. Cats are said to cause 6 per cent. of the cases (Cumming, in "Jour. Am. Med. Assoc.," May 18, 1912). Lack of water is never a cause. It is far more common in the carnivora than the herbivora. In Russia wolves are responsible for many cases. It is said that poultry may suffer from it. Human hydrophobia in most instances follows dog bites. Roux estimates that about 14 per cent. of the people bitten by mad animals develop the disease. If the bite is on an exposed part, it is far more apt to cause rabies than if the rabid animal's teeth passed through clothing. The saliva is the usual vehicle of contagion, but other fluids and tissues contain the virus, especially the brain and cord. The blood and urine do not contain it. Hydrophobia has been known for centuries. It is not spoken of by Hippocrates, but is described in animals by Aristotle, Pliny, and Celsus, and is alluded to by Ovid, Horace, Virgil, and Plutarch. Celsus first described the disease in man and first used the term "hydrophobia." At the present day some ardent antivivisectionists dispute its existence. The fact that an infant bitten by a rabid animal may develop rabies proves that the disease is not due to the imagination. Hydrophobia is almost invariably fatal. No causative micro-organism has been demonstrated. One must exist, but it probably escapes detection because of its very small size.[1] Negri has discovered in the central nervous system bodies which are probably protozoa and are perhaps the cause of the disease. They are called Negri bodies. The poison cannot gain entrance through sound mucous membrane. It used to be thought that the disease was particularly apt to arise in hot weather, but it is now known that it may occur any time of the year. There was a veritable epidemic of it among the animals in Greenland in 1860, and at this time the temperature averaged 25 degrees below zero (F. W. Dudley, in "Jour. Am. Med. Assoc.," Dec. 19, 1908). It is common in Russia. No

[1] Since the above was written Noguchi has announced the discovery of the causative protozoön.

portion of the world is completely exempt. No constant postmortem lesions have been certainly demonstrated in those dead of rabies. Gowers believes that in the spinal cord there is hyperemia, but no infiltration with cells, whereas in the medulla, especially about the respiratory center, there are hyperemia and cellular infiltration of the perivascular spaces; but such perivascular infiltration can occur in some other acute conditions and hence is not characteristic. What is known as the *rabic tubercle* is found in the medulla and about the motor cells of the upper part of the spinal cord. Each tubercle consists of an aggregation of embryonal cells, which destroy and finally replace the nerve-cells which they surround. Babés thinks the tubercle characteristic. Infiltration of the ganglia with epithelioid cells and round cells has been held by some to be characteristic, but both the rabic tubercle and ganglion infiltration occur in other conditions. The disease is extremely rare in the United States and the author has not seen a single case.

If a dog is poisoned with barium carbonate the symptoms are similar to those of rabies ("Penna. Health Bulletin," Aug., 1909).

Symptoms.—The period of incubation of human hydrophobia is from a few weeks to several months, and it has been alleged that it may even be two years, but it is very doubtful if there is ever a period of incubation of over six or seven months. The average incubation period in man is forty days (Ravenel). The initial symptoms are mental depression, anxiety, sleeplessness, restlessness, headache, malaise, and often pain or even congestion in the cicatrix. The anxiety which is usually present may be deepened into actual fear. In dogs the condition of fear is so evident that Cælius Aurelianus centuries ago called the disease *pantophobia* (fear of everything). The previously mentioned symptoms are quickly followed by dysphagia. It is not only water that is difficult to swallow, but everything the patient tries to drink or eat. The difficulty in swallowing results apparently from apnea produced instantly when an attempt is made to swallow. Curtis points out that the difficulty is not spasm of the pharynx and larynx, but a sense of immediate suffocation due to reflex stimulation of respiratory inhibition. If spasms occur—and they may occur—they are secondary to this suffocative state, a state in which the action of the diaphragm ceases for a time. The air-passages become congested and the sufferer makes frequent and painful efforts to expel thick mucus, and the efforts produce paroxysms of suffocation. Between the paroxysms the patient is evidently somewhat breathless, and Warren tells us that his speech is not unlike that "of a child who has recently been crying and is endeavoring to control itself" ("Surgical Pathology and Therapeutics"). As the condition grows worse, suffocative attacks, which were at first induced by attempts at swallowing, come to be caused also by bright lights, sudden or loud noises, irritations of the skin, or even thinking of swallowing. At length suffocative paroxysms occur spontaneously and the patient jumps, or hurls himself about, or the muscles of the entire body are thrown into clonic spasm. Tonic spasm does not occur. A condition of general hyperesthesia exists. The mind is usually clear, although during the periods of excitement there may be maniacal furor with hallucinations which pass away in the stage of relaxation. The temperature is moderately elevated (101° to 103° F. or higher). The spasmodic stage lasts from one to three days, and the patient may die during this stage from exhaustion or from asphyxia. If he lives through this period, the convulsions gradually cease, the power of swallowing returns, and the patient succumbs to exhaustion in less than twenty-four hours, or he develops ascending paralysis which soon causes cardiac and respiratory failure. In what is known as *paralytic rabies*, a very rare form of the disease in human beings, the attack comes on with the same early symptoms met with in the commoner form,

but paralysis soon begins about the bitten part and spreads to all the limbs and to the trunk.

In hydrophobia death is almost inevitable. Practically all cases in which it is alleged that recovery ensued were not true hydrophobia, but hysteria. An exception must be made of Murri's case. Wood says that in hysteria, especially among boys, "beast-mimicry" is common, the sufferer snarling like a dog; and in the form known as "*spurious hydrophobia*," in which there may or may not be convulsions, there are a dread of water, emotional excitement, snarling, and attempts to bite the bystanders (in genuine hydrophobia no attempts are made to bite, and no sounds are uttered like those made by a dog).

Lyssa is separated from lockjaw by the paroyxsms of suffocation and the absence of tonic spasms in the former, as contrasted with the fixation of the jaws and the tonic spasms with clonic exacerbations of lockjaw.

Treatment.—When a person is bitten by a supposed rabid animal and is seen soon after the injury, constriction should be applied if possible above the wound, the wounded area should be incised, allowed to bleed freely, and should then be washed with a 5 per cent. solution of formaldehyd and dressed for twelve hours with a like solution. It is held that formaldehyd is a specific disinfectant of the virus (Cumming, in "Jour. Am. Med. Assoc.," May, 8, 1912). If not seen for a day or two, open the wound and scrub with a 5 per cent. solution of formaldehyd. Many physicians advocate excising the wounded area and cauterizing with pure nitric acid, a hot iron, or the Paquelin cautery. Fuming nitric acid is warmly commended by Paul Bartholow and others. Ravenel believes it may save a man even after twenty-four hours have elapsed since the bite. After the wound has been treated with formaldehyd or cauterized it is to be dressed antiseptically. If the patient is not seen for a day or two after the injury, cauterization is useless; it is not only useless, but it may delude the patient and his friends into a feeling of security. In any case, early or late, send the patient at once to a Pasteur institute. If the animal which inflicted the injury was not hydrophobic, no harm will result from inoculations; if it was hydrophobic, preventive treatment may save the patient. The method known as the preventive treatment was devised by Pasteur, who discovered the following remarkable facts: If the virus of a rabid dog (street rabies) be placed beneath the dura of another dog, it *always* causes hydrophobia in from sixteen to twenty days, and invariably causes death. If the virus is passed through a series of rabbits it gets stronger (laboratory virus), and if inserted beneath the dura of a dog it causes the disease in from five to six days, and kills in four or five days. The virus can be attenuated by passing it through a series of monkeys or by keeping it for a definite time. To obtain attenuated preparations in a convenient form Pasteur made emulsions from the spinal cords of hydrophobic rabbits, the animals having been dead two or three weeks. He found that the emulsion obtained from the rabbit longest dead is the weakest. He injected a dog with emulsions of progressively increasing strength and made it immune to hydrophobia. The patient is injected with an emulsion made from the dried spinal cords of hydrophobic rabbits. In this emulsion the virus is attenuated, and day by day the strength of the injected virus is increased. These emulsions cause the body-cells to form antitoxin, and either the virus of street rabies does not develop at all or by the time it begins to develop a quantity of antitoxin is present to antagonize it. In the New York Pasteur Institute patients remain under treatment for fifteen days, two inoculations being given daily. In cases in which treatment is begun late, or in which the head or face was bitten, from four to six inoculations are given each day. The report of the Parisian Pasteur Institute shows that since its foundation there has been a mortality of 0.5 per cent. The lowest estimated number of those attacked by hydrophobia before this method was used was 5

per cent. of those bitten, and all attacked died; hence, the Pasteur treatment as applied in the Parisian Institute shows one-twenty-fifth of the mortality which attends other preventive methods. In the Paris Pasteur Institute during 1910 401 patients were treated without a death. Ravenel, in 1901, estimated that 55,000 persons have been treated by the Pasteur method and that less than 1 per cent. have died. The value of this plan seems definitely established. The general public believes that the dog which did the biting should be killed. The dog should, if possible, be locked up and watched rather than killed. It may be proved in this way that it did not have hydrophobia. If it were necessary to kill the dog, or if the dog was killed at once or soon after, the physicians of the New York Pasteur Institute advise that the dog's head be cut from the body with an aseptic knife and a piece of the medulla oblongata be abstracted. The bit of medulla should be placed in a mixture of equal parts of glycerin and water which was previously sterilized by boiling. The bottle should be sealed and sent to the institute, in order that inoculations may be made upon animals to prove the existence or absence of hydrophobia. Babés tubercles and Negri's bodies are at once sought for in the specimen, and if they are found, treatment should be started at once. In the paroxysm of hydrophobia the treatment in the past was purely palliative. If we employ only palliative methods, keep the patient in a dark, quiet room, relieve thirst by enemata, saturate him with morphin, empty the bowels by enemata, attend to the bladder by regular catheterization, and during the paroxysms anesthetize. Murri, of Bologna, cured a case of hydrophobia by injecting emulsions of cords of rabbits dead six, five, four, and three days respectively. It would be proper to try this remedy if hydrophobia develops. A serum has been prepared by Tizzoni and Centani which they claim is successful in treating the disease as experimentally induced in the laboratory. The remarkable suggestion has come from Tizzoni that rabies be treated with rays of radium, it having been shown that rabic virus can be destroyed by radium.

Glanders, Malleus, Farcy, or Equinia.—Glanders is an infectious eruptive fever occurring in horses, mules, and asses, sometimes noted in goats, hogs, dogs, cats, and some other animals, and communicable to man. Cattle, house mice, house rats, white mice, and white rats are immune. The disease is most common in the horse and is due to the Bacillus mallei (see page 52). These bacilli are found chiefly in the nasal discharge and the recent nodules. There are few in older ulcerations. They are not found in the blood. Human glanders is by no means as uncommon as was once thought. Not a few cases die undiagnosticated. In a recent study 156 cases of chronic glanders were discussed (Robin, "Studies from the Royal Victoria Hospital of Montreal," 1906). If the nodules occur in the nares, the disease is called "glanders"; if beneath the skin, it is termed "farcy." The Bacillus mallei is communicated to man through an abraded surface or a mucous membrane. Bernstein and Carling reported 6 cases of human glanders. They say: "In none of our cases was there definite evidence of the point of inoculation or path of infection, and the general evidence, clinical and experimental, on both of these questions is so conflicting that the time is hardly ripe for the expression of decided opinions. The hypothetic paths are by direct inoculation through a wound or by the hair-follicles, by inhalation or by ingestion ("Brit. Med. Jour.," Feb. 6, 1909). The characteristic lesions are infective granulomata in the nares, skin, lungs, and subcutaneous tissue. In the nares granulomata result in ulcers and under the skin break down into abscesses. In some cases there is no nasal discharge. Multiple abscesses anywhere should excite suspicion of the existence of glanders. From the site of inoculation the bacilli are disseminated and the cutaneous and muscular structures and lungs become involved. There is usually a remittent fever. There is no known method of immunizing animals and mallein

has no immunizing power. One attack does not prevent another. Man may be infected from a diseased animal, and as the common source of infection is the horse, the usual victims are those who use or work about horses, and yet people who have never been about horses may develop the disease. The period of incubation after infection is four or five days.

Acute and Chronic Glanders.—In acute glanders there is septic inflammation at the point of inoculation; nodules may form in the nose and ulcerate; there is profuse nasal discharge; the glands of the neck enlarge; there is weakness, frontal headache, chilliness, pain in the back and limbs; often diarrhea; after a time the muscles become painful; there is fever, the evening temperature being 100° F. or higher and the morning temperature being lower. Chills may occur. There may be chest pains, severe muscular pain, bronchitis, and signs of pulmonary congestion. The lungs may be infected by inspiration of the bacilli in the discharge of the ulcers. It may not be suspected that the patient has glanders and the diagnosis of typhoid may perhaps be made. Twelve to fourteen days after the beginning of the trouble little hard lumps arise in the muscles and just beneath the skin. In a few days the lumps soften, break down, and discharge a bloody fluid which contains the bacilli of glanders. In a number of cases an eruption resembling small-pox appears on the face and about the joints, and this exanthem is usually prophetic of approaching death. It differs from small-pox in not being umbilicated. Leukocytosis may or may not exist. In chronic glanders there are like symptoms which last six weeks or more. Acute glanders is nearly always fatal. Chronic glanders lasts for months, is rarely diagnosticated, being mistaken for catarrh, may be recovered from, but if not soon eradicated will sooner or later eventuate in a fatal acute condition. The mortality is about 90 per cent.

Acute and Chronic Farcy.—Acute farcy arises at the site of a skin inoculation; it begins as an intense inflammation, from which emerge inflamed lymphatics that present nodules or "*farcy-buds*." Abscesses form, but the pus differs in appearance from ordinary pus, is often gelatinous, and may be red in color. There are joint-pains and the constitutional symptoms of sepsis, but no involvement of the nares. In it nodules occur upon the extremities, which nodules break down into abscesses and eventuate in ulcers resembling those of tuberculosis or, perhaps, of syphilis. The ulcers form rapidly and often heal.

Diagnosis of Glanders and Farcy.—Mallein is a concentration of the glycerin broth in which the bacilli of glanders were grown. Injection of mallein into an infected animal produces a significant reaction (fever, malaise, restlessness, perhaps a distinct rigor, sometimes vomiting, marked swelling at the point of inoculation). The dose used is 10 to 15 min. (Bernstein and Carling, in "Brit. Med. Jour.," Feb. 6, 1909).

Mallein has proved highly valuable in the hands of veterinarians. The reaction when it is injected into an animal with glanders is like the reaction produced by tuberculin on a tuberculous animal.

Animal injection is very valuable in diagnosis. The highly susceptible guinea-pig is used for this purpose. The doubtful material (nasal mucus or pus or a tissue fragment) is injected into the peritoneal sac of a male guinea-pig. Usually in three or four days the testicles enlarge and later suppurate.

The pig is killed and the pus examined for the bacillus of glanders. Testicular enlargement does not always occur even when the inoculated material was from a lesion of glanders. In some cases it does not occur for weeks. As a rule, it does occur.

In the lesions of glanders the bacilli of the disease are scanty and in many lesions are mingled with other bacteria, hence the bacteriologic diagnosis is always difficult and is often impossible without animal inoculation. The

value of an agglutination test is as yet undetermined, but it is regarded with confidence by some.

Treatment.—In treating this disease the point of infection is at once to be incised and cauterized, dusted with iodoform, and dressed antiseptically. The skin over enlarged glands and swollen lymphatics is to be painted with iodin and smeared with ichthyol. Bandages are applied to edematous extremities. Ulcers are curetted, touched with pure carbolic acid, dusted with iodoform, and dressed antiseptically. In glanders the nostrils should be sprayed at frequent intervals with peroxid of hydrogen and syringed with a solution of sulphurous acid. The mouth must be rinsed repeatedly with solutions of chlorate of potassium. Abscesses are to be opened, mopped with pure carbolic acid, and dressed antiseptically. Stimulants and nourishing diet are imperatively demanded. Morphin is necessary for the muscular pain, restlessness, and insomnia. Digitalis is given to stimulate the circulation and kidney secretion. Sulphur iodid and arsenite of strychnin have been used. Diseased horses ought at once to be killed and their stalls should be torn to pieces, purified, and entirely rebuilt. A man with chronic glanders should be removed to the seaside. The nasal passages must be kept clean and the ulcers must be cauterized and dressed with iodoform gauze. Nutritious foods, tonics, and stimulants are necessary.

Treatment of recent cases by frequent small doses of mallein finds advocates. It has been suggested that injection of the serum of the blood of an immune animal (the ox, for instance) might be serviceable. Most observers assert that serum of naturally immune animals and the serum of animals which have been repeatedly injected with mallein are equally worthless.

Actinomycosis (*streptotrichosis*) is a specific infectious disorder characterized by chronic infiltrating, granulomatous inflammation, and is due to the presence in the tissues of some variety of streptothrix. It was long believed that the *actinomyces bovis* or ray-fungus was the only cause of the disease. We now believe that other members of the streptothrix group may be responsible. As stated on page 19 the streptothrices are usually regarded as molds, but they possibly constitute a transition stage between filamentous fungi and bacteria. At present many pathologists use the term "actinomyces" as the generic name for the various forms of these parasites. Other pathologists designate them as streptothrix forms, of which the actinomyces bovis is one. In 1877 Bollinger recognized and described these parasites as causative of disease in cattle. In 1878 Israel described human actinomycosis. Acland, in 1884, reported the first English case of human actinomycosis. Some of the varieties of the organism are pathogenic, others do not seem to be. Some forms are anaërobic, others are aërobic. When dried they are not killed at once, but months after may develop if placed under favorable conditions. When growing in the tissues they usually form numerous distinct yellow, reddish, black, or gray aggregations, each about the size of a sand grain, and called from their color *sulphur grains* or *red pepper grains*. They grow from mycelia. Usually the growths lie in thick and sticky purulent matter. If purulent matter containing growths is rubbed between the fingers, it will give a gritty sensation like sand if the growth is not very recent. The grit is due to lime-salts. The growth of the fungi causes the formation of an infective granuloma, and great masses of granulation tissue may form with collections of necrotic or purulent matter here and there, and zones of fibrous tissue. The fungi are easily discovered in the sulphur grains by the microscope, but if the fungi are mycelial and are scattered instead of being gathered into granules it is difficult to discover them. This disease occurs in cattle (*lumpy jaw*) and in pigs, and can be transmitted to man. It is believed by many that the fungi exist normally inside the husks of barley and other grasses and that animals are inoculated by eating

the contaminated grasses, scratches on the mucous membrane of the tongue, mouth, or pharynx being inoculated. In man the fungus may be taken in with food, by chewing the mold-bearing grass or straw, or by inhalation of contaminated dust. Its development seems dependent upon processes of decay. It may lodge and develop in a breach of mucous continuity, a crypt of the tonsil, or a hollow tooth.

Lord, of Boston, has found the parasite in carious teeth of those free from actinomycosis, and has produced actinomycosis in guinea-pigs by inoculating them with the contents of carious teeth ("Publications of the Massachusetts General Hospital," Oct., 1911). Lord reaches the conclusion that true actinomycosis (the disease due to ray-fungi) arises from within the individual, carious teeth being the cause.

The disease is at first local; later there may be general blood infection and abscesses may form in the lung, liver, kidney, etc.

The fungi may pass into the lungs, causing pulmonary actinomycosis; into the intestines, causing intestinal actinomycosis; into the skin, the bones, the subcutaneous tissues, the heart, the brain, the liver, the urinary organs, etc. Abdominal anthrax is the commonest form and comprises nearly 50 per cent. of cases. Cases of human actinomycosis until recently were looked upon as sarcomata. Many sinuses form, ulcers develop, but large abscesses do not arise.

Cutaneous actinomycosis may be secondary to visceral infection with the disease, may be a purely local condition due to inoculation of a wound, or may be associated with some adjacent area of bone infection. The gummatous form of actinomycosis resembles a gummatous syphilitic area, and in it many small purulent pockets open by fistulæ.

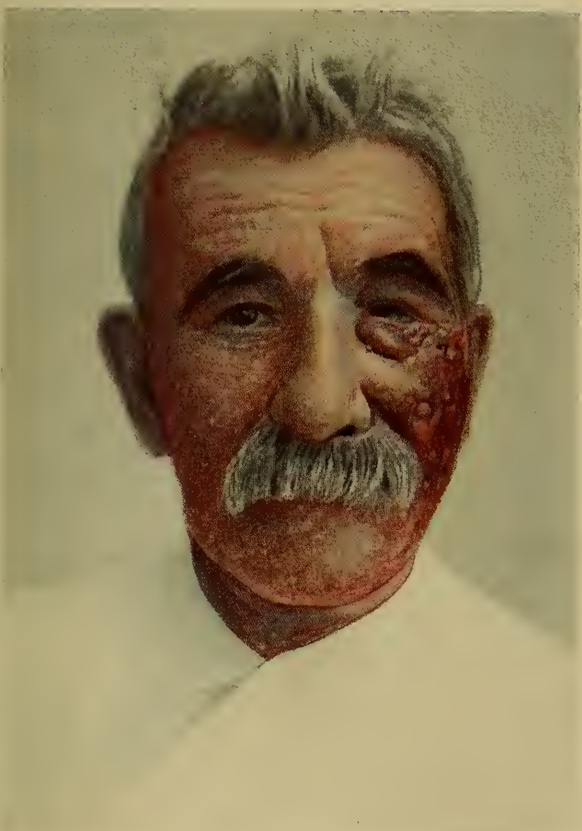
In actinomycosis there is no spread by lymphatics until very late in the case. In fact, the adjacent lymph-glands are very seldom involved unless there is secondary pyogenic infection, and if metastasis occurs it takes place by the veins. The condition causes but slight pain. A diagnosis must be made from syphilis, sarcoma, carcinoma, and tuberculosis. The formation of a tumor, followed by sinuses and ulceration, the ulcer having thin, non-indurated, undermined edges and edematous granulations, and adjacent pus cavities joining by sinuses, the appearance of the pus and the microscopic study of the discharge are significant. An actinomycotic ulcer may partially heal here and there. It has been stated that an individual with actinomycosis may react to tuberculin like a person with tuberculosis (see page 227). The muscular and connective tissues become infiltrated and hard, as though a coagulating material had been injected into them (Poncet and Bérard, in "Lyon Médicale," March 27, 1904). Edema and induration extend wide of the active focus of disease (Plate 2). Actinomycosis may last for years or it may prove fatal.

In the anthracoid form there are no distinct purulent collections, but many fistulæ discharge pus at various points (Monestié).

An area of cutaneous actinomycosis is characterized by the existence of violet, blue, gray, or black maculæ, varying in size from that of a pin's head to that of a bean, the center of each macule being white and containing a minute quantity of pus (Derville).

In actinomycosis of bone the bone enlarges and becomes painful, the parts adjacent swell from infiltration and soften, pus forms and reaches the surface through fistulæ, and the skin becomes involved secondarily.

Abdominal actinomycosis takes origin from the gastro-intestinal tract, an actinomycotic nodule of the intestine having ulcerated, adhesions having formed, and an actinomycotic abscess having arisen, or actinomycotic disease of the intestine having spread. In over 50 per cent. of cases of abdominal actinomycosis the cecum is the part attacked. A fecal fistula may form and the liver may be involved. At least 150 cases of actinomycosis of the appendix



Author's case of facial actinomycosis.

have been reported. A mass containing putrid pus develops. If not evacuated fistulæ form. It is a very chronic condition, and although fistulæ may heal, they break open again and again (Short, in "Lancet," Sept. 14, 1907). The fungi may be found in the stools.

The mortality of actinomycosis depends upon the site of infection, the question of secondary infection, and the plan of treatment. If pyogenic infection occurs, fatal pyemia may arise. The prognosis is reasonably good in many cases. The majority of cutaneous cases (nearly 90 per cent.) and many osseous cases can be cured. The mortality in the abdominal cases is large. Grill says that of 77 abdominal cases treated surgically 45 died, 22 recovered, and 10 were improved. Frazier ("Keen's System of Surgery") tells us that the mortality of the reported cases of actinomycosis in the United States was 47 per cent., and quotes Jiron as follows regarding the mortality of the various forms: Face and neck, 11 per cent.; thorax, 83 per cent.; abdomen, 71 per cent.; brain, 100 per cent. Actinomycosis has a strong tendency to redevelop even after apparently thorough excision. A case of cutaneous actinomycosis of the arm, seen by the author, was operated on twenty times. Ulceration took place into the axillary artery and death was narrowly averted. Recovery finally ensued. I have seen 4 cases of human actinomycosis: one was the patient just referred to; another was a mattress stuffer (straw being used), his lesions were on the chest and jaw and recovery followed operation; the third was a stable hand, who died from lesions of the face, jaw, and neck; the fourth was a railroad watchman who had nothing to do with horses (Plate 2).

Treatment.—Free excision if possible; otherwise incision, scraping, cauterization with pure carbolic acid or silver nitrate, and packing with iodoform gauze. If possible, remove the entire area; if not possible, remove all that can be safely taken away. Sinuses must be widely opened, each collection of pus must be drained, and granulation tissue if not extirpated must be scraped away with a sharp spoon. Give internally large doses of iodid of potassium. This drug alone has cured many cases. It is given for a week or two and is then discontinued for one week. It is curious that though iodid of potash seems to influence actinomycosis favorably, the fungus will live unharmed in a 2 per cent. solution of that drug (Harbitz and Grandahl, in "Amer. Jour. Med. Sci.," Sept., 1911). In a fistula from intestinal or appendical actinomycosis give potassium iodid and sulphate of copper (Bevan) and irrigate the sinuses with diluted tincture of iodin. Cases of actinomycosis should be placed under the best hygienic conditions, should live as much as possible in the sunlight and open air, and should be given nutritious diet, tonics, and often stimulants.

Blastomycosis.—May, in 1894, called attention to the disease. In 1894 Busse described a fatal infection due to a pathogenic yeast. The very existence of this disease has been denied, but numerous cases have been reported and most observers regard it as an entity. Many cases have been reported from Chicago and its neighborhood by Bevan, Hektoen, Hyde, and others. It may be a local infection (cutaneous blastomycosis), but in some cases the disease is generalized (systemic blastomycosis). The disease is found in North America, South America, Europe, and the East. In generalized blastomycosis the lungs are usually primarily infected. Generalized blastomycosis is usually fatal. The yeasts when found in the tissues are in the budding stage.

Cutaneous blastomycosis (blastomycetic dermatitis or oïdiomycosis) was first described by Gilchrist in 1894. It is due to infection with a variety of yeast fungus. In the skin it begins as a papule or an indurated pustule, which becomes crusted and finally warty, enlarges at the periphery, and becomes surrounded by more recently developed lesions. The area becomes studded with minute abscesses, crusted foci, and areas of bleeding granulations. Here and there healing may occur.

The disease may arise on any portion of the body, but the hands and face are most liable to it. It is slow in progress and lasts for many months. If it progresses, it will finally produce systemic blastomycosis or secondary infection will produce fatal septicemia. Bevan (Lexer's "General Surgery," edited by Arthur Dean Bevan) says the evidences of general infection are: "irregular temperature, loss of appetite, general weakness, emaciation, cough, rapid, feeble pulse, acceleration of the respiration, at times albumin in the urine, multiple subcutaneous nodules and abscesses resulting in superficial, irregular ulcers, abnormal physical findings in the lungs, edema of the extremities, and various grades of anemia." Coccidial disease is caused by an organism strongly resembling the yeast of blastomycosis. Bevan places the two diseases in the same group. Some observers regard them as identical. The symptoms are indistinguishable. Montgomery regards iodid of potassium as a test agent—it is without effect on coccidial disease, but acts strongly and favorably upon blastomycosis.

Treatment.—In some cases excision, in others the *x*-rays. Potassium iodid in very large doses is given. It greatly benefits most cases and cures many. Its employment in this disease is due to Bevan. He also gives copper sulphate internally ($\frac{1}{4}$ gr. three times a day), and applies a 1 per cent. solution of that chemical to local lesions.

XVI. BURNS AND SCALDS; EFFECTS OF COLD

Burns and scalds are injuries due to the action of caloric. Scalds are due to heated fluids or vapors. There is no true pathological difference between burns and scalds. Dupuytren classified burns into six degrees, as follows: (1) Characterized by erythema; (2) characterized by dermatitis with the formation of vesicles; (3) characterized by partial destruction of the skin, which structure is not, however, entirely burned through; (4) characterized by destruction of the skin to the subcutaneous tissue; (5) characterized by destruction of all superficial structures and of part of the muscular layer; (6) characterized by "carbonization" of the whole thickness of the muscles.

The **symptoms** of a severe burn are local and constitutional. *Local symptoms* are pain and inflammation, which vary in nature, in intensity, or in degree according to the extent of tissue damage. *Constitutional symptoms* are very weak pulse, shallow respiration, and subnormal temperature—in other words, the condition of shock exists. The patient may die without reacting from shock, but in most cases there is reaction, followed by a severe reactionary fever, with a strong tendency to congestion of internal parts. During the existence of fever there may be vomiting, diarrhea, hemoglobinuria, albuminuria and enlargement of the liver, spleen, lymph-glands, and tonsils. Marked blood changes follow burns (see "Clinical Hematology," by J. C. DaCosta, Jr.). There is a marked and rapid increase in red blood-cells (polycythemia). This is due in part to venous stasis and in part to loss of blood-plasma. Leukocytosis is rapid and pronounced and there is a notable increase in blood-plaques.

The blood has a marked disposition to clot, and clots may damage various structures or organs. Further, the altered blood damages the organs of excretion, and the liver and kidneys may cease to perform their functions properly. After a severe burn there are imperfect oxygenation and a tendency to universal fatty degeneration. The symptomatic stages are often designated as *prostration*, *reaction*, and *suppuration*. During the first forty-eight hours after a burn there are congestion in and about the burned area,

severe pain, and possibly internal congestions. There may be shock and possibly toxic delirium or convulsions. From the end of the second to the end of the eighth or ninth day there are severe inflammation of the burned area, formation of sloughs, and a strong tendency to inflammation of the brain in head burns, of the lungs in chest burns, of the abdominal organs in abdominal burns. Duodenal inflammation may arise after any burn. Septic emboli in very unusual cases cause *Curling's ulcer* of the duodenum (see page 162). Duodenitis and Curling's ulcer are possibly due, as Wm. Hunter suggested, to the bile having become irritant by the excretion in it of toxic matter. After the eighth or ninth day the sloughs separate from the burned area and healing begins. The raw surface is slow to heal, hemorrhages may occur, the granulations are apt to be exuberant and edematous, and the scars are very contractile and often produce hideous or disabling deformity. If over one-half of the body surface is badly burned, death will almost certainly occur, and probably within two days. The danger of a burn depends upon its extent, its depth, and its situation. Burning of a large area superficially is much more dangerous than burning a small area deeply. Burns of the extremities are not so dangerous as are burns of the head, chest, or abdomen. Death after severe burns is positively not due to loss of body-heat in the burned area. Some think it is produced by auto-intoxication with retained body secretions. High temperature produces blood changes—viz., disintegration of red corpuscles. Thrombosis may occur, and irritation of the kidneys and other organs is produced by "products of corpuscular degeneration."[1]

The blood of burned animals contains toxins (Kijanitzen), and so does the urine (Reis). It seems probable that the constitutional symptoms and death, if it occurs, are due partly to corpuscular disorganization and partly to the absorption of toxic matter from the seat of injury, this matter having been formed by the action of heat on the body-cells and fluids. Sepsis is not infrequent. Death may be directly due to shock, to sepsis, to exhaustion, to tetanus, to embolism or thrombosis, to congestion of the brain, lungs or kidneys, or to Curling's ulcer of the duodenum.

Treatment.—The *local treatment* of slight burns is to moisten the parts frequently with a saturated solution of bicarbonate of sodium or with normal salt solution. In burns of moderate degree a mixture of zinc ointment with iodoform, though not antiseptic, is a comfortable dressing.

If a large surface is burned, remove the clothing with great care, and before applying dressings give a hypodermatic injection of morphin, administer stimulants, and if the patient has a chill, place him in a warm bath. Use all ordinary means to secure reaction from shock. Waterhouse makes a recommendation which I have frequently used with advantage, viz., dress the burn with a 1 per cent. solution of acetate of aluminum, wrap the patient in blankets, hold up the other bedclothes with a cradle, and put under the bedclothes an electric light of 32 candlepower. This will make the temperature under the clothes from 100° to 105° F. ("Brit. Med. Jour.," July 9, 1910). If we desire to dress a large burn aseptically, anesthetize the patient, spray the burnt area with peroxid of hydrogen, irrigate it with a solution of boric acid, dry with sterile cotton, dust with *Senn's powder* (3 parts of boric acid and 1 part of salicylic acid), and dress with salicylated cotton. Senn's powder is better than iodoform. Iodoform may allay pain, but is apt to produce dermatitis. Change the dressing no oftener than is required, and at each change proceed as above described, although it will not be necessary to anesthetize. Peroxid of hydrogen softens and loosens the dressings, and they can be readily removed. The custom in the Jefferson Medical College Hospital is to give morphin and stimulants, to cut away the clothing, to wrap the unburned parts

[1] Bardeen, in "Johns Hopkins Hospital Bulletin," April, 1897.

with blankets, and place about them cans or bags of hot water. The burned region is sprayed with diluted peroxid of hydrogen contained in an atomizer, and is irrigated with salt solution. Portions of epidermis which remain are retained. Any blisters are opened with a sterile needle, and the part is dressed with several layers of sterile lint or tarlatan soaked in normal salt solution, and the dressing is kept moist. During the second or inflammatory stage use stimulants and concentrated food, allay pain by opium or morphin, favor elimination by the skin, bowels and kidneys, and combat any tendency to internal congestion or inflammation. In very extensive burns complete and continuous immersion of the part in warm salt solution is an excellent treatment.

The *picric acid treatment*, first suggested by Thiery, has many advocates. It greatly mitigates the pain. It is used early only in limited burns of the first and second degrees, but it can be employed in late stages of deep burns to stimulate the formation of epidermis. If used early in a large or a deep burn, it may poison the patient. It may poison a child when used upon a burn of the second degree. A case was reported by Dr. J. Stuart Rose ("Scottish Med. and Surg. Jour.," Dec., 1903), occurring in a boy of nine, who was treated with picric acid for a scald of the first degree, there being only one or two small blisters in addition to the redness. Ointment of picric acid was used ($\frac{1}{2}$ dr. to 1 oz. of vaselin). Symptoms were noted three days after beginning the treatment. The symptoms of poisoning are dark-colored urine (carboluria), albuminuria, marked yellowness of the skin, yellowness perhaps of hair at the scalp margins, diarrhea, and elevated temperature. Rose considers a 1 per cent. solution safe. It is applied as follows: The part should be disinfected, gauze saturated with a 1 per cent. watery solution of picric acid should be laid upon the burned area, and be covered with absorbent cotton and a bandage. This dressing is not changed for three to five days, and the next dressing can be left in place until the burn is healed. D'Arcy Power has carefully studied the real status of picric acid as a remedy for burns, and some of his conclusions have been set forth above.

Périer dresses a burn with a tarlatan compress, folded six times and soaked in the following solution: boric acid, $2\frac{1}{2}$ dr.; antipyrin, $1\frac{1}{2}$ dr.; sterile water, 8 oz. The following ointment is used by Reclus: iodoform, 15 gr.; antipyrin, 75 gr.; boric acid, 75 gr.; vaselin, $1\frac{1}{2}$ oz.

Carron oil consists of equal parts of linseed oil and lime-water. It allays the pain of a burn, but it is a filthy preparation, and its use is followed by much pus formation. Cosmolin gives comfort as a dressing, but should not be used on the face, lest it cause pigmentation. The elder Gross used lead paint. A solution of nitrate of potassium allays the pain. Bismuth paste is a very satisfactory dressing. In every burn of the fingers and toes keep the burnt digits separated by gauze, lint, or rubber tissue during healing, otherwise adjacent fingers will adhere and "*webbing*" will result. When extensive destruction of tissue has taken place and healing has begun, use splints and extension to limit contractures, and skin-graft as soon as possible. If granulation is slow, stimulate with copper sulphate or mild silver nitrate solutions. Exuberant granulations require burning down. Flabby granulations require pressure. If healing is slow, or if the burn is extensive, skin-graft. Skin-grafting should be done early in an extensive burn. If performed before much cicatricial tissue has formed, the graft will be more apt to adhere, and if the graft does adhere, further formation of scar tissue will be greatly limited. When an extremity has been carbonized, amputation must be performed. The *constitutional treatment* of a severe burn is to bring about reaction; combat pain with opium, and keep the bowels and kidneys active. If suppuration

occurs, give tonics, stimulants, and concentrated foods. Complications are treated according to general rules.

Burns and Scalds of the Tongue, Pharynx, Glottis, and Epiglottis.—A child or lunatic may drink boiling fluid or inhale steam from a tea-kettle. Firemen occasionally suffer from scalds of the tongue and pharynx after being suddenly enveloped in a cloud of hot steam, and from burns by the inhalation of hot vapor or flame. Caustic may be taken into the mouth or swallowed. The tongue and pharyngeal mucous membrane swell greatly, large vesicles form, there are shock, severe pain, dysphagia, and dyspnea. Edema of the glottis may arise.

Treatment.—Combat shock; give morphin for pain; puncture vesicles, and have the patient almost constantly suck bits of ice. If great swelling occurs, make multiple longitudinal incisions through the mucous membrane of the dorsum of the tongue. If edema of the glottis begins, scarify it. If this fails, perform intubation or tracheotomy.

Burns of the Esophagus.—The esophagus is seldom scalded, as a boiling fluid rarely gets below the pharynx. The swallowing of an acid or alkali produces severe burns at the constricted portions of the gullet (see page 933). Such an accident produces shock, dyspnea, violent pain, vomiting of blood, and thirst. Death may occur from shock or perforation of the stomach. In many cases severe gastritis follows a burn of the esophagus. As the acute symptoms of a burn of the gullet gradually abate, sloughs are cast off, ulcers form, cicatrization begins, and the signs of stricture develop (see page 933).

Treatment.—Give a remedy to neutralize the caustic. Administer several large drafts of water and wash out the stomach. Combat shock. Give morphin for pain. Feed by the rectum as long as the patient's strength does not begin to fail. On beginning mouth-feeding, use at first milk and then beef-juice, jelly, and ice-cream. In from two to four weeks after the infliction of the burn begin the use of bougies to limit contraction.

Effects of Cold.—*Local Effects.*—Cold produces numbness, pricking, a feeling of weight, redness of the surface followed by stiffness, local insensibility, and mottling or pallor. Sudden intense cold causes the formation of blebs, the coagulation of blood in the superficial veins, and violent pain in the part. Cold locally produces frost-bite (see page 177).

The *constitutional effects* of cold are at first stimulating, then depressing, and are exhibited by uneasiness, pain, and an intense drowsiness which, if yielded to, is the road to death by way of internal congestion. Death from prolonged cold resembles in appearance death from apoplexy. Death from sudden and overwhelming cold is caused by anemia of the brain from weak circulation and capillary embolism. To bring a partly frozen person into a warm room may cause death by embolism.

Treatment.—Frost-bite is treated as outlined on page 177. When a person is nearly frozen to death place him in a *cool* room, but under no circumstance in a cold bath; make artificial respiration, rub him briskly with flannel soaked in alcohol or in whisky, and follow this by rubbing by dry hands. After a time wrap the patient in warm blankets and give an enema of brandy. Mustard-plasters are to be applied over the heart and spine. As soon as swallowing is possible, brandy is administered by the mouth. As the condition improves gradually raise the temperature of the room and give *hot* drinks.

Chilblain or **pernio** is a secondary effect of cold. It is really an area of local asphyxia (see page 173). It usually appears as a local congestion upon the toes, the ears, the fingers, or the nose, and now and then inflames and ulcerates. A chilblain is apt to become congested on the victim approaching a fire

or on taking exercise, and when congested it itches, tingles, and stings. Frequent attacks of congestion produce crops of vesicles; these vesicles rupture and expose ulcers, which in rare instances slough.

Treatment.—If chilblain affects the toes, prevent congestion of the legs and feet. Order large shoes and woolen stockings and forbid tight garters. The patient with pernio must take regular outdoor exercise and must not loiter around a hot fire. Every morning and evening he should take a general cold sponge-bath, followed by rubbing with alcohol and friction by a coarse towel, and in winter he should sleep wearing warm stockings or with his feet upon a warm-water bag. When a chilblain is only a congested spot, it should be washed twice a day in cold salt water, rubbed dry with flannel, and subjected to applications of tincture of iodin and soap liniment (1 : 2), tincture of cantharides and soap liniment (1 : 6), or equal parts of turpentine and olive oil (W. H. A. Jacobson). Jacobson says itching is relieved by painting belladonna liniment upon the part and allowing it to dry. Tincture of iodin may relieve it, and so may a mustard foot-bath. A valuable preparation for itching is composed of 1 dr. of powdered camphor and 4 oz. of cosmolin. A little of this ointment is rubbed in twice a day. The following prescription, the source of which I do not remember, is very valuable for itching: 1 dr. of powdered camphor, 1½ dr. of ichthyol, ½ dr. of lanolin, and 4 oz. of cosmolin, rubbed into the part and covered with cotton-wool. If vesicles form, paint with contractile collodion; if ulcers form, dress antiseptically. If ulcers are sluggish, use equal parts of resin cerate and spirits of turpentine. A good antiseptic and protective is the following: oxid of zinc, 6 gr.; chlorid of zinc, 20 gr.; gelatin, 2 oz.; distilled water, 1 oz.

XVII. SYPHILIS, OR POX

The name comes from the title of a poem which was published in Italy in 1530, "Syphilis sive Morbus Gallicus," by Hieronymus Fracastorius. For centuries there has been fierce dispute as to the origin of syphilis. Many assert that Europe was free of it until the discovery of America and that the sailors of Columbus brought it from Hayti. Others claim that the disease has always existed in Europe and the East. We know there was a violent outbreak of it in 1494 among the French soldiers besieging Naples.

Definition.—Syphilis is a chronic contagious, and sometimes hereditary, constitutional disease. It is one of the most common of diseases and were facts known would rank high as a cause of death. Lesser states that in Berlin, of men over twenty-five years of age who come to autopsy, 9 per cent. are syphilitic. In the United States it is twice as frequent among negroes as compared with whites, although in them the disease is apt to be more curable and less disastrous. It was long believed that only members of the human family could take syphilis, but Metchnikoff and Roux have succeeded in inoculating chimpanzees ("Annals of Pasteur Institute," Dec., 1903). These two observers have inoculated many animals and have shown that the nearer the animal is to man, the more nearly the disease resembles human syphilis. Anthropoid apes can be successfully inoculated, but only in the chimpanzee are human symptoms accurately produced. At first the causitive protozoöns are localized. Metchnikoff in 1906 inoculated a student and a monkey with syphilitic virus. An hour after inoculating the man the seat of inoculation was rubbed for five minutes with mercurial ointment and the man escaped syphilis. The ointment was not used on the monkey and a chancre developed. Its first lesion is an infecting area or chancre, which is followed by lymphatic enlargements, eruptions upon the skin and mucous membranes, affections of the appendages of the skin

(hair and nails), "chronic inflammation and infiltration of the cellulovascular tissue, bones, and periosteum" (White), and, later, often by gummata. The disease is due to a protozoön, the Spirochæta pallida. This fact was demonstrated by Schaudinn in 1905 (see page 55). The Spirochæta pallida is demonstrated in recent scrapings from specific lesions. The more contagious the lesion, the more of the organisms are found. The later the lesion, the fewer the organisms found. Spirochetes are always discoverable in the chancre. They can usually be found in the secondary lesions and sometimes in the blood during the secondary stage. Spirochetes are present in tertiary lesions, although in less number than in secondary lesions. The presence of a great number of spirochetes means a malignant case. They tend to disappear under mercurial treatment (see pp. 336 and 340). Syphilitic fever is due to absorption of toxins. Skin eruptions and eruptions on the mucous membranes in the secondary stage arise from local deposit and multiplication of the spirochetes. The spirochetes continue to exist in the body after the cessation of secondary symptoms, and may die out or may awaken into activity, producing *reminders*.

Up to about twelve days after the appearance of a chancre a person can still be infected by a fresh exposure to inoculation. After twelve days he cannot be unless inoculated with a very large amount of virus (Pinard). In other words, after twelve days there is immunity to fresh inoculation, but the immunity is not powerful enough to kill the spirochetes already in the body. During the primary stage, from the twelfth day after the appearance of the chancre, and during the secondary stage fresh poison cannot infect, and this is true for a long time after the disappearance of secondary symptoms. As a matter of fact, the immunity generally lasts for life and reinfection is one of the rarest of occurrences. Most supposed cases of reinfection were really instances of a fresh outbreak of an old disease, but a few undoubted cases of reinfection have been reported. Immunity in the primary stage is due to products absorbed from the infected area. Colles's immunity is that acquired by mothers who have borne syphilitic children, but who themselves show no sign of the disease. Profeta's immunity is the immunity against infection possessed by children born of syphilitic parents. Some of these children have never shown signs of disease, but nevertheless they are immune. It is claimed that a person long free from active syphilis, but still immune, can transmit immunity to his children. Tertiary syphilis is not nearly as readily transmissible as secondary syphilis, but it secures immunity.

Transmission of Syphilis.—This disease can be transmitted: (1) by contact with the virus—*acquired* syphilis, and (2) by hereditary transmission—*hereditary* syphilis. The poison cannot enter through an intact epidermis or epithelial layer, and abrasion or solution of continuity is requisite for infection. Syphilis is usually, but not always, a venereal disease. It may be caught by infection of the genitals during coition, by infection of the tongue or lips in kissing, by smoking poisoned pipes, by drinking out of infected vessels, or by beastly practices. Syphilis not due to sexual relations is called *syphilis of the innocent.* The barber is a danger, and cases are reported as following razor cuts and particularly the application of the alum stick to arrest bleeding. This stick is used over and over again and dried blood is often to be found upon it. I was consulted by a man who had been thus infected. I have treated two young girls infected by dentists' instruments, a policeman infected by a pipe, a glassblower infected from the blowpipe, a street car driver who got the disease from a borrowed whistle, a police officer who got it striking a prisoner on the mouth and cutting his own knuckle on the teeth, a hospital orderly who infected his nose picking it by a contaminated finger, and three physicians who caught it from

patients. Schamberg makes a valuable contribution to the accumulation of facts which demonstrates the danger of promiscuous osculations ("Jour. Am. Med. Assoc.," Sept. 2, 1911). A party of young men and women indulged in a kissing game. One of the young men had a sore lip. As a result of the party 6 men and 1 woman developed labial chancres. A girl kissed at another party by the contaminator of the first party got a chancre. The solitary male victim of the first party evidently got the disease by kissing a girl recently kissed by the syphilitic man. Bulkley (Ibid., March 4, 1905) collected 1863 cases following vaccination; 179 following circumcision; 82 following tattooing, and 745 following cupping or venesection. The initial lesion of syphilis may be found on the finger, penis, eyelid, lip, tongue, cheek, palate, tonsil, labium, vagina, anus, nipple, etc. A person may be a host for syphilis, carry it, give it to another, and yet escape it himself (a surgeon may carry it under his nails and a woman may have it lodged in her vagina). Syphilis can be transmitted by vaccination with human lymph which contains the pus of a syphilitic eruption or the blood of a syphilitic person. Vaccine lymph, even after passage through a person with pox, will not convey syphilis if it is free from blood and the pus of specific lesions; it is not the lymph that poisons, but some other substance which the lymph may carry. When syphilis is caught from one of a different race the disease is apt to run a peculiarly severe course. The apprehensions of the sailor regarding "Chinese pox" are probably well founded. John Knott says ("New York Med. Jour.," Oct. 31, 1908): "The Swan Alley sore of the days of Benjamin Travers was immeasurably more severe and more rapidly destructive in its progress than any average London chancre; for it was the fruit of the continuous patronizing culture of the foreign sailors and refugees who were derived from the veriest social and moral dregs of the population of all foreign countries."

Effect of Syphilis Upon Longevity.—This is a difficult matter to determine. Many deaths result from diseases caused by syphilis and yet they are not certified as due to syphilis. My own belief is that the mortality directly due to syphilis is very small indeed (except in cases of congenital syphilis), but that the mortality indirectly due to it is very large. I think that the life insurance companies are justified in requiring those who have had syphilis to pay higher premiums than those who have never had the disease.

Syphilis and Tuberculosis.—Syphilis and tuberculosis may coexist. The syphilis may be severe and the tuberculosis mild, or vice versâ. In some cases neither is severe and in some cases both are. As a rule, they have an unfavorable influence on each other. Tuberculosis is not very unusual in the course of secondary syphilis. It is apt to run a rapid course because of the patient's debility and worry and because of the treatment employed for the syphilis. Old syphilitics may develop tuberculosis, but do not seem particularly prone to do so. A child born syphilitic is very apt to become tuberculous, more apt even than is a child born of tuberculous parents. If a patient who is thought to be well of syphilis becomes tuberculous the syphilis may crop out again. If a tuberculous patient becomes syphilitic the tuberculosis usually gets worse. It is well known that syphilitic ulcers may become tuberculous. This sometimes occurs in the larynx. (See chapter on Syphilis in Bonney's treatise on "Pulmonary Tuberculosis").

Syphilitic Stages.—Syphilis was divided by Ricord into three stages: (1) The *primary* stage—chancre and indolent bubo; (2) the *secondary* stage—disease of the upper layer of the skin and mucous membranes; and (3) the *tertiary* stage—affections of connective tissues, bones, fibrous and serous membranes, and parenchymatous organs. This division, which is useful clinically, is still largely employed, but it is not so sharp and distinct as was believed by Ricord; it is only artificial. For instance, ozena may

develop during a secondary eruption, and bone disease may appear early in the case.

Syphilitic Periods.—White divides the pox into the following periods: (1) Period of *primary incubation*—the time between exposure and the appearance of the chancre, from ten to ninety days, the average being twenty-five days; (2) period of *primary symptoms*—chancre and bubo of adjacent lymph-glands; (3) period of *secondary incubation*—the time between the appearance of the chancre and the advent of secondary symptoms, about six weeks as a rule; (4) period of *secondary symptoms*—lasting from one to three years; (5) *intermediate* period—there may be no symptoms or there may be light symptoms which are less symmetrical and more general than those of the secondary period: it lasts from two to four years, and ends in recovery or tertiary syphilis; (6) period of *tertiary symptoms*—indefinite in duration. The fifth and sixth periods may never occur, the disease having been cured.

Primary Syphilis.—The primary stage comprises the chancre or infecting sore and bubo. A chancre or initial lesion is an infective granuloma resulting from the poison of syphilis and is most usually met with upon the genital organs. A chancre may be derived from the discharges of another chancre, from the secretion of mucous patches and moist papules, from syphilitic blood, or from the pus or secretion of any secondary lesion. Tertiary lesions seldom cause chancre. It appears at the point of inoculation (see page 316), and is the first lesion of the disease. During the three weeks or more requisite to develop a chancre the poison is continuously entering the system, and when the chancre develops the system already contains a large amount of poison. A chancre is not a local lesion from which syphilis springs, but is a local manifestation of an existing constitutional disease, hence excision is entirely useless. If twelve days or more after the appearance of a chancre we take some of the discharge and insert it at some indifferent point, into the person from whom we took it, a new indurated chancre will not be formed. This means that the subject has become immune to inoculation, but the immunity is not sufficiently powerful a factor to kill the spirochetes already in the body. When inoculation fails it means that the individual already has constitutional syphilis. If a syphilitic is inoculated with the discharge of a chancre twelve days or more after the chancre began, no indurated sore develops, but if the chancre furnishing the virus was *irritated*, a *non-indurated* sore may arise at the point of inoculation. If we take the discharge of a chancre and insert it into a healthy person, an indurated chancre follows. Hence we say that primary syphilis is not auto-inoculable, but is hetero-inoculable. A soft sore can be produced in the lower animals by inoculation with the virus of a chancre, but a hard sore cannot except in monkeys. Some observers, notably Kaposi, of Vienna, advocate the *unity theory*. This theory maintains that both hard and soft sores are due to the same virus, the infective power of the soft chancre simply being less than that of the hard sore, the possibillty of constitutional infection depending, not upon differences in the poison, but rather upon differences in the soil and in the local processes. The unicists advocate excision of chancres, soft or hard, to prevent, if possible, constitutional involvement. Most syphilographers believe in the *duality theory*, which we have previously set forth. This theory took origin from the classical investigations of Bassereau and Rollet. The duality theory maintains that the soft sore is caused by a poison different from the one which originates the hard sore, and that a true soft sore never infects the system. The discovery of the micro-organism causing syphilis proves the dualists to be correct.

Initial Lesions.—An initial lesion, hard chancre, or infecting sore never appears until at least ten days after exposure; it may not appear for many weeks, but it usually arises in about twenty-five days. There are three

chief forms of initial lesion: (1) A purple patch exposed by peeling epidermis, without induration and ulceration—a rare form; (2) an indurated area under the epidermis, without ulceration—a very common form; and (3) a round, indurated, cartilaginous area with an elevated edge, which ulcerates, exposing a velvety surface looking like raw ham; it bleeds easily, rarely suppurates, does not spread, and the discharge is thin and watery. This is the *Hunterian chancre*, which is rarer than the second variety, but commoner than the first, and which ulcerates because of dirt, caustic applications, or friction.

A chancre is rarely multiple, but if it is so, all the sores usually appear together as a result of the primary inoculation; they seldom follow one another because of auto-infection, although during the first twelve days such a result is possible. A hard sore does not suppurate unless irritated by caustics, friction, or dirt, or unless there be mixed infection with chancroid; its nature is not to suppurate. The hardness may affect only the base and margins of an ulcer or it may affect considerable areas, but it has well-defined margins and feels like cartilage encapsuled, so that it can be picked up between the fingers. This hardness or sclerosis is due to gradual inflammatory exudation into "the tissue at the base of the ulcer and to growth of the nodule" (von Zeissl). It feels distinct from the surrounding tissues, like a foreign body lying in the part. A chancre untreated may last many months. The induration usually disappears soon after the appearance of secondary symptoms. A copper-colored spot remains, and does not disappear until the disease is cured. Induration may again appear before the outbreak of some distant lesion.

Mixed Infection of Chancre and Chancroid.—Von Zeissl says: "If syphilitic contagion is mixed with pus, a chancre begins as a circumscribed area of hyperemia and swelling, which undergoes ulceration, and does not develop hardness for a period of from ten days to several weeks, and may develop a nodule after the first ulcer has entirely healed." This condition is seen when mixed infection occurs, the chancroid poison being quick, and the syphilitic poison being slow, to act. If chancroid poison is deposited some time after the syphilitic poison has been absorbed, the induration may appear in a few days after the chancroid begins. A soft chancre may arise upon an existing syphilitic nodule and may eat out the induration.

Diagnosis of Chancre.—It is necessary to distinguish a chancre from a chancroid and from ulcerated herpes. A chancroid appears in from two to five days after contagion (always less than ten days); it may be multiple from the start, but, even if beginning as one sore, other sores appear by auto-inoculation; it begins as a pustule, which bursts and exposes an ulcer; the ulcer is circular, has thin, sharp-cut, or undermined edges, a sloughy, non-granulating base, and gives origin to a thin, purulent, offensive discharge which is both auto- and hetero-inoculable. These soft sores have no true sclerotic area, do not bleed, produce no constitutional symptoms, and are apt to be followed by acute inflammatory buboes which tend to suppurate. A chancroid causes pain, and the original ulcer enlarges greatly. A chancre appears in about twenty-five days after inoculation (never before ten days); it is generally single, but if multiple sores exist they usually all appear together, for their discharge is not auto-inoculable after the twelfth day if the sore is not irritated; an auto-inoculation of the products of an irritated chancre may produce a soft purulent ulcer. A chancre begins as a desquamating area, an excoriation, or a nodule; if an ulcer forms, its floor is covered with granulations and it is red and smooth; the discharge is thin and scanty and not offensive; the edges are thick and sloping; it is surrounded by an area of induration, and bleeds when touched; there appear about the same time with the induration or very soon after it indolent multiple, unfused enlargements of the adjacent glands, which rarely

occurs, give tonics, stimulants, and concentrated foods. Complications are treated according to general rules.

Burns and Scalds of the Tongue, Pharynx, Glottis, and Epiglottis.—A child or lunatic may drink boiling fluid or inhale steam from a tea-kettle. Firemen occasionally suffer from scalds of the tongue and pharynx after being suddenly enveloped in a cloud of hot steam, and from burns by the inhalation of hot vapor or flame. Caustic may be taken into the mouth or swallowed. The tongue and pharyngeal mucous membrane swell greatly, large vesicles form, there are shock, severe pain, dysphagia, and dyspnea. Edema of the glottis may arise.

Treatment.—Combat shock; give morphin for pain; puncture vesicles, and have the patient almost constantly suck bits of ice. If great swelling occurs, make multiple longitudinal incisions through the mucous membrane of the dorsum of the tongue. If edema of the glottis begins, scarify it. If this fails, perform intubation or tracheotomy.

Burns of the Esophagus.—The esophagus is seldom scalded, as a boiling fluid rarely gets below the pharynx. The swallowing of an acid or alkali produces severe burns at the constricted portions of the gullet (see page 933). Such an accident produces shock, dyspnea, violent pain, vomiting of blood, and thirst. Death may occur from shock or perforation of the stomach. In many cases severe gastritis follows a burn of the esophagus. As the acute symptoms of a burn of the gullet gradually abate, sloughs are cast off, ulcers form, cicatrization begins, and the signs of stricture develop (see page 933).

Treatment.—Give a remedy to neutralize the caustic. Administer several large drafts of water and wash out the stomach. Combat shock. Give morphin for pain. Feed by the rectum as long as the patient's strength does not begin to fail. On beginning mouth-feeding, use at first milk and then beef-juice, jelly, and ice-cream. In from two to four weeks after the infliction of the burn begin the use of bougies to limit contraction.

Effects of Cold.—*Local Effects.*—Cold produces numbness, pricking, a feeling of weight, redness of the surface followed by stiffness, local insensibility, and mottling or pallor. Sudden intense cold causes the formation of blebs, the coagulation of blood in the superficial veins, and violent pain in the part. Cold locally produces frost-bite (see page 177).

The *constitutional effects* of cold are at first stimulating, then depressing, and are exhibited by uneasiness, pain, and an intense drowsiness which, if yielded to, is the road to death by way of internal congestion. Death from prolonged cold resembles in appearance death from apoplexy. Death from sudden and overwhelming cold is caused by anemia of the brain from weak circulation and capillary embolism. To bring a partly frozen person into a warm room may cause death by embolism.

Treatment.—Frost-bite is treated as outlined on page 177. When a person is nearly frozen to death place him in a *cool* room, but under no circumstance in a cold bath; make artificial respiration, rub him briskly with flannel soaked in alcohol or in whisky, and follow this by rubbing by dry hands. After a time wrap the patient in warm blankets and give an enema of brandy. Mustard-plasters are to be applied over the heart and spine. As soon as swallowing is possible, brandy is administered by the mouth. As the condition improves gradually raise the temperature of the room and give *hot* drinks.

Chilblain or **pernio** is a secondary effect of cold. It is really an area of local asphyxia (see page 173). It usually appears as a local congestion upon the toes, the ears, the fingers, or the nose, and now and then inflames and ulcerates. A chilblain is apt to become congested on the victim approaching a fire

or on taking exercise, and when congested it itches, tingles, and stings. Frequent attacks of congestion produce crops of vesicles; these vesicles rupture and expose ulcers, which in rare instances slough.

Treatment.—If chilblain affects the toes, prevent congestion of the legs and feet. Order large shoes and woolen stockings and forbid tight garters. The patient with pernio must take regular outdoor exercise and must not loiter around a hot fire. Every morning and evening he should take a general cold sponge-bath, followed by rubbing with alcohol and friction by a coarse towel, and in winter he should sleep wearing warm stockings or with his feet upon a warm-water bag. When a chilblain is only a congested spot, it should be washed twice a day in cold salt water, rubbed dry with flannel, and subjected to applications of tincture of iodin and soap liniment (1 : 2), tincture of cantharides and soap liniment (1 : 6), or equal parts of turpentine and olive oil (W. H. A. Jacobson). Jacobson says itching is relieved by painting belladonna liniment upon the part and allowing it to dry. Tincture of iodin may relieve it, and so may a mustard foot-bath. A valuable preparation for itching is composed of 1 dr. of powdered camphor and 4 oz. of cosmolin. A little of this ointment is rubbed in twice a day. The following prescription, the source of which I do not remember, is very valuable for itching: 1 dr. of powdered camphor, 1½ dr. of ichthyol, ½ dr. of lanolin, and 4 oz. of cosmolin, rubbed into the part and covered with cotton-wool. If vesicles form, paint with contractile collodion; if ulcers form, dress antiseptically. If ulcers are sluggish, use equal parts of resin cerate and spirits of turpentine. A good antiseptic and protective is the following: oxid of zinc, 6 gr.; chlorid of zinc, 20 gr.; gelatin, 2 oz.; distilled water, 1 oz.

XVII. SYPHILIS, OR POX

The name comes from the title of a poem which was published in Italy in 1530, "Syphilis sive Morbus Gallicus," by Hieronymus Fracastorius. For centuries there has been fierce dispute as to the origin of syphilis. Many assert that Europe was free of it until the discovery of America and that the sailors of Columbus brought it from Hayti. Others claim that the disease has always existed in Europe and the East. We know there was a violent outbreak of it in 1494 among the French soldiers besieging Naples.

Definition.—Syphilis is a chronic contagious, and sometimes hereditary, constitutional disease. It is one of the most common of diseases and were facts known would rank high as a cause of death. Lesser states that in Berlin, of men over twenty-five years of age who come to autopsy, 9 per cent. are syphilitic. In the United States it is twice as frequent among negroes as compared with whites, although in them the disease is apt to be more curable and less disastrous. It was long believed that only members of the human family could take syphilis, but Metchnikoff and Roux have succeeded in inoculating chimpanzees ("Annals of Pasteur Institute," Dec., 1903). These two observers have inoculated many animals and have shown that the nearer the animal is to man, the more nearly the disease resembles human syphilis. Anthropoid apes can be successfully inoculated, but only in the chimpanzee are human symptoms accurately produced. At first the causitive protozoöns are localized. Metchnikoff in 1906 inoculated a student and a monkey with syphilitic virus. An hour after inoculating the man the seat of inoculation was rubbed for five minutes with mercurial ointment and the man escaped syphilis. The ointment was not used on the monkey and a chancre developed. Its first lesion is an infecting area or chancre, which is followed by lymphatic enlargements, eruptions upon the skin and mucous membranes, affections of the appendages of the skin

(hair and nails), "chronic inflammation and infiltration of the cellulovascular tissue, bones, and periosteum" (White), and, later, often by gummata. The disease is due to a protozoön, the Spirochæta pallida. This fact was demonstrated by Schaudinn in 1905 (see page 55). The Spirochæta pallida is demonstrated in recent scrapings from specific lesions. The more contagious the lesion, the more of the organisms are found. The later the lesion, the fewer the organisms found. Spirochetes are always discoverable in the chancre. They can usually be found in the secondary lesions and sometimes in the blood during the secondary stage. Spirochetes are present in tertiary lesions, although in less number than in secondary lesions. The presence of a great number of spirochetes means a malignant case. They tend to disappear under mercurial treatment (see pp. 336 and 340). Syphilitic fever is due to absorption of toxins. Skin eruptions and eruptions on the mucous membranes in the secondary stage arise from local deposit and multiplication of the spirochetes. The spirochetes continue to exist in the body after the cessation of secondary symptoms, and may die out or may awaken into activity, producing *reminders*.

Up to about twelve days after the appearance of a chancre a person can still be infected by a fresh exposure to inoculation. After twelve days he cannot be unless inoculated with a very large amount of virus (Pinard). In other words, after twelve days there is immunity to fresh inoculation, but the immunity is not powerful enough to kill the spirochetes already in the body. During the primary stage, from the twelfth day after the appearance of the chancre, and during the secondary stage fresh poison cannot infect, and this is true for a long time after the disappearance of secondary symptoms. As a matter of fact, the immunity generally lasts for life and reinfection is one of the rarest of occurrences. Most supposed cases of reinfection were really instances of a fresh outbreak of an old disease, but a few undoubted cases of reinfection have been reported. Immunity in the primary stage is due to products absorbed from the infected area. Colles's immunity is that acquired by mothers who have borne syphilitic children, but who themselves show no sign of the disease. Profeta's immunity is the immunity against infection possessed by children born of syphilitic parents. Some of these children have never shown signs of disease, but nevertheless they are immune. It is claimed that a person long free from active syphilis, but still immune, can transmit immunity to his children. Tertiary syphilis is not nearly as readily transmissible as secondary syphilis, but it secures immunity.

Transmission of Syphilis.—This disease can be transmitted: (1) by contact with the virus—*acquired* syphilis, and (2) by hereditary transmission—*hereditary* syphilis. The poison cannot enter through an intact epidermis or epithelial layer, and abrasion or solution of continuity is requisite for infection. Syphilis is usually, but not always, a venereal disease. This stick is used over and over again and dried blood is often to be found upon it. I was consulted by a man who had been thus infected. I have treated two young girls infected by dentists' instruments, a policeman infected by a pipe, a glassblower infected from the blowpipe, a street car driver who got the disease from a borrowed whistle, a police officer who got it striking a prisoner on the mouth and cutting his own knuckle on the teeth, a hospital orderly who infected his nose picking it by a contaminated finger, and three physicians who caught it from

patients. Schamberg makes a valuable contribution to the accumulation of facts which demonstrates the danger of promiscuous osculations ("Jour. Am. Med. Assoc.," Sept. 2, 1911). A party of young men and women indulged in a kissing game. One of the young men had a sore lip. As a result of the party 6 men and 1 woman developed labial chancres. A girl kissed at another party by the contaminator of the first party got a chancre. The solitary male victim of the first party evidently got the disease by kissing a girl recently kissed by the syphilitic man. Bulkley (Ibid., March 4, 1905) collected 1863 cases following vaccination; 179 following circumcision; 82 following tattooing, and 745 following cupping or venesection. The initial lesion of syphilis may be found on the finger, penis, eyelid, lip, tongue, cheek, palate, tonsil, labium, vagina, anus, nipple, etc. A person may be a host for syphilis, carry it, give it to another, and yet escape it himself (a surgeon may carry it under his nails and a woman may have it lodged in her vagina). Syphilis can be transmitted by vaccination with human lymph which contains the pus of a syphilitic eruption or the blood of a syphilitic person. Vaccine lymph, even after passage through a person with pox, will not convey syphilis if it is free from blood and the pus of specific lesions; it is not the lymph that poisons, but some other substance which the lymph may carry. When syphilis is caught from one of a different race the disease is apt to run a peculiarly severe course. The apprehensions of the sailor regarding "Chinese pox" are probably well founded. John Knott says ("New York Med. Jour.," Oct. 31, 1908): "The Swan Alley sore of the days of Benjamin Travers was immeasurably more severe and more rapidly destructive in its progress than any average London chancre; for it was the fruit of the continuous patronizing culture of the foreign sailors and refugees who were derived from the veriest social and moral dregs of the population of all foreign countries."

Effect of Syphilis Upon Longevity.—This is a difficult matter to determine. Many deaths result from diseases caused by syphilis and yet they are not certified as due to syphilis. My own belief is that the mortality directly due to syphilis is very small indeed (except in cases of congenital syphilis), but that the mortality indirectly due to it is very large. I think that the life insurance companies are justified in requiring those who have had syphilis to pay higher premiums than those who have never had the disease.

Syphilis and Tuberculosis.—Syphilis and tuberculosis may coexist. The syphilis may be severe and the tuberculosis mild, or vice versâ. In some cases neither is severe and in some cases both are. As a rule, they have an unfavorable influence on each other. Tuberculosis is not very unusual in the course of secondary syphilis. It is apt to run a rapid course because of the patient's debility and worry and because of the treatment employed for the syphilis. Old syphilitics may develop tuberculosis, but do not seem particularly prone to do so. A child born syphilitic is very apt to become tuberculous, more apt even than is a child born of tuberculous parents. If a patient who is thought to be well of syphilis becomes tuberculous the syphilis may crop out again. If a tuberculous patient becomes syphilitic the tuberculosis usually gets worse. It is well known that syphilitic ulcers may become tuberculous. This sometimes occurs in the larynx. (See chapter on Syphilis in Bonney's treatise on "Pulmonary Tuberculosis").

Syphilitic Stages.—Syphilis was divided by Ricord into three stages: (1) The *primary* stage—chancre and indolent bubo; (2) the *secondary* stage —disease of the upper layer of the skin and mucous membranes; and (3) the *tertiary* stage—affections of connective tissues, bones, fibrous and serous membranes, and parenchymatous organs. This division, which is useful clinically, is still largely employed, but it is not so sharp and distinct as was believed by Ricord; it is only artificial. For instance, ozena may

develop during a secondary eruption, and bone disease may appear early in the case.

Syphilitic Periods.—White divides the pox into the following periods: (1) Period of *primary incubation*—the time between exposure and the appearance of the chancre, from ten to ninety days, the average being twenty-five days; (2) period of *primary symptoms*—chancre and bubo of adjacent lymph-glands; (3) period of *secondary incubation*—the time between the appearance of the chancre and the advent of secondary symptoms, about six weeks as a rule; (4) period of *secondary symptoms*—lasting from one to three years; (5) *intermediate* period—there may be no symptoms or there may be light symptoms which are less symmetrical and more general than those of the secondary period: it lasts from two to four years, and ends in recovery or tertiary syphilis; (6) period of *tertiary symptoms*—indefinite in duration. The fifth and sixth periods may never occur, the disease having been cured.

Primary Syphilis.—The primary stage comprises the chancre or infecting sore and bubo. A chancre or initial lesion is an infective granuloma resulting from the poison of syphilis and is most usually met with upon the genital organs. A chancre may be derived from the discharges of another chancre, from the secretion of mucous patches and moist papules, from syphilitic blood, or from the pus or secretion of any secondary lesion. Tertiary lesions seldom cause chancre. It appears at the point of inoculation (see page 316), and is the first lesion of the disease. During the three weeks or more requisite to develop a chancre the poison is continuously entering the system, and when the chancre develops the system already contains a large amount of poison. A chancre is not a local lesion from which syphilis springs, but is a local manifestation of an existing constitutional disease, hence excision is entirely useless. If twelve days or more after the appearance of a chancre we take some of the discharge and insert it at some indifferent point, into the person from whom we took it, a new indurated chancre will not be formed. This means that the subject has become immune to inoculation, but the immunity is not sufficiently powerful a factor to kill the spirochetes already in the body. When inoculation fails it means that the individual already has constitutional syphilis. If a syphilitic is inoculated with the discharge of a chancre twelve days or more after the chancre began, no indurated sore develops, but if the chancre furnishing the virus was *irritated*, a *non-indurated* sore may arise at the point of inoculation. If we take the discharge of a chancre and insert it into a healthy person, an indurated chancre follows. Hence we say that primary syphilis is not auto-inoculable, but is hetero-inoculable. A soft sore can be produced in the lower animals by inoculation with the virus of a chancre, but a hard sore cannot except in monkeys. Some observers, notably Kaposi, of Vienna, advocate the *unity theory*. This theory maintains that both hard and soft sores are due to the same virus, the infective power of the soft chancre simply being less than that of the hard sore, the possibillty of constitutional infection depending, not upon differences in the poison, but rather upon differences in the soil and in the local processes. The unicists advocate excision of chancres, soft or hard, to prevent, if possible, constitutional involvement. Most syphilographers believe in the *duality theory*, which we have previously set forth. This theory took origin from the classical investigations of Bassereau and Rollet. The duality theory maintains that the soft sore is caused by a poison different from the one which originates the hard sore, and that a true soft sore never infects the system. The discovery of the micro-organism causing syphilis proves the dualists to be correct.

Initial Lesions.—An initial lesion, hard chancre, or infecting sore never appears until at least ten days after exposure; it may not appear for many weeks, but it usually arises in about twenty-five days. There are three

chief forms of initial lesion: (1) A purple patch exposed by peeling epidermis, without induration and ulceration—a rare form; (2) an indurated area under the epidermis, without ulceration—a very common form; and (3) a round, indurated, cartilaginous area with an elevated edge, which ulcerates, exposing a velvety surface looking like raw ham; it bleeds easily, rarely suppurates, does not spread, and the discharge is thin and watery. This is the *Hunterian chancre*, which is rarer than the second variety, but commoner than the first, and which ulcerates because of dirt, caustic applications, or friction.

A chancre is rarely multiple, but if it is so, all the sores usually appear together as a result of the primary inoculation; they seldom follow one another because of auto-infection, although during the first twelve days such a result is possible. A hard sore does not suppurate unless irritated by caustics, friction, or dirt, or unless there be mixed infection with chancroid; its nature is not to suppurate. The hardness may affect only the base and margins of an ulcer or it may affect considerable areas, but it has well-defined margins and feels like cartilage encapsuled, so that it can be picked up between the fingers. This hardness or sclerosis is due to gradual inflammatory exudation into "the tissue at the base of the ulcer and to growth of the nodule" (von Zeissl). It feels distinct from the surrounding tissues, like a foreign body lying in the part. A chancre untreated may last many months. The induration usually disappears soon after the appearance of secondary symptoms. A copper-colored spot remains, and does not disappear until the disease is cured. Induration may again appear before the outbreak of some distant lesion.

Mixed Infection of Chancre and Chancroid.—Von Zeissl says: "If syphilitic contagion is mixed with pus, a chancre begins as a circumscribed area of hyperemia and swelling, which undergoes ulceration, and does not develop hardness for a period of from ten days to several weeks, and may develop a nodule after the first ulcer has entirely healed." This condition is seen when mixed infection occurs, the chancroid poison being quick, and the syphilitic poison being slow, to act. If chancroid poison is deposited some time after the syphilitic poison has been absorbed, the induration may appear in a few days after the chancroid begins. A soft chancre may arise upon an existing syphilitic nodule and may eat out the induration.

Diagnosis of Chancre.—It is necessary to distinguish a chancre from a chancroid and from ulcerated herpes. A chancroid appears in from two to five days after contagion (always less than ten days); it may be multiple from the start, but, even if beginning as one sore, other sores appear by auto-inoculation; it begins as a pustule, which bursts and exposes an ulcer; the ulcer is circular, has thin, sharp-cut, or undermined edges, a sloughy, non-granulating base, and gives origin to a thin, purulent, offensive discharge which is both auto- and hetero-inoculable. These soft sores have no true sclerotic area, do not bleed, produce no constitutional symptoms, and are apt to be followed by acute inflammatory buboes which tend to suppurate. A chancroid causes pain, and the original ulcer enlarges greatly. A chancre appears in about twenty-five days after inoculation (never before ten days); it is generally single, but if multiple sores exist they usually all appear together, for their discharge is not auto-inoculable after the twelfth day if the sore is not irritated; an auto-inoculation of the products of an irritated chancre may produce a soft purulent ulcer. A chancre begins as a desquamating area, an excoriation, or a nodule; if an ulcer forms, its floor is covered with granulations and it is red and smooth; the discharge is thin and scanty and not offensive; the edges are thick and sloping; it is surrounded by an area of induration, and bleeds when touched; there appear about the same time with the induration or very soon after it indolent multiple, unfused enlargements of the adjacent glands, which rarely

suppurate, and it is followed by secondary symptoms. A chancre causes little pain, and after it has existed for a few days rarely shows any tendency to spread. For the first few days after the appearance of a chancre the Wassermann reaction is negative, then, in nearly three-fourths of the cases, it becomes positive. There is, however, dispute as to the value of the reaction in the diagnosis of primary syphilis. Finding the Spirochæta pallida in scrapings from or the discharge of the sore is proof that the lesion is a chancre. A urethral chancre appears after the usual period of incubation; it is situated near the meatus, one lip of which is usually indurated; the discharge is slight, often bloody, seldom purulent; indurated multiple buboes arise; the sore can be seen, and constitutional symptoms follow.

Herpetic ulceration has no period of incubation; it may follow fever, but usually arises from friction or irritation due to dirt or acrid discharges. It appears as a group of vesicles, all of which may dry up, or some may dry up and others ulcerate, or they may run together and ulcerate. The edges of a herpetic ulcer are in segments of circles; the ulcer is superficial, has but little discharge, and does not have much tendency to spread; it has no induration; it is painful; it is not accompanied by bubo unless suppuration is marked. Herpes is not followed by constitutional involvement.

A chancre may be mistaken for cancer of the tongue. "A chancre of this region is brownish red, a cancer being bright red. A chancre is soft in the center; a cancer presents uniformity of induration. A chancre gives origin to a thin, purulent discharge, free from blood; a cancer furnishes a non-purulent, bloody discharge. A chancre is soon followed by indolent lymphatic enlargements under the jaw; a cancer is followed by painful enlargements." A cancer is slower in evolution, is not followed by constitutional symptoms, and the lymphatic enlargements are much later in appearing than in chancre.

Phagedena.—A chancre or a chancroid may be attacked by phagedena, a destructive form of ulceration which was once common, but at present is rare. The ulceration often spreads on all sides and also deeply into the tissues. In some cases it spreads at the edge in one direction (*serpiginous ulceration*), in some cases sloughing occurs. Phagedena occurs only in the debilitated (anemics, drunkards, strumous subjects, sufferers from diabetes, Bright's disease, etc.; salivation can cause it). The phagedenic ulcer is irregular, with congested and edematous edges, and a foul, sloughy floor.

Chancre Redux.—Some observers believe that reinfection with syphilis is not very unusual. Most authorities maintain that it is very rare. The latter school maintains that the region once occupied by a chancre may, after months or several or even many years, become indurated anew. Occasionally such a relapse occurs during full treatment. Fournier pointed out this fact thirty years ago. Such a reinduration is called *chancre redux*, or relapsing chancre.

If syphilitic manifestations follow such an induration, we must conclude that reinfection has truly occurred. If they do not follow, and this is the rule, the lesion is not really a chancre, but is probably a gumma in an early stage of development. Mauriac pointed out this last fact.[1]

In **syphilitic bubo** anatomically related lymphatic glands enlarge about the same time as or at least very soon after induration of the initial lesion begins. In the very beginning these glands may be a little painful, but the pain is slight and of temporary duration. These enlargements are called "indolent buboes"; they may be as small as peas or as large as walnuts, are freely movable, and very rarely suppurate. The lesion of the glands is hyperplasia of all the gland-elements and of their capsules, due to absorption of the virus. If the patient is tuberculous, the bubo is apt to become enormous,

[1] Mracek, in "Wien. klin. Rundschau," 1896; H. G. Antony, in "Chicago Medical Recorder," April, 1899.

lobulated, and persistent. If the chancre appears on the penis, the superficial inguinal and femoral glands enlarge, usually on the same side of the body as the sore. If the sore is on the frenum, both groins are involved. If a chancre appears on the lip or tongue, the bubo is beneath the jaw. These buboes may remain for many months; they do not break down unless the sore suppurates or unless the patient is of the tuberculous type; and they finally disappear by absorption or fatty degeneration. About six weeks after buboes have formed in the glands related to the lesion all the lymphatics of the body enlarge. General lymphatic involvement arises about the time the secondary eruption appears. The enlargement of the postcervical and epitrochlear glands is diagnostically important. Glandular enlargements persist until after the eruptions have disappeared.

Glandular enlargement always occurs in syphilis, but the bubo exists in only one-third of the chancroid cases. The bubo of syphilis is multiple, consisting of a chain of movable glands (the glandulæ Pleiades of Ricord); the bubo of chancroid is one inflamed and immovable mass. The bubo of syphilis is indurated, painless, small, and slow in growth; the bubo of chancroid shows inflammatory hardness, is painful, large, and rapid in growth; the first rarely suppurates, the second often does. The skin over a syphilitic bubo is normal; that over a chancroidal bubo may become red and adherent. A syphilitic bubo is not cured by local treatment, but is cured by the internal use of mercury and is followed by secondary symptoms. A chancroidal bubo requires local treatment, is not cured by mercury, and is not followed by secondaries. Herpes, balanitis, and gonorrhea rarely cause bubo, but when they do the bubo in each case is similar to that caused by chancroid. A positive diagnosis of syphilis can be made when an indurated sore on the penis is followed by multiple indolent buboes in the groin and by enlargement of distant glands.

General Syphilis.—As the general lymphatic enlargement becomes manifest a group of symptoms known as *syphilitic fever* may appear. In many mild cases, however, fever is absent and the eruption is the first sign of constitutional involvement. The patient usually thinks he has a severe cold, is feverish and restless; complains of headache, lassitude, sleeplessness, and anorexia; his face is pale; he has intermitting rheumatoid pains in the joints and muscles, especially of the shoulders, arms, chest, and back, which pains change their location constantly and prevent sleep; night-sweats occur, and the pulse is quite frequent. The fever usually reaches its height in forty-eight hours, and falls as the eruption develops. The eruption develops usually in from forty-eight to seventy-two hours after the onset of the fever, but may not do so for one week or even more. The fever and the discomfort are worse at night. In type the fever may be intermittent, remittent, or continued. It is usually intermittent. There may or may not be chills, and chills may occur every day or irregularly. Prolonged syphilitic fever with delay in the appearance of the eruption gives rise sometimes to great errors in diagnosis. Prolonged and irregular fever is apt to arise in visceral syphilis, especially syphilis of the liver. In syphilitic fever there are anemia, trivial leukocytosis, and a marked fall in hemoglobin. Syphilitic fever may reappear during the progress of the disease.

Secondary Syphilis.—The phenomena of secondary syphilis are due to poisoned blood. They are "local reactions against the spirochetes which have now become disseminated by the blood-stream" (H. G. Adamson, in the "Lancet," April 6, 1912). During untreated active secondary syphilis the Wassermann reaction is practically always positive. Scrapings from a lesion may show the causal organisms. Secondary syphilis is characterized by plastic inflammation, by the formation of fibrous tissue, and by thickening of tissue.

Superficial ulcerations may occur. Structural overgrowths appear (for instance, warts).

Syphilitic Skin Diseases.—*Syphilodermata* (*syphilids*) are due to circumscribed inflammation, and may be dry or purulent. There is no one eruption characteristic of syphilis. This disease may counterfeit any skin disease, but it is an imitation which is not perfect and is never a counterpart. Syphilitic eruptions are often circumscribed; they terminate suddenly at their edges, and do not gradually shade into the sound skin. In color they are apt to be brownish red, like tarnished copper; especially is this the case in late syphilids. Hutchinson cautions us to remember that an ordinary non-specific eruption may be copper colored, especially in people with dark complexions and when it occurs on the legs. Eruptions are apt to leave a brownish stain. Early syphilitic eruptions are symmetrical. Syphilitic eruptions have an affection for particular regions, such as the forehead, the abdomen and chest, the neck and scalp, about the lips and the alæ of the nose, the navel, anus, groins, between the toes, and upon the palms and soles. Early secondary eruptions rarely appear on the face or hands. Specific eruptions are polymorphous, various forms of eruption being often present at the same time, so that roseola is seen here, papules there, etc. These syphilids do not cause as much itching as do non-specific eruptions, except when they occur upon the scalp, about the anus, or between the toes. The late secondary eruptions tend to an arrangement in curved lines.

Forms of Eruption.—The chief forms of eruption are: (1) erythema, (2) papular syphilids, (3) pustular syphilids, and (4) tubercular syphilids. Besides these eruptions pigmentation may occur (pigmentary syphilid), and blood may extravasate (purpuric syphilid).

Prince A. Morrow does not believe in erecting the vesicular syphilids into a special group. He tells us that vesicles sometimes form on erythemato-papular lesions, but their presence is an accident and not a regular phenomenon. So, too, the bullous syphilid is a rare accident in a case, and even when it occurs soon becomes pustular. The pemphigoid syphilid is found almost exclusively in hereditary disease.[1]

1. **Erythema** (*Maculæ, Roseola,* or *Spots*).—This eruption usually comes on gradually, crop after crop of spots appearing, and many days passing before an extensive area is covered. Occasionally, however, it arises suddenly (after a hot bath, after taking violent exercise, or after eating an indigestible meal). This eruption consists of circumscribed, irregularly round, hyperemic spots, about $\frac{1}{2}$ inch in diameter, whose color does not entirely disappear on pressure in an old eruption, but does in a recent one. The color is at first light pink, but it becomes red, purple, or even brown. In the papular form of erythema the spots are slightly elevated. Erythema is rare upon the face and the dorsum of the hands and feet. It attacks especially the chest and belly, but appears often on the forehead, the bend of the elbow, and the inner portion of the thigh, the neck, and the flexor surface of the forearms and arms. It appears first on the abdomen and last on the legs. Usually erythema follows syphilitic fever, about six weeks after the chancre appears, and the number and distinctness of the spots are in proportion to the violence of the fever. No fever or slight fever means there will be but few spots and they will soon disappear. In rare cases the eruption is very transitory, lasting but a few hours, but it usually continues for several weeks if untreated. It may pass away or may be converted into a papular eruption. Mercury will cause it to disappear in a couple of weeks. In examining for this form of eruption in a doubtful case, let cold air blow upon the chest and belly; this blanches the sound skin and makes clear any discoloration. No desquam-

[1] Morrow's "System of Genito-urinary Diseases, Syphilology, and Dermatology."

ation attends the macular eruption, but a brownish stain remains for a variable time after the eruption fades. Erythema means, as a rule, a mild and curable attack. Maculæ may be combined with the next form, constituting a maculopapular eruption.

The maculopapular syphilids are evolved from the macular syphilids. They are slightly elevated, are situated upon hyperemic bases, and the summits of some of them may undergo slight desquamation. A roseolar area may show one or several of these macular papules. They are apt to arrange themselves in segments of circles and are symmetrically distributed. This eruption usually appears early, but may appear late. It may fade and reappear several times in the same patient. The eruption lasts a few weeks.

Fig. 134.—Condylomata (Horwitz).

2. **Papular syphilids,** which are papules or elevations covered with dry skin, may or may not desquamate. If they do desquamate, the process begins over the center. They usually appear from the third to the sixth month of the disease. They may be preceded by fever, and often reappear again and again. They are at first small and red, but become larger and brownish. They are firm in feel and vary in size from the head of a pin to a five-cent piece or larger. Very large papules constitute nummular syphilids. They all tend to scale. The epiderm becomes thin, red, and glistening, splits in the center and desquamates, and a fringe of epidermis surrounds the desquamated area. This process may be repeated once or oftener. When lenticular papules recur in the late secondary stage they are apt to group themselves in circles limited to particular regions (annular or circinate syphiloderm). They may be present as miliary papules, lenticular papules, moist papules, and papules with marked epidermic proliferation resembling psoriasis (papulosquamous eruption). Papules on fading leave very persistent coppery-looking stains. Papules upon the palms and soles constitute the so-called "palmar and plantar *psoriasis*," which appears from three months to one year after the appearance of the chancre. Papules just below the line of the hair on the forehead constitute the *corona veneris*. Papular syphilids appear especially upon the forehead, the neck, the abdomen, and the extremities. The papular or squamous syphilid of the palms and soles begins as a red spot, which becomes elevated and brownish; the epidermis thickens and is cast off, and there then remains a central red spot surrounded by undermined skin. If papules are in regions where they are kept moist (as about the anus), they become covered with a sodden gray film, which after a time is cast off and leaves the papule without epidermis. The sodden papules are called *flat condylomata*, moist or humid papules or plates (Fig. 134). Papules which are at first small may become large. The small or miliary papules constitute *syphil-*

itic lichen. The lenticular papules are most common, and strongly tend to scale off. The papular syphilids give a worse prognosis for the constitutional disease than do spots. The syphilitic negro is particularly apt to develop the annular syphiloderm.

3. **Pustular syphilids** arise from papules. The condition is known as *acne* when the apex of the papule softens, *impetigo* when the whole papule suppurates, and *ecthyma* or *rupia* when the corium is also deeply involved. Vesicles occasionally precede pustules. The pustular eruption appears a number of months after infection and later than the papular. The pustular eruption gives a very bad prognosis for the constitutional disease. Rupia is formed by a pustule rupturing or a papule ulcerating, the secretion drying and forming a conical crust which continually increases in height and diameter, while the ulceration extends at the edges. When the crust is pulled off there is seen a foul ulcer with congested, jagged, and undermined edges. Rupia may be secondary or tertiary, and it invariably leaves scars. It appears only after at least six months have passed since the chancre began. Secondary rupia is symmetrical. Tertiary rupia is asymmetrical.

4. **Tubercular syphilids** are greatly enlarged papules intermediate between ordinary papules and gummata.

Diagnosis Between Secondary and Tertiary Syphilids.—A secondary eruption is distinguished from a tertiary eruption by the following: the first tends to disappear, the second tends to persist and to spread; the first is general and symmetrical, the second is local and asymmetrical; the first does not spread at its edge, the second tends to spread at its edge, and this tendency, which is designated *serpiginous*, produces an ulcer shaped like a horseshoe (Jonathan Hutchinson). Secondary lesions appear within certain limits of time, develop regularly, and are dispersed by mercurial treatment. Tertiary lesions appear at no fixed time, develop irregularly, and are not cleared up by mercury.

Affections of the Mucous Membranes.—The chief lesions in syphilitic affections of the mucous membranes are mucous patches, warts, and condylomata. The first phenomena of secondary syphilis are, as a rule, symmetrical ulcers of the tonsils, painless, of temporary duration, and superficial (Hutchinson). The borders of the ulcers are gray and the areas are reniform in shape. Catarrhal inflammations often occur. Eruptions appear on the mucous membranes as upon the skin. *Mucous patches* are papules deprived of epithelium; they are gray in color, are moist, and give off an offensive and virulent discharge. They usually appear as areas of congestion, swelling, and abrasion of the epidermis upon the lips, palate, gums, tongue, cheeks, vagina, labia, vulva, scrotum, anus, and under the prepuce. A moist papule of the skin is really a mucous patch. These patches, which are always circular or oval, are among the most constant lesions of the secondary stage, appearing from time to time during many months. If a patch has the papillæ destroyed, it is called a *bald patch.* If the papules present hypertrophied papillæ fused together, there appear enlargements with flat tops, termed *condylomata* (Fig. 134); if the papillæ of the papules hypertrophy and do not fuse, the growths are called *warts.* Mucous lesions of the mouth are commonest in smokers and in those with bad or neglected teeth. Hutchinson says that persistence in smoking during syphilis may cause leukomata, or persistent white patches. The vagina and lips of the vulva during the secondary stage are often covered with mucous patches. The uterus may contain mucous lesions which poison the uterine discharge. The larynx may suffer from inflammation, eruptions, and ulceration (hence the hoarse voice which is so usual). The nasal mucous membrane may also suffer. The rectal mucous membrane may be attacked by patches, and so may the glans penis, the inner surface of the prepuce,

and the urethra. Early in the secondary stage in some cases there is a slight mucopurulent urethral discharge, and examination with an endoscope shows redness of the mucous membrane of the anterior urethra. The discharge is contagious. The condition may be followed by constriction of the urethral caliber. Distinct ulceration may take place.

Affections of the Hair.—In syphilis the hair is usually shed to a great extent. This loss may be widespread (beard, mustache, hair of head, eyebrows, pubic hair, etc.) or it may be limited. Complete baldness sometimes ensues, but it is rarely permanent. The hairs of the head are first noticed to come out on the comb; on pulling them they are found loose in their sheaths—so loose that Ricord has said "a man would drown if a rescuer could pull only upon the hair of the head." The falling out of the hair, which is known as *alopecia*, usually begins soon after the fever or about the time of the eruption, but it may be postponed until much later. The skin of a syphilitic bald spot is never smooth, but is scaly. The hair may thin generally, baldness may appear in twisting lines, or it may be complete only in limited areas. Alopecia results from shrinking of the hair-pulp, death of the hair, and casting off of the sheath.

Affections of the Nails.—*Paronychia* is inflammation and ulceration of the skin in contact with a nail and extending to the matrix. The nail is cast off partially or entirely. *Onychia* is inflammation of the matrix, and is manifested by white spots, brittleness or extended opacity, twisting, and breaking off of the nail. The parts around are not affected. The damaged nail drops off and another diseased nail appears.

Affections of the Ear.—Temporary impairment of hearing in one or both ears is not uncommon in syphilitic affections of the ear. Rarely, permanent symmetrical deafness is produced. Ménière's disease is sometimes caused by syphilis.

Affections of the Bones and Joints.—In syphilis there may be slight and temporary periostitis. Pain and tenderness arise in various bones, the pain being worse at night (*osteocopic pains*). Osteoperiostitis usually arises with or after the onset of the secondary eruption, but in rare instances precedes the syphilids. The bones usually involved are the tibiæ, clavicles, and skull. Intense headache may be due to periostitis of the inner surface of a cranial bone. Local periostitis may form a *soft node*, which by ossification becomes a *hard node*. Pain like that of rheumatism may affect the joints. It is not increased by motion and is worse at night. Such pains are by no means uncommon and in some cases are very severe. The joints are not stiff except perhaps on rising. Paton reminds us that such arthralgia is an early symptom and may actually antedate the secondary eruption ("Brit. Med. Jour.," Nov. 28, 1903). More common than the above condition is synovitis, acute or chronic. It often comes on rapidly without other symptoms and is announced by swelling, tenderness, and pain. In some cases the pain is severe, and the patient is feverish or actually ill. Such cases constitute what is called *syphilitic rheumatism*, but the profuse sweats of acute rheumatism are absent, the heart is never attacked, the skin is not red, the fever is not high, and the condition is not migrating (Ibid.). Hydrarthrosis may arise in the knee as a sequence of either of the above conditions, or, late in the secondary stage, it may arise without such an antecedent trouble (Paton). Symmetrical synovitis has been noted. Secondary syphilitic disease of bone, periosteum, and joints lasts only a short time and is never destructive.

Affections of the Eye.—*Iritis* is the commonest eye trouble which may arise during secondary syphilis. It appears from three to six months after the chancre, and begins in one eye, the other eye soon becoming affected. The symptoms are a pink zone in the sclerotic, a congested, red or muddy iris, irregularity of the pupil accentuated by atropin, the existence of pain and photo-

phobia, and sometimes hazy or even clouded pupil. Rheumatic iritis causes much pain and photophobia, syphilitic iritis comparatively little; there is less swelling in the first than in the second; the former tends to recur, the latter does not. Iritis is usually recovered from, good vision being retained. Diffuse retinitis and disseminated choroiditis never occur until a number of months have passed since the infection. The symptoms are failure of sight, muscæ volitantes, and very little photophobia. The diagnosis of retinitis and choroiditis is made by the ophthalmoscope.

Affections of the Testes.—**Syphilitic Sarcocele.**—The testicle enlarges because of plastic inflammation. Both glands usually suffer, but not always. Fluid distends the tunica vaginalis. The epididymis escapes. The testicle is not the seat of pain, is troublesome because of its weight, and has very little of the proper sensation on squeezing. The plastic exudate is generally largely absorbed, but it may organize into fibrous tissue, the organ passing into atrophic cirrhosis.

Nervous System.—Syphilis of the nervous system may arise as early as the sixth month after infection, although the nervous system is far more apt to suffer in the intermediate period or in the tertiary stage. Actual deposits in the brain or cord do at times take place in the secondary stage. These deposits call for prompt and active treatment or they will cause permanent damage. Such lesions are particularly common in untreated cases and in cases in which secondary manifestations were slight or perhaps even unobserved.

The Albuminuria of Secondary Syphilis.—It is not very unusual for nephritis with albuminuria to develop early in the secondary stage. There may be the ordinary symptoms of nephritis, but in many cases there is albuminuria and nothing more. Large amounts of albumin run away from the kidneys and the high percentage of albumin in the urine is a notable feature. Many of these cases recover completely, some become chronic, and in some death occurs. It seems probable that mercurial treatment is, in part at least, responsible for some of these cases. The syphilitic poison causes the others. Those in which there is albuminuria and nothing more are due to syphilis rather than to mercury. Those in which there is dropsy are aggravated and perhaps caused by mercury (Fleissinger, in "Journal des Practicens," August 3, 1907).

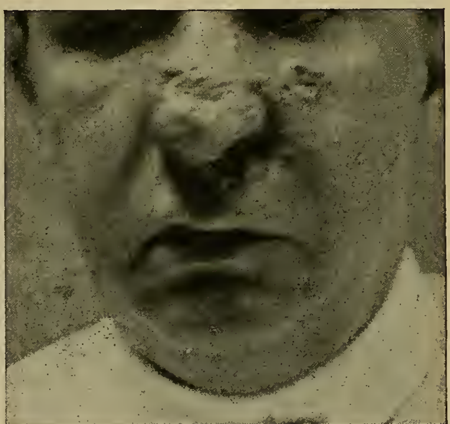


Fig. 135.—Serpiginous ulcers.

Intermediate Period.—Secondary lesions cease to appear in from eighteen months to three years. In the intermediate period no symptoms may appear, yet the disease may be still for some time latent and not cured. The Wassermann reaction may be negative. Symptoms may arise from time to time. These symptoms, which are called *reminders*, are not so severe as tertiary symptoms, are apt to be symmetrical, and do not closely resemble secondary lesions. Among the reminders we may name palmar psoriasis and sarcocele. Sarcocele in this stage is bilateral and rarely painful. Bilateral indolent epididymitis occasionally occurs. Sores on the tongue, a papular skin eruption, and choroiditis may arise. Gummata occasionally occur in this stage, but they are apt to be symmetrical and non-persistent. Sym-

metrical superficial dactylitis may occur. Arteritis may develop, beginning in the intima or adventitia, and causing, it may be, aneurysm, thrombosis, or embolism. Obliterative endarteritis may cause gangrene. Vascular changes are notably common in the vessels of the brain, and thrombosis may occur, in which case paralysis usually comes on gradually, preceded by numbness, although sudden paralysis may take place. The paralysis may be limited, extensive, transitory, or permanent. The nervous system often suffers in this stage (anesthetic areas and retinitis). The viscera are often congested and infiltrated (liver, spleen, kidneys, and lungs).

Tertiary Syphilis.—This stage is not often reached, the disease being cured before it has been attained. About 85 per cent. of syphilitics escape it entirely. In this stage there is greatly impaired nutrition the result of the prolonged disease. Until recently it was generally thought that tertiary lesions are not contagious. This statement is now known to be untrue. They are not nearly as contagious as the primary lesions, as secondary lesions, or as blood of the secondary stage, but they are contagious, though feebly so. A tertiary lesion contains spirochetes, but not nearly so many as a secondary lesion. The primary stage disappears without treatment, the secondary stage tends ultimately to spontaneous disappearance, but tertiary lesions tend to persist and to recur. Tertiary lesions may be single or may be widely scattered; when multiple they are not symmetrical except by accident. These lesions may attack any tissue, even after many years of apparent cure; they all tend to spread locally, they all leave permanent atrophy or thickening, they all tend to relapse, and a local influence is often an exciting cause. Tertiary syphilis may cause marked anemia and it is sometimes the cause of pernicious anemia (Dumas and Pirrot, in "La Presse Médicale," xv, Nos, 39 and 40).

Tertiary skin eruptions are liable to ulcerate. Various eruptions may occur: papular syphilids, pustular syphilids, gummatous syphilids, serpiginous syphilids, and pigmentary syphilids. The characteristic syphilid is *rupia*, which is formed by a pustule rupturing or a papule ulcerating. A brown or black crust forms because of the drying of the discharge, ulceration continues under the crust, new crusts form, and, as the ulcer is constantly increasing peripherally, the new crusts are larger in diameter than the old ones and the mass assumes the form of a cone. An ulcer which has destroyed the deeper layers of the skin is exposed by tearing off the crust. On healing, a rupial ulcer always leaves a permanent scar.

Serpiginous ulcers (Fig. 135) are common in tertiary syphilis, and are especially common about the knees, nostrils, forehead, and lips. Serpiginous ulceration is spoken of as *syphilitic lupus*. It is preceded by a widespread brown-colored nodular cutaneous infiltration. The nodules suppurate, run together, crust, and produce an ulcer which spreads rapidly and assumes the shape of a horseshoe.

The **gumma** (Fig. 136) is the typical tertiary lesion. In some cases there is a solitary gumma; in others, two or three or even many gummata. A gumma is a mass of granulation tissue, grayish-yellow in color, containing many cells and few fibers. Organization of the gumma fails to take place because of a want of sufficient blood-supply, the cellular mass is apt to undergo caseation, and when this occurs an ulcer forms. One portion of the mass may caseate, another portion may become fibrous. In some cases the entire gumma becomes fibrous. A gumma varies in diameter from $\frac{1}{8}$ inch to 2 or 3 inches, presents a center of gummy degeneration, a surrounding area of immature fibrous tissue, and an outer zone of embryonic tissue and leukocytes. A gumma, when it is spontaneously evacuated, exhibits a small opening or many openings with very thin red and undermined edges; the ulcer is slow to heal, and forms a thin scar, white in the center, but pig-

mented at the margins and usually depressed (Jonathan Hutchinson, Jr.). The *gummatous ulcer* is deep, circular in outline, with undermined edges and an uneven floor, which is usually covered with a thick, white, adherent slough. Sometimes there is no slough, but an extensive area is infiltrated. A gummatous

Fig. 136.—Gumma of the clavicle.

ulcer may coalesce with one or more adjacent ulcers. The discharge is scanty and tenacious. These ulcers are often seen upon the legs, and when once healed rarely recur. A gumma in the internal organs may become a fibrous mass. Gummata form in the skin, subcutaneous tissues, submucous structures, muscles, tongue, joints, bones, bursæ, testes, spinal cord, brain, and internal organs. In tertiary syphilis an inflammation may not form a circumscribed gumma, but, instead, may produce a diffuse degenerating mass. This type of inflammation, which is seen in bones, is called "gummatous." In the nasal cavity a gumma is rapidly followed by an ulcer and there is a strong tendency to necrosis of the vomer and sometimes of the turbinated bones. This condition produces a foul discharge and is known as syphilitic *ozena*. Advanced necrosis of the nasal bones causes the nose to "fall in," which is a hideous deformity (Fig. 137). The commonest laryngeal lesion is multiple ulceration following minute gummata. A healing gumma in a mucous canal such as the rectum or larynx causes thickening and stricture. Tertiary syphilis is a common cause of amyloid degeneration and the most frequent cause of arterial and nervous sclerosis.

Fig. 137.—Destruction of the nose in tertiary syphilis.

Various Lesions.—Hutchinson enumerates the lesions of tertiary syphilis as follows: *Periostitis*, forming nodes or causing sclerotic hypertrophy, suppuration, or necrosis; gummata in various parts; disease of the skin of the type of rupia or lupus; gumma or inflammation of the tongue, causing sclerosis;

structural changes in the nervous system, causing ataxia, ophthalmoplegia externa and interna, general paresis, optic atrophy, and paralyses of cerebral nerves; amyloid degenerations; and chronic inflammation of certain mucous membranes (of the mouth, pharynx, vagina, rectum, etc.), with thickening and ulceration. Gummatous infiltration of the eyelid is sometimes observed. Gummatous osteoperiostitis of the vertebræ may arise, and this may be associated with disease of the membranes or cord. Syphilitic inflammation of vertebræ is called syphilitic spondylitis. Unilateral enlargement of the epididymis is sometimes noted, the mass feeling heavy, aching a little, but not being very tender. Unilateral sarcocele may be met with. Gummata may arise in the iris, the larynx, the rectum, and the nose.

Tertiary Syphilis of Bones.—The bones particularly liable to disease are the skull, sternum, clavicle, nasal septum, and tibia. There may be productive periostitis. This arises in the deeper layer of the periosteum. It may be one limited area, several, or many areas; may be circumferential, or may involve the length of the shaft of a long bone. In most cases the bone is also involved (osteoperiostitis). The bone thickens under the periosteum or toward the medullary cavity, or in both directions. The cuticular spongy substance may be the seat of disease. The lesion may be small and circumscribed or extensive. The thick bone becomes dense (sclerosis). In protracted cases of bone overgrowth in a long bone, if growth occurs in the direction of the long axis, the bone will become bent. As a matter of fact, each of the above lesions is a gumma which undergoes resolution or organization. Syphilitic periostitis is a superficial gumma. Syphilitic osteitis is a deep gumma. Syphilitic osteomyelitis is a deep gumma which has not undergone resolution or organization. The bone about a deep gumma is thickened. There is usually but one gumma in a bone, but there may be two or several. A large gumma weakens bone so that fracture may take place from slight force. Caries or necrosis may arise. A sequestrum seldom forms unless there is mixed infection. Periostitis affects particularly the superficial bones (tibia, clavicle, sternum, ulna, etc.). It begins in the deeper layer of the periosteum, swelling arises, gummy changes occur, and the bone beneath is more or less destroyed. In the skull the bone may be completely penetrated. Not unusually syphilitic periostitis arises at the seat of a trivial injury. Syphilitic osteomyelitis occurs particularly in the phalanges and skull. An area of syphilitic bone disease may undergo repair, osteosclerosis usually and osteoporosis sometimes resulting. After perforation of the skull there is no bony repair. Syphilis of the bones of the nose is necrosis resulting from gummatous ulceration. The *x*-ray picture is usually most valuable in reaching a diagnosis of tertiary syphilis of bone. A syphilitic lesion, if visible, usually has a distinct outline. A pure periosteal mass may not show at all. The bone lesion shows the deep shadow of thickening throughout or, as in the gumma, thickening around a much lighter region. Tuberculosis produces absorption of bone and light areas in the plate. Sarcoma of the periosteum always shows. Sarcoma has not a distinct margin like syphilis.

Tertiary Dactylitis (Fig. 138).—This condition is a gummatous formation in a finger or toe. There is a superficial form in which the deposit begins in the subcutaneous tissue and subsequently involves the joint ligaments. In a toe the entire digit is usually involved, in a finger the condition is usually limited to the proximal phalanx. Superficial dactylitis is a very early tertiary phenomenon. A painless swelling gradually forms and it is most distinct on the dorsal surface. The swelling becomes purplish or reddish-blue in color and the joint becomes preternaturally mobile. The swelling may ulcerate.

Deep dactylitis is a very late tertiary manifestation and is osteomyelitis or periostitis of the fingers or perhaps of the toes. One or more proximal pha-

langes are apt to suffer. The skin seldom suffers. Caries and necrosis may occur and the joint may be destroyed, or the bone may be partially absorbed and shortened from dry caries. Ulceration of the skin is rare.

Tertiary Syphilis of Joints.—(See the careful study of E. Percy Paton, in "Brit. Med. Jour.," Nov. 28, 1903.) The knee-joint is most commonly affected. Chronic synovitis may arise with considerable or even great swelling (hydrarthrosis), trivial pain, slight functional impairment, some thickening of synovial membrane, and some harshness or grating on movement. Gummatous synovitis may arise, a condition which sometimes follows the ordinary synovitis, but more often exhibits very little swelling. The synovial membrane exhibits irregular areas of thickening and the symptoms resemble those of a tuberculous joint (Paton).

In some syphilitic joints the disease begins in the bone and cartilage. In such a condition there is rigidity, marked limitation of movement, pains, not often severe, and some deformity (Ibid.). Again, as Paton points out, a joint may be involved by an adjacent syphilitic area, synovitis arising, or, if a gumma breaks into a joint, secondary pyogenic infection may follow. Ankylosis may follow joint syphilis.

Visceral Syphilis.—Amyloid changes may occur in any of the viscera of an individual with tertiary syphilis, and such changes may be found in people in whom suppuration never occurred. The lungs may undergo fibroid induration (*syphilitic phthisis*). Syphilitic phthisis is often a non-febrile malady. The sputum does not contain the bacilli of tuberculosis, night-sweats and diarrhea are unusual, and emaciation and exhaustion are less decided than in tuberculosis. Gummata may form in the heart, liver, spleen, or kidneys. The capsule and fibrous septa of the liver may thicken, the organ being puckered by contraction. Albuminuria may occur in tertiary syphilis. It may be caused by fibroid changes in the kidneys, by the formation of gummata, or by amyloid degeneration. Its occurrence should be watched for. Mercury and iodid of potassium have been regarded as causative of albuminuria in some cases. When albuminuria is associated with arterial disease and elevated tension, the condition is to be regarded as parasyphilitic rather than syphilitic. When albuminuria results from a true syphilitic lesion of the kidney, there is enlargement of the liver, that organ is often painful, there is ascites, and sometimes jaundice (Fiessinger).

Syphilis may cause disease of the stomach, and probably does so more frequently than was formerly supposed, because it is difficult to distinguish from more common diseases. The condition may be gummatous infiltration of the walls of the stomach, multiple and minute gummata, ulcerations resulting from breaking down of gummata, or syphilitic endarteritis of the gastric vessels. When ulcers heal, cicatricial contraction results. Sometimes a large mass can be palpated. The symptoms last for years. There is pain after eating, but hemorrhage does not occur unless ulcer forms. Syphilitic ulcers and gummata of the stomach may be cured by efficient antisyphilitic treatment. Like lesions may form in the intestines. Flexner, Fränkel, Fournier, and others have discussed this subject.[1]

Nervous syphilis may be manifested by disorders of the brain, cord, or nerves. It is rare after severe secondaries, and is most common when secondaries were light or so trivial as to have escaped observation. Severe secondaries seem to cast off, mitigate, or exhaust the poison. Nervous syphilis may result directly from the specific disease, and such lesions are truly syphilitic. Paresis, locomotor ataxia, myelitis, meningitis, neuritis, arteritis may be directly due to the presence of spirochetes causing the formation of syphilitic

[1] See editorial in "Jour. Amer. Med. Assoc.," March 24, 1900, and Roudnitzky, quoted in "Progressive Medicine," June, 1908, from "Prakt. Vratch," August and September, 1907.

tissue. Nervous syphilis may result indirectly from the specific disease, but not be directly caused by spirochetes having formed syphilitic tissue. Such lesions are called *parasyphilitic.* For instance, a gumma of the brain is a true syphilitic lesion, but locomotor ataxia following syphilis is often a parasyphilitic lesion. As a matter of fact, the spirochetes may act directly on nerve matter without forming syphilitic tissue. Such a condition, though degenerative, is syphilitic, not parasyphilitic. Syphilitic lesions are improved or cured by antisyphilitic treatment, parasyphilitic conditions are not. The diagnosis between syphilitic and parasyphilitic lesions is often impossible without the therapeutic test (mercury, salvarsan). The former are far more apt to show positive Wassermann reactions than the latter. We must remember that brain syphilis is usually a late phenomenon (from one to thirty years after infection). The lesion may be gumma of the membranes (tumor), gummatous meningitis, arterial atheroma, or obliterative endarteritis. A gumma may eventuate in a scar, a cyst, or a calcareous mass. The symptoms of brain syphilis depend on the nature, seat, and rate of development of the lesions. It is to be noted that syphilitic palsy is apt to be limited, progressive, and incomplete. Epilepsy appearing after the thirtieth year is very probably specific if alcohol as a cause can be ruled out. Persistent headache, tremor, insomnia or somnolence, transitory, limited, and erratic palsies, unnatural slowness of utterance, amnesia, vertigo, and epilepsy are very suggestive of syphilis. Sudden ptosis is very significant; so is sudden palsy of one or more of the extrinsic eye-muscles. In syphilitic insomnia the patient cannot get to sleep at night for a long while, but when he once gets to sleep he reposes well. The type of insanity which is most apt to arise is a likeness or counterpart of general paralysis, and, like ordinary paresis, it is not curable. Most paretics have a syphilitic history. Spinal syphilis may cause sclerosis, a condition like Landry's paralysis, softening, and tumor. Neuritis is not uncommon in syphilis.

Justus's Test for Syphilis.—The test described by Justus, in 1894, consists in first estimating the amount of hemoglobin present, then making a single mercurial inunction, and again estimating the hemoglobin. It is claimed that the corpuscles of an untreated syphilitic are unduly sensitive, and if the disease is present a mercurial inunction will cause a loss of 10 to 20 per cent. of hemoglobin within twenty-four hours, which fall persists a few hours and is then followed by a rise to a level above that which existed when the test was applied. It is often demonstrable in secondary, tertiary, or congenital syphilis. It usually fails in latent cases, when an initial lesion is recent, and in early secondary syphilis, and in some diseases other than syphilis the reaction can be obtained.

The Serum Diagnosis of Syphilis (Wassermann's Test).—This test can only be employed in institutions possessed of the best laboratory facilities. It is technical in the extreme. In order to understand it certain facts must be known.

Every normal serum contains an activating material known as *complement,* and complement is destroyed by heat. When bacteria or alien corpuscles are injected into a living animal, the tissues of that animal react and *amboceptor* is formed. Amboceptor includes all antibodies. Amboceptor brings together complement and the bacterial cell and it is not destroyed by heat. If we inject the corpuscles of sheep's blood into a rabbit, amboceptor forms and appears in the rabbit's serum. Amboceptor unites with complement and with alien corpuscles and the sheep's corpuscles are dissolved, and the blood of the rabbit now contains a distinct excess of amboceptor. If some of this blood is drawn and the serum is placed in a test-tube, it will dissolve in the tube corpuscles of sheep's blood if they are added to it. If, however, the rabbit serum is heated for one-half hour to 50° C. before being placed in a test-tube, the heat

destroys the complement, and then the rabbit serum will be unable to dissolve the corpuscles of sheep's blood, if they are added, because amboceptor without complement is incapable of effecting the solution.

If, however, after destroying the complement by heat, any other serum is added, the added serum furnishes the necessary complement and the mixture is now able to dissolve sheep's corpuscles.

On these facts the serum diagnosis of syphilis depends.

Wassermann proved that if an extract made of a syphilitic organ is placed in the serum of a syphilitic individual, the amboceptor or antibody will unite with the complement and the organ extract, although the union cannot be recognized by inspection. In order to be able to identify the occurrence of such a union a process must be gone through.

The serum of the patient thought to be syphilitic is heated and complement is thus destroyed. It is then mixed with the organ extract, which unites with the amboceptor of the serum, one arm of the amboceptor being still unsaturated and open for union. Guinea-pig serum is now added to furnish complement. If the patient is syphilitic, the serum complement just added will unite with the unsaturated arm of the antibody or amboceptor. To find out if this has taken place we add the heated serum of a rabbit, which will destroy sheep's corpuscles if fresh serum is added to it.

"Sheep's corpuscles are also added. If the complement contained in the guinea-pig serum that was added was taken up or united with by the syphilitic antibody, there will be none left over, and consequently the added sheep's corpuscles will not be dissolved. If, however, the serum was not syphilitic, the complement will not have been taken up, but will be left over for union with the hemolytic amboceptor of the inactivated rabbit serum, which latter unites with the blood-corpuscles, and the combination causes the solution of the latter" (Wm. J. Butler, "N. Y. Med. Journal," Jan. 30, 1909).

The test is usually made with blood of the suspected individual, but may be made with cerebrospinal fluid. The test can be made with milk taken from the breast of a lactating syphilitic.

Major Harrison (quoted by D'Arcy Power, in "Brit. Med. Jour.," Dec. 7, 1912) applied the test in 489 cases. It was positive in 71.8 per cent. of cases of primary syphilis, in 90 per cent. of cases of secondary syphilis, and in 83.5 per cent. of cases of tertiary syphilis. It was present in 50 per cent. of those in a stage of latency. In paretics it was found in over 80 per cent. of cases; in tabetics in over 50 per cent. of cases.

A positive Wassermann reaction may be obtained in noma, leprosy, scarlet fever, sleeping sickness, and some cases of malaria. Practically, a positive reaction obtained from a patient in the United States nearly always means syphilis. A negative Wassermann does not prove that syphilis is absent, unless it is constantly negative and the patient is not taking mercury. In latent stages of syphilis the reaction often becomes negative for a considerable time. Active mercurial treatment or an injection of salvarsan should cause a positive reaction to become negative. The earlier mercury is given in a case of syphilis, the sooner is a negative reaction obtained.

It seems certain that the serum test has high diagnostic value. It may enable us to be sure of the diagnosis long before the appearance of secondaries. A positive reaction indicates that the poison is active and calls upon the physician to apply active treatment. This should be the rule, no matter how long it has been since there were any external manifestations of the disease. Wet nurses should be tested by this method before being allowed to assume charge of an infant.

Noguchi's Cutaneous Reaction ("Jour. of Exper. Med.," 1911).—Noguchi gives the name luetin to an emulsion of dead cells of pure culture of

Spirochæta pallida. Rubbed into the skin it produces a marked reaction in tertiary and hereditary syphilis, but seldom gives a reaction in primary or secondary syphilis (Noguchi, in "Jour. Am. Med. Assoc.," 1912, vol. lviii).

Diagnosis by Finding the Spirochæta Pallida.—This method is of the greatest value. The organism, if carefully searched for, is found in chancre, in all the lesions of early secondary syphilis, and in congenital syphilis. Spirochetes, though comparatively few, are found in tertiary lesions. Hence, the old idea that tertiary lesions are not contagious must be cast aside. It is not found in lesions other than syphilis. Spirochetes can be found in a few minutes in material from a syphilitic papule or sore. Williams ("Archives of Diagnosis," Jan., 1910) scrapes the papule or sore lightly with a scalpel, drops a little warm salt solution on it, and examines the salt solution at once.

Prevention of Syphilis.—I shall not discuss the various plans at present under consideration for the diminution or extinction of syphilis in communities. It is sufficient to say that no method has yet been decided upon. Desirable as it would be to entirely prevent syphilis, it is at present impossible, as promiscuous sexual intercourse and prostitution are still with us, and destined, for some time at least, to remain.

The individual in endeavoring to avoid syphilis should avoid, as far as possible, all the acts spoken of on pages 317 and 318, which may be responsible for infection. Metchnikoff discovered that if within twenty-four hours of inoculation calomel ointment is rubbed in the area syphilis can be prevented. He used 1 part of calomel and 2 of lanolin. This fact is widely utilized. In the United States Navy when a sailor returns from shore leave and admits to a suspicious connection, the penis and foreskin are rubbed with a mixture containing 33 parts of calomel, 10 parts of vaselin, and 67 parts of lanolin.

If before connection the glans and prepuce are smeared with soap or calomel ointment, the liability to tearing and abrasion is lessened and crypts and follicles are blocked up. If this plan is followed, and if after connection the parts are washed and bathed with a solution of corrosive sublimate (1:2000) or permanganate of potash (1:3000), the danger of infection is greatly lessened. To apply the calomel ointment gives additional assurances of safety.

Abortive Treatment.—I do not believe that syphilis can be aborted by cauterization, by excision, or by the administration of mercury, luetin, or salvarsan. Several observers, even during recent years, have claimed that ablation of the chancre will sometimes prevent the disease. In the reported cases there is some doubt as to the diagnosis. Neisser's experiments upon apes demonstrate the futility of excision. He found spirochetes in adjacent glands before the sore had indurated. Injection of another ape with material from these glands was followed by the development of syphilis. Excision causes pain and diagnostic uncertainty and is invariably useless.

Treatment of the Primary Stage.—It has long been taught that a chancre should not be excised because the disease is constitutional when the chancre appears, and excision and cauterization inflict needless pain and do no good. The initial lesion should never be cauterized unless it is phagedenic or becoming so. Order the patient to soak the penis for five minutes twice daily in warm salt water (a teaspoonful of salt to a cupful of water), and then to spray the sore with peroxid of hydrogen diluted with an equal bulk of water. The ulcer is then dried with absorbent cotton and on it is dusted a powder composed of equal parts of bismuth and calomel or, better, is dressed with calomel ointment. The buboes in the groin require no local treatment unless they tend to suppurate. If they persist or become large, paint them with iodin or rub ichthyol ointment or mercurial ointment into them, and apply a spica bandage to the groin. Some authorities give mercury in this stage in order to prevent secondaries. The younger Gross opposed this strongly, and affirmed

a wish to see the secondary eruption—first, because it proves the diagnosis; and, second, because it affords valuable prognostic indications (an erythematous eruption means a light case, an early pustular eruption means a grave case with serious complications); I long followed the plan of my old master, and did not order mercury until constitutional symptoms developed. We now know that the development of a positive Wassermann reaction may be regarded as confirmatory of the diagnosis, the finding of spirochetes proves it, and early treatment may prevent disastrous lesions. We make the diagnosis early and at once begin constitutional treatment (see page 336). If phagedena arises, place the patient promptly upon stimulants and nutritious diet, secure sleep, and destroy the ulcer by the use of nitric acid or the cautery while the patient is anesthetized. After cauterization dust the sore with iodoform and dress with wet antiseptic gauze. Several times a day change the dressings, and at each change spray the sore with peroxid of hydrogen, irrigate with bichlorid of mercury solution, and dust with iodoform. It may be necessary to cauterize several times. In some cases it will be necessary to employ continuous irrigation by an antiseptic fluid. These cases are sometimes fatal and usually produce great destruction of tissue. In chancre redux watch carefully for the symptoms in order to determine if the condition is really one of reinfection or if we are dealing with a gumma which resembles a chancre in appearance.

A chancre usually heals promptly after the administration of salvarsan, and quite rapidly when the patient is placed on mercury. It is not wise to give iodid of potash during the primary stage and it is not probable that it is helpful at all. Some teach that iodid of potash helps the absorption of granulation tissue and so lessens induration and promotes healing. It certainly is not as efficient as mercury for this purpose; it does not kill spirochetes, the tissues of the patient soon become "habituated to its presence and excrete it as rapidly as it is ingested" (D'Arcy Power, in "Brit. Med. Jour.," Dec. 7, 1912).

Treatment of the Secondary Stage.—The chance of cure in most cases is excellent if the patient follows advice. The prognosis is much worse if the patient is a hard drinker or is the victim of Bright's disease, diabetes, tuberculosis, or other chronic exhausting malady. In the secondary stage the aim is to cure the disease. That it can be cured is known because reinfection occurs in some persons. The old axiom, "Syphilis once, syphilis ever," is not true.

Diet and General Care.—In the beginning of treatment the patient must see his physician every day or two until the proper dose of mercury has been ascertained. For the following six months he should see his physician once a week, and during the next six months once every other week. During the second year he needs to see him once every month. Of course, if complications arise at any period the visits must be more frequent. At the beginning of the attack he must have his teeth put in perfect order. Tobacco is absolutely forbidden because its use favors the development of mucous patches in the mouth. Alcohol as a beverage is prohibited. It is used only as a medicine. The teeth should be gently scrubbed with a soft brush in the morning, in the evening, and after each meal, and a mild astringent or antiseptic mouth-wash and gargle is to be used several times a day. If the gums become red and tender, chlorate of potash is used as a gargle and mouth-wash (1 oz. of the drug to 1 pint of water). The patient should wear flannel in winter. The author believes Guiteras's rules are sound, and in accordance with them directs the patient to refrain from kissing any one on the lips and from using a common towel, wash-rag, cup, glass, pipe, or razor. He is told to sleep alone in bed, to wash his hands often, to wear gloves, and to keep his fingers out of his mouth. Every morning he should take a warm bath, being especially careful to cleanse the anus, perineum, axillæ, groins, and between the toes; and after the bath these parts should be dusted with borated talc powder.

A Turkish bath once a week is ordered by Guiteras when no skin eruption exists. The patient must avoid drafts, cold, and wet; must take a moderate amount of gentle outdoor exercise, and must sleep eight hours out of the twenty-four. The diet is of importance, and in this, too, the author follows Guiteras and orders the patient to avoid eating anything fried, or any meat or fish which has been canned, salted, or preserved. Fruits, pickles, tea, condiments, alcoholic beverages, clams, pork, veal, and pastry are not to be taken. (See article by Luke Beggs, in "Phila. Med. Jour.," June 7, 1901.)

Medical Treatment.—Mercury cures syphilis. We no longer give it only to remove symptoms, we give it to produce cure. It is given in small doses for a long period. We were taught this by Fournier, Lang, and Sir Jonathan Hutchinson (D'Arcy Power, in "Brit. Med. Jour.," Dec. 7, 1912). Mercury kills the spirochetes. This is proved by the experiments upon apes made by Metchnikoff and Roux. Iodid of potash is seldom used in the secondary stage for the same reasons that it is avoided in the primary stage. Mercury must be used, the form being a matter of choice. Fournier advocated intermittent treatment. In this plan give $\frac{1}{3}$ gr. of protiodid of mercury daily for six months, then stop for a month; then give mercury for three months, then stop two months. During the first year the patient is under treatment nine months, and during the second year eight months. Some prefer the intermittent and others the continuous plan of treatment. The author prefers the continuous plan. In following the continuous plan find the patient's tolerance to mercury, and keep him for two years on daily doses below the amount he will tolerate. Gross's rule for continuous treatment is to order pills of green iodid of mercury, each pill containing $\frac{1}{5}$ gr. The patient is ordered one pill after each meal to begin with; the next day the after-breakfast dose is increased to two pills; the following day the after-dinner dose is two pills, and so on, one pill being added every day. This advance is continued until there is slight diarrhea, griping, a metallic taste, or tenderness on snapping the teeth together, whereupon one pill is taken off each day until all unfavorable symptoms disappear. Then the dose is reduced one-half and this amount is called the tonic dose. This experimentation finds a dose on which the patient can be kept with entire safety for a long time; but if it is found that colic or diarrhea is apt to recur, there must be added to each pill $\frac{1}{12}$ gr. of opium. The patient is given mercury in this way for two years. Every time new symptoms appear the dose is raised, and as soon as they disappear it is lowered to the standard. If the protiodid is not tolerated, give the bichlorid:

℞. Hydrarg. chlor. corros.,	gr. j;
Syr. sarsaparillæ comp.,	f℥iij.—M.

Sig.—One fluidram, in water, after meals.

Mercury with chalk in 1- or 2-gr. doses four times a day, with or without Dover's powder in 1-gr. doses, may be used. Mercurial inunctions produce a rapid effect, but irritate the skin. The drug should be rubbed in with a gloved hand. There can be used once a day $\frac{1}{2}$ dr. of oleate of mercury (10 per cent.) or 1 dr. of mercurial ointment, rubbed into the skin. The first day it is rubbed into the inside of one thigh; the second day into the inside of the other thigh; the third day into the inside of one arm; the fourth day into the other arm; next, into one groin and then into the other groin, and then inunction is again made at the point of original application, and so on. After the rubbing the patient puts on underclothes and goes to bed, and in the morning takes a bath. The ointment may be smeared on a rag, which is then worn between the stocking and sole of the foot during the day.

Fumigation is performed by volatilizing each night 1 dr. of calomel. The patient sits naked on a cane-seat chair, and is wrapped up to the neck in a

blanket which drops tent-like to the floor; the calomel is put upon an iron plate under the chair, and is heated by an alcohol lamp beneath the plate. The skin becomes coated with calomel, and the subject, after putting on woolen drawers and an undershirt, gets into bed. Hypodermatic injections of mercury are used by some physicians. They cause an eruption to disappear rapidly, but may produce abscesses, and relapses are prone to occur. The injection method will not abort the disease; should never be a routine treatment; in suitable cases it is very valuable for symptomatic use, as when lesions on the face or in important structures make a rapid impression desirable or necessary; in cases which obstinately relapse under other treatment, and in syphilis of the nervous system. J. William White, after a large experience with this method, says that hypodermatic injections of corrosive sublimate are painful and are strongly objected to by many patients; that this method of treatment is occasionally dangerous and even fatal; that it is liable to be followed by local complications (erythema, nodosities, cellulitis, abscess, sloughing); that it cannot be carried out by the patient, but requires the surgeon's constant intervention. This syphilographer concludes that hypodermatic medication does not offer advantages justifying its use as a systematic method of treatment, and that it encourages insufficient treatment—those "short heroic courses" which Hutchinson shows are followed by the gravest tertiary lesions. "The claim that by a few injections the time of treatment can be measured by months or even by weeks, instead of by years, would seem, as Mauriac has said, to involve the idea that mercury given hypodermically acquires some new and powerful curative property which, given in other ways, it does not possess."[1] The usual plan is to give daily a hypodermatic injection of corrosive sublimate deep into the back or buttock, the dose being $\frac{1}{4}$ gr. of the drug. Thirty such injections are used unless some contra-indication demands their discontinuance sooner. The treatment is then stopped. If the symptoms recur, however, the patient is given another course, the daily dosage being $\frac{1}{6}$ gr., the treatment being again stopped after thirty injections, but being continued anew in $\frac{1}{8}$-gr. doses if the symptoms recur. The following preparation is used by some syphilographers: 0.5 part of corrosive sublimate, 3 parts of guaiacol, and 97 parts of sterile olive oil. Thirty minims contain $\frac{1}{16}$ gr. of corrosive sublimate. This mixture should be thrown deeply into the buttock and it causes no pain. The use of gray oil hypodermatically has warm advocates. It is claimed that it provokes little pain and irritation, and that it is a very efficient remedy. The oil should not be thick like an ointment, because such a preparation could not be used without warming, and heat causes the mercury to aggregate in lumps. Olive oil should not be used, as it becomes rancid. Dumesnil's formula is the best ("Brit. Med. Jour.," Jan. 18, 1908):

"The ingredients must be sterilized before they are incorporated, as it is impossible to sterilize the product. If the directions given below are carefully followed no risk of septic poisoning is to be apprehended. The formula proposed by M. Dumesnil has been accepted by a committee especially appointed by the Société de Pharmacie of Paris, to investigate the methods of preparing gray oil. Twenty-six gm. of anhydrous wool-fat and 60 gm. of pure liquid paraffin (*huile de vaselin médicinale*) are sterilized separately in glass flasks at 120° C. for twenty minutes. A pestle and mortar are sterilized by means of burning alcohol and placed therein are 40 gm. of mercury and then the wool-fat. The metallic particles are triturated until they are sufficiently minute when examined under a magnification of 480 diameters, and then the liquid paraffin is added in small portions. The product should weigh 126 gm. and

[1] J. William White, in Morrow's "System of Genito-urinary Diseases, Syphilology, and Dermatology."

measure 100 c.c. and should be transferred immediately to phials of 2-, 5-, and 10-c.c. capacity, previously sterilized at 180° C."

An injection is given twice during the first week, once during the second week, and after this once a week or once every other week for an indefinite period of time. It may be given oftener if symptoms arise or persist.

Taylor believes that gray oil may give rise to unpleasant and sometimes even dangerous symptoms, and that it should be used with extreme care and only in selected cases in which other remedies are contra-indicated. He says that in reading about the hypodermatic method he has been struck with the fact that "the most serious results have almost invariably followed injections in which fatty matters have been the vehicle of suspension."[1]

Some surgeons employ intravenous injections of mercury. Lane injects, at first every other day and later daily, 20 min. of a 1 per cent. solution of cyanid of mercury. The skin in front of the elbow is rendered aseptic, a fillet is tied around the arm, the needle is inserted into a vein, the fillet is loosened, the fluid is injected, and the needle is withdrawn. This method of using mercury is painless and produces a rapid effect. It may be used in nervous syphilis, but should not be used as a routine. In whatever way mercury is given, do not allow it to produce salivation (hydrargyrism or ptyalism). Always remember that mercury may cause albuminuria and examine the urine at regular intervals during a course of the drug. If albumin appears in the urine, cut down the dose of mercury or stop the drug for a time. In the beginning of a case of syphilis, if the kidneys are found to be diseased, give the mercury cautiously, and never fail to examine the urine at regular intervals. An individual can take more mercury in summer than in winter because during the warm weather perspiration favors elimination.

Sometimes, when a patient has a secondary eruption, the eruption grows temporarily worse when mercury is administered. This is called *Herxheimer's reaction.* It is due, according to Adamson, to having killed some spirochetes and thus caused the liberation of more endotoxins, the endotoxins causing "a further local defensive reaction" ("Lancet," April 6, 1912).

In order to cure syphilis mercury should be given for two years, and the mercurial course must be followed by at least a six months' course of iodid of potash. Reminders require both iodid of potash and mercury (mixed treatment). Throughout the mercurial course the patient should be weighed once a week, and if it is at any time found that the weight is decreasing, tonics, concentrated food, and cod-liver oil are ordered. If the weight continues to grow less and the health begins obviously to fail, stop the mercury for a time, continue the cod-liver oil, tonics and nourishing food, and order hot baths, fresh air, iron, and chlorid of gold and sodium. If during the mercurial course albumin appears in the urine and some edema is noted, the mercury should be stopped for several or a number of weeks and the patient should be given a milk diet. If marked albuminuria is noted, but no other symptoms exist, mercury need not be discontinued, but the patient is watched most carefully for the advent of any other symptom (Fiessinger, in "Journal des Practiciens," August 3, 1907).

Acute Ptyalism, or Salivation.—In acute ptyalism the saliva becomes thick and excessive in amount; the gums become spongy and tender and liable to bleed. Tenderness can be detected early by snapping the teeth. A metallic taste is complained of; the breath becomes fetid; the oral structures swell; the teeth loosen; the saliva is produced in great quantity; and there are purging, colic, and exhaustion. Sometimes there are fever and a diffuse scarlatiniform eruption upon the skin. A chronic hydrargyrism may be shown by salivation, gastro-intestinal disorder, emaciation, mental depression,

[1] "Venereal Diseases," by Robert W. Taylor.

weakness, albuminuria, and tremor. To avoid salivation, advance the dose with great caution and instruct the patient as to the first sign of the trouble. He should use a soft tooth-brush and an astringent mouth-wash (48 gr. of boric acid to 4 oz. each of listerine and water). When ptyalism is noted, discontinue the administration of the drug. Employ the above mouth-wash or one composed of a saturated solution of chlorate of potassium. Order $\frac{1}{120}$ gr. of atropin twice a day, and in bad cases spray the mouth with peroxid of hydrogen and use silver nitrate locally (20 gr. to 1 oz.). Give stimulants (iron, quinin, and strychnin) and nutritious food. A weekly Turkish bath is of great service. In chronic hydrargyrism stop the administration of the drug, use tonics, stimulants, open-air exercise, Turkish baths, and nutritious food. The chlorid of gold and sodium forms a substitute for mercury. The use of iodid of potassium is of questionable value in ptyalism.

Treatment of Complications in the Secondary Stage.—The complications of the secondary stage usually require local applications in addition to general remedies. Mucous patches in the mouth should be touched with bluestone every day, an astringent mouth-wash being employed several times daily. If the patches ulcerate, they should be touched once a day with lunar caustic; if these areas proliferate, they should be excised and cauterized. Vegetations or growing papules on the skin must, if calomel powder fails to remove them, be cut away with scissors and be cauterized with chromic acid or with the Paquelin cautery. Condylomata demand washing with ethereal soap several times daily, thorough drying, dusting with equal parts of calomel and subnitrate of bismuth or with borated talcum, and covering with dry bichlorid gauze. If these simple procedures fail, excise and cauterize.

For psoriasis of the palms and soles diachylon ointment, mercurial plaster, or painting with tincture of iodin should be employed. Ulcers of paronychia are dressed with iodoform and corrosive sublimate gauze. Deep cutaneous ulcers are cleaned once a day with ethereal soap, sprayed with peroxid of hydrogen, dressed with iodoform and corrosive sublimate gauze, and bandaged. When the process of granulation is well established dress with 1 part of unguent. hydrarg. nitratis to 7 parts of cosmolin. In sarcocele mercurial ointment should be rubbed into the skin of the scrotum or the testicle be strapped. In alopecia the hair should be kept short, and every night the scalp should be cleaned with equal parts of green soap and alcohol rubbed into a lather with water. After the soap has been washed out some hair tonic should be rubbed into the scalp with a sponge. A favorite preparation of Erasmus Wilson's consisted of the following ingredients:

℞. Ol. amygd. dil.,
Liq. ammoniæ, āā f℥j;
Sp. rosemarini,
Aquæ mellis, āā f℥iij.—M.
Ft. lotio.

One part of tincture of cantharides to 8 parts of castor oil may be rubbed into the scalp. Solutions of quinin are esteemed by some. A useful wash for the scalp is the following: 1 dr. of borate of sodium, 1 dr. of spirits of camphor, 2 dr. of glycerin, and sufficient orange-flower water to make 4 fl.oz.

In treating persistent skin-lesions, inunctions, injections, fumigations, or mercurial baths may be used. Baths are suited to patients with delicate skins, to those whose digestion fails when mercury is given by the mouth, and to those whose lungs will not tolerate fumigations. Corrosive sublimate, ½ oz., and 4 scruples of sal ammoniac are mixed in about 4 oz. of water; this is added to a bath at a temperature of 95° F. The patient gets into this bath,

covers the tub with a blanket, leaving only his head exposed, and remains in the bath an hour or so. Mercurial baths may rapidly cause salivation.

Tertiary Stage.—If at any time during the case there appear tertiary symptoms, the patient should be put on mixed treatment, that is, mercury and an iodid. In any case, after two years of mercury add iodid of potassium to the treatment. If any tertiary symptoms appear, the rule is to use mixed treatment and to continue it for at least six months after all symptoms disappear, the six months' course dating from their disappearance. This emphasizes the fact that the iodids alone will not cure tertiary syphilis. Iodid of potash does not cure, but is very valuable in removing symptoms. In late syphilis both iodid and mercury are given. It is the mercury that cures. The mercury is given in small or tonic doses. Since the days of Ricord iodid of potash has been held in high esteem. In obstinate tertiary lesions and in nervous syphilis the iodids should be run up to an enormous amount (from 30 to 250 gr. per day). Sometimes people can take large doses of iodid when small doses produce iodism. Cyon explains this curious fact as follows: small doses combine with some products of the thyroid gland and form toxic iodothyrin. Large doses are diuretic, form soluble salts, and are rapidly eliminated. An easy way to give iodid is to order a saturated solution each drop of which equals about 1 gr. of the drug. Each dose of the iodid is given one hour after meals and in at least half a glass of water. If the iodid disagrees, it may be given in water containing 1 dr. of aromatic spirit of ammonia, or 5 drops of fluidextract of ergot, or it may be given in milk. The iodid of sodium may be tolerated better than the potassium salt, as it is less depressing to the circulation, or the iodids of sodium, potassium, and ammonium may be combined. Gotheil sometimes gives tincture of iodin in 10-drop doses, well diluted. Iodid may be given as an enema in milk. In giving the iodids, begin with a small dose. During a course of the iodids always give tonics and insist on plenty of fresh air. Arsenic given daily tends to prevent skin eruptions. The iodids may disagree for a time, but tolerance may be established as the administration is continued. The value of the newer organic iodin preparations is as yet uncertain. Some of them are given hypodermatically. An iodized oil, known as iodipin, can be given by the mouth or by intramuscular injection. If given by the stomach it may be taken in capsules, in tablets, or in milk (Coates, in "Brit. Med. Jour.," May 7, 1910). The iodids when they radically disagree produce *iodism*—a condition which is made manifest by a flow of mucus from the nose, conjunctival irritation, a bad taste in the mouth, exhaustion, anorexia, nausea, and tremor. In some subjects there are outbreaks of acne, vesicular eruptions, or even bullæ or hemorrhages. Iodism calls for the abandonment of the drug, and the administration of increasing doses of Fowler's solution of arsenic, of laxatives, of diuretic waters, or, if there is great exhaustion, of stimulants. In some cases belladonna is of service. Some patients who cannot take the alkaline iodids may take syrup of hydriodic acid. After the patient has been for six months under mixed treatment without a symptom, stop all treatment and await developments. If during one year no symptoms recur, the patient is probably cured; if symptoms do recur, there must be six months more of mixed treatment and another year of watching. It would be wise were every person who has had syphilis to take a six weeks' course of mercury and iodid twice a year for the balance of life. It is probable that such a plan would save many from visceral syphilis and late nervous syphilis. Syphilitic ulcers are treated locally by cleanliness, antiseptic applications, and, if the situation admits of it, by the daily use of the hot-air apparatus or by the induction of hyperemia by means of the rubber bandage or the cupping-glass. If albuminuria arises during the tertiary stage and there is arterial disease with high tension, mercury

will do harm. In albuminuria without high tension it may be given (see pages 327 and 338).

The Question of Marriage.—Fournier has insisted that it is a great wrong to tell a syphilitic that he can never marry. He must not marry until he is cured, and he is not cured until, after the cessation of the use of mercury and iodid, he goes one year without treatment and without symptoms.

Treatment of Syphilis by Salvarsan or "606" (Hydrochlorid of Dioxydiamido-arsenobenzol).—Various arsenic compounds have been tried in syphilis (atoxyl, cacodylate of sodium, arsacetin, soamin), but salvarsan and neosalvarsan are the most important. Ehrlich introduced "606" (salvarsan) in 1909 and "914" (neosalvarsan) early in 1912. It was hoped that a single intravenous injection would kill all the spirochetes and immediately cure the disease. This hope has not been realized, though the remedy has great power for good. It kills multitudes of spirochetes by directly poisoning them, not by causing the tissues to form antibodies. It causes symptoms to rapidly pass away, but if the administration is not continued at intervals or if mercury is not given, relapse, and probably disastrous relapse, is almost certain to occur. In many cases, but not in all, the Wassermann reaction becomes negative after the injection. The test is rendered negative more quickly than by mercury, but it may soon become positive again. The beneficial effects of these arsenic preparations are particularly manifest in early syphilis, and are very evident in tertiary syphilis. The drugs are of little or no use in parasyphilitic lesions.

In some cases "a spirochete infection which has been in abeyance" can be roused by salvarsan "into sufficient activity to cause the Wassermann reaction to become positive," when it was before negative. Hence, salvarsan and neosalvarsan may be used as tests for syphilis and as tests to determine if syphilis has been cured (D'Arcy Power, in "Brit. Med. Jour.," Dec. 7, 1912).

Salvarsan is not to be given as routine treatment of syphilis because it does not cure; and mercury does. It is not a substitute for mercury, but is used in particular cases for particular reasons. Even when salvarsan is given, mercury and iodid should be given in the same doses and for the same time as they would have been given had salvarsan not been administered. Salvarsan should be given when the patient is intolerant to mercury or when mercury fails to control the disease; when an important structure is threatened with damage or destruction; when the sore becomes phagedenic; for malignant syphilis; for persistent or spreading ulcerations; for laryngeal syphilis; for tertiary syphilis; for glossitis and ulceration of the tongue with leukoplakia, and for periostitis and osteitis in congenital or acquired syphilis. It does no good to syphilitic necrosis, probably because pyogenic organisms are active in such cases, and it is useless for symmetrical synovitis of the knees, possibly because the child victims have also tuberculosis (Ibid.).

A man with persistent mucous patches in the mouth and every prostitute with syphilis should be given salvarsan because of the danger to the community of such syphilitics. A characteristic and disfiguring eruption calls for it. A married man with a chancre should receive it promptly. Salvarsan is contra-indicated when there is advanced disease of the heart and arteries; in degenerative conditions of the brain and cord, when there is optic atrophy; in diabetes; in diseases of the liver or kidneys (even if syphilitic); in pulmonary tuberculosis, and in children before the age of three.

It is estimated by some that salvarsan is responsible for 1 death in every 1000 cases treated. Others set the rate at a much higher figure. Major French ("Lancet," Nov. 18, 1911) refers to 41 deaths as having occurred in less than one year. Levy-Bing, of Paris, says that the deaths number 70 or 80 and that death may occur in a healthy person. Hallopeau, Gaucher and Ra-

vant reported 3 deaths ("Bull. de l'Acad. de Med.," Oct. and Nov., 1911). A man of nineteen developed arsenical poisoning and died of uremia on the sixth day after the injection. A girl of eighteen died in a similar manner. Géronne, Finger, and others seem to prove that the symptoms which may follow the administration of salvarsan are manifestations of acute intoxication by arsenic, and are not, as Neisser claims, produced by endotoxins from destroyed spirochetes. Finger had a fatal case due to arsenical poisoning ("Brit. Med. Jour.," Jan. 27, 1912). Auditory and ocular complications may occur. In 9 per cent. of patients to whom Finger gave salvarsan nerve complications developed. Most of the deaths followed a second injection, hence the claim that anaphylaxis was the cause.

The drug may be given by intramuscular injection. It causes pain which is often severe and prolonged inflammation. This method is employed in children from three to seven years of age, because the veins are small and hard to find. In adults the intravenous method is always to be preferred. It is given in a vein in front of the elbow. One capsule containing .6 gm. of salvarsan is opened, and the drug, which is an acid salt, is dissolved in a hot alkaline solution. A pint of recently sterilized salt solution is used and ten minutes are occupied in running the fluid into the vein. The fluid is given at a temperature a little above blood heat. Neosalvarsan to the amount of .9 gm. is dissolved in 6 oz. of freshly distilled water. It gives a neutral solution and is very soluble. The fluid is injected at a temperature of 60 to 70° F.

Several hours after the injection of salvarsan symptoms may arise (chills, elevation of temperature, diarrhea, vomiting, headache). In a few hours, as a rule, the symptoms pass away. One must be on the watch for dangerous symptoms (cardiac depression, dyspnea, great restlessness, excitement, edema of the face, cyanosis of the face, persistent vomiting, diarrhea, albuminuria, spasm of the limb muscles, and collapse).

The effect of salvarsan on the Wassermann reaction has been much discussed. Theoretically, it should always make a positive reaction negative. Practically, it often does not. It may require a second injection to do it. After the administration of salvarsan the reaction may become negative, remain so for several months, and again become positive. Neisser claims that in only 10 per cent. of latent cases is a negative reaction converted into a positive one. It was stated above that in latent syphilis with a negative reaction salvarsan may actually cause a positive reaction. Evidently, a negative Wassermann is not to be regarded as absolute and unassailable proof that a patient is cured.

Hereditary Syphilis.—**Transmitted congenital syphilis** is hereditary syphilis manifest at birth. Acquired syphilis (except in the case of a woman who obtains the disease from a fetus) always presents the chancre as an initial lesion; hereditary syphilis never does. Hereditary syphilis may present itself at birth, and usually shows itself within, at most, the first six months of extra-uterine life. In rare cases (tardy hereditary syphilis) the disease does not become manifest until puberty.

Rules of Inheritance.—According to von Zeissl,[1] the rules of inheritance are as follows:

1. If one parent is syphilitic at the time of procreation, the child may be syphilitic.

2. Syphilitic parents may bring forth healthy children.

3. If a mother, healthy at procreation, bears a child syphilitic from the father, the mother must have latent pox, having become infected through the placental circulation, or must be immune. She often shows no symptoms, having received the poison gradually in the blood, and having thus received,

[1] "Pathology and Treatment of Syphilis."

it may be said, preventive inoculations. Certain it is that mothers are almost never infected by suckling their syphilitic children (Colles's law).

4. If both parents were healthy at the time of procreation, and the mother afterward contracts syphilis, the child may become syphilitic, and the earlier in the pregnancy the mother is diseased, the more certain is the child to be tainted. This is known as "infection *in utero*."

5. The more recent the parental syphilis, the more certain is infection of the offspring. The children are often stillborn.

6. When the disease is latent in the parents it is apt to be tardy in the children.

7. The longer the time which has passed since the disappearance of parental symptoms, the more improbable is infection of the children.

8. In most instances parental syphilis grows weaker, and after the parents beget some tainted children they bring forth healthy ones.

Syphilis in the mother is more dangerous to the offspring than syphilis in the father. The frequent immunity of the mother is due to the fact that her tissues produce antitoxins under the influence of the slowly absorbed virus. The milk of a syphilitic mother contains quantities of antibodies (Bab, "Zeitschrift f. Geb. und Gynäkologie," vol. x, No. 2).

Many women affected with hereditary syphilis are sterile. Many syphilitic women abort before the eighth month, most commonly in the fifth month. The fetus very often dies at an early period of gestation. This may be due to a gummatous placenta or to a degeneration of placental follicles. Bab (Ibid.) reports that out of 33 infants, victims of congenital syphilis, 16 were born alive and 7 of these died within a few days. Hyde says that about 90 per cent. of those born living subsequently die of the disease.

Evidences of Hereditary Syphilis Manifest At or, Oftener, Soon After Birth. —Hutchinson says that at birth the skin is almost invariably clear. In from six to eight weeks "snuffles" begin, which are soon followed by a skin eruption, by body wasting, and by a chain of secondary symptoms (iritis, mucous patches, pains, condylomata, etc.). The child looks like a withered-up old man. Eruptions are met with on the palms and soles. Intertrigo is usual. Cracks occur at the angles of the mouth and leave permanent radiating scars. The abdomen is tumid and there is apt to be exhausting diarrhea. The secreting and absorbing glands of the intestinal tract atrophy.[1] It is seldom that distinct gummatous tumors form in hereditary syphilis. The type of disease induced is a diffuse interstitial cellular change in the viscera, and the viscera are much more apt to suffer than in acquired syphilis. The liver, spleen, and pancreas often enlarge from interstitial changes, and the lungs sometimes are attacked in the same manner. Synovitis or arthritis may arise, the condition being similar to that met with in acquired syphilis. A form encountered between the third month and end of the second year, according to Paton, is characterized by growth into the joint of fungating granulation tissue, the joint is useless, and the parts about are swollen and edematous. Atrophic lesions may appear in the bones. In the skull the bone may be softened by removal of its lime salts or be thinned by the pressure of the brain. In the long bones the epiphyseal lines suffer, the attachment of the epiphysis to the shaft is weak, and separation is easily induced. Epiphysitis is common, seldom causes pain, and rarely leads to suppuration, except in children who are old enough to walk (Coutts). Osteophytic lesions of the skull are shown by symmetrical spots of thickening upon the parietal and frontal bones (*natiform skulls*). In the long bones osteophytes are frequently formed. In some cases osteophytes grow from the epiphysis, and in consequence deformity and impaired function are noted and a certain amount

[1] Coutts, in "Brit. Med. Jour.," 1894, p. 1643.

of ankylosis may occur. This condition of osteophytic growth from an epiphysis was called by Fournier *arthropathie deformant.* A child with precocious hereditary syphilis is apt to die, but if it lives from six months to one year the symptoms for a time disappear, and for years the disease may be latent. Diagnosis is difficult after the third or fourth year, especially if the disease be associated with rickets or tuberculosis. When later symptoms arise they may be various, namely: noises in the ears, often followed by deafness; interstitial keratitis; synovitis in any joint, particularly painless but marked symmetrical effusion in the knee-joints, with trivial functional disturbance; ossifying nodes; developmental osseous defects; suppurative periostitis; ulcerations; death of bone; falling in of the nose; nervous maladies; occasionally sarcocele, dactylitis, etc.

Fig. 138.—Dactylitis.

Dactylitis (Fig. 138) is common in hereditary syphilis. There is a superficial and a deep form (see p. 330). Commonly, a swelling gradually forms. It is fusiform in shape and becomes purple in color. It lasts for months. One or more fingers may be involved and the fingers are more apt to suffer than the toes. The proximal phalanx is most liable to the lesion. The superficial form is apt to soften and ulcerate. Sinuses seldom form. The deep form not infrequently causes tissue destruction and shortening of the digit from rarefying osteitis or dry caries. Some cases of superficial dactylitis are symmetrical and of short duration and are to be regarded as late secondary lesions.

In hereditary syphilis the eye symptoms are of great diagnostic importance. In 212 cases of congenital syphilis Fournier found eye trouble in 101. Keratitis and choroiditis are the most usual forms. Bone trouble occurs in almost half of the cases, but is not often severe enough to cause symptoms. The tongue often shows a smooth base (Virchow's sign). It is due to lymphoid atrophy and fibrosis (Symmers, in "Amer. Jour. Med. Sci., Dec., 1910). Hirschberg believed choroiditis to be pathognomonic. The descendants of syphilitic parents may exhibit certain pathological conditions which are not directly syphilitic. Fournier calls such phenomena parasyphilitic. Among these phenomena are arrest of development of the body at large or of special structures, weakness of constitution, and other stigmata of degeneration.

Fig. 139.—Hutchinson teeth.

In the **diagnosis** of hereditary syphilis the condition of the teeth is of considerable importance: the temporary teeth decay soon, but present no characteristic defect. If the upper permanent central incisors are examined, they are often, but by no means always, found defective. Other teeth may show defects, but in these alone are characteristic defects likely to appear. In hereditary syphilis they may present an appearance of marked deviation from health, and are then called *Hutchinson teeth* (Fig. 139). Hutchinson stated that if they are dwarfed, too short and too narrow, and if they display a single central cleft in their free edge, then the diagnosis of syphilis is probable. If the cleft is present and the dwarfing absent, or if the peculiar form of dwarfing be

present without any conspicuous cleft, the diagnosis may still be made. The view that teeth of this nature *prove* the existence of hereditary syphilis and that they occur only in syphilis has been abandoned by Hutchinson himself. In fact, only one-fifth of congenital syphilitics have these teeth, and one-third of the cases of Hutchinson teeth are in individuals free from syphilis. In early infancy the diagnosis of syphilis is made by the snuffles, the broad nose, the skin eruptions, the wasted appearance, the sores at the mouth-angles, the tenderness over bones, condylomata, and the history of the parents. The diagnosis at a later period is made by the existence of symmetrical interstitial keratitis, choroiditis, the smooth base of the tongue, deafness, which comes on without pain or running from the ear, ossifying nodes, white radiating scars about the mouth-angles, sunken nose, natiform skull, deformity of long bones, painless inflammation of epiphyses, and Hutchinson teeth. It must be remembered that a child born apparently healthy and presenting no secondary symptoms may show bone disease, keratitis, or syphilitic deafness at puberty. Finding the spirochetes is of immense importance in arriving at a diagnosis. They can always be found unless the organ examined is decomposed or the fetus is macerated. (See article by Wm. S. Gottheil, "Progressive Medicine," Sept., 1908.)

Treatment.—In infants mercurial inunctions are to be used until the symptoms disappear, but mercury must not be forced or be continued too long after the symptoms are gone. There must be rubbed into the sole of each foot or the palm of each hand 5 gr. of mercurial ointment every morning and night. Brodie advised spreading the ointment (in the strength of 1 dr. to the ounce) upon flannel and fastening it around the child's belly. If the skin is so tender that mercury must be administered by the mouth, order that $\frac{1}{12}$ to $\frac{1}{8}$ gr. of mercury with chalk, with 1 gr. of sugar, be taken three times a day after nursing. If tertiary symptoms appear, and in any case when the secondaries have passed away, give $\frac{1}{2}$ to 1 gr. or more of iodid of potassium several times a day in syrup. The mixed treatment should be continued intermittently until puberty. Local lesions require local treatment, as in the adult. A syphilitic child should, if possible, be nursed by its mother, as it will poison a healthy nurse, and also because the mother's milk contains antibodies. In some cases the mother is given salvarsan. If the baby has a sore mouth, it must be fed from a bottle, and if the mother cannot nurse the child, it must be brought up on the bottle. For the cachexia use cod-liver oil, iodid of iron, arsenic, and the phosphates. Salvarsan is not given to a syphilitic child under three years of age. It may be given to children over three and under seven and only by intramuscular injection. To a child over seven it may be given intravenously. The dose for a child of seven is 0.2 gm.

XVIII. TUMORS OR MORBID GROWTHS

Division.—Morbid growths are divided into (1) neoplasms and (2) cysts.

Neoplasms.—A neoplasm is a pathological new growth which tends to persist independently of the structures in which it lies, and which performs no physiological function. We say that a tumor performs no physiological function in order to make clear that it is never a useful addition to the economy, but we must not imagine that the cells of every tumor are devoid of physiological activity. As Fütterer ("Medicine," March, 1902) has shown, the cells of a carcinoma of the liver may secrete bile, and even the cells of a secondary focus developing in the course of hepatic carcinoma may also secrete bile. The cells of a tumor may be active, but this activity is not useful and does not con-

stitute physiological function. A hypertrophy is differentiated from a tumor by the facts that it is a result of increased physiological demands or of local nutritive changes, and that it tends to subside after the withdrawal of the exciting stimulus. Further, a hypertrophy does not destroy the natural contour of a part, while a tumor does. Inflammation has marked symptoms: its swelling does not tend to persist, it terminates in resolution, organization, or suppuration, and examination of a section of tissue under the microscope differentiates it from tumor. Inflammation, too, has an assignable exciting cause. A new growth is a mass of newly formed *tissue;* hence it is improper to designate as tumors those swellings due to extravasation of blood (as in hematocele), or of urine (as in ruptured urethra), to displacement of parts (as in hernia, floating kidney, or dislocation of the liver), or to fluid distention of a natural cavity (as in hydrocele or bursitis).

Classes of Tumors.—There are two classes of tumors: the first class includes those derived from or composed of ordinary connective tissue or of higher structures. These all originate from cells which are developed from the mesoblast. There are two groups of connective-tissue tumors: (*a*) the typical, innocent, or benign, which mimic or imitate some connective tissue of the healthy adult human body; and (*b*) the atypical or malignant, which find no counterpart in the healthy adult human body, but rather in the immature connective tissues of the embryo.

The second class of tumors includes those which are derived from or composed of epithelium: (*a*) the typical, or innocent, composed of adult epithelium; and (*b*) the atypical, or malignant, composed of embryonic epithelium.

Müller's law is that the constituent elements of neoplasms always have their types, counterparts, or close imitations in the tissues, either embryonic or mature, of the human body.

Virchow's law is that the cells of a tumor spring from pre-existing cells. There is no special tumor-cell or cancer-cell.

The starting-point of a tumor is a focus of embryonal cells, which focus may have originated before the person was born or may have resulted after birth from some disease or injury. The nature of the tumor depends, first, upon the embryonal layer from which it took origin. Connective-tissue tumors spring from the mesoblast; epithelial tumors spring from the epiblast or the hypoblast. The nature of the tumor depends also upon the stage in which the growth of its cells is arrested. If the cells remain embryonal, the growth is regarded as malignant; if they become fully developed, it is regarded as innocent.

The term "heterologous" is no longer used to signify that the cellular elements of a tumor have no counterpart in the healthy organism, but is employed to signify that a tumor deviates from the type of the structure from which it takes its origin (as a chondroma arising from the parotid gland). Tumors when once formed almost invariably increase and persist, though occasionally warts, exostoses, and fatty tumors disappear spontaneously. Tumors may ulcerate, inflame, slough, be infiltrated with blood, or undergo mucoid, calcareous, or fatty degeneration.

The **causes** of tumors are not positively recognized, those alleged being but theories varying in probability and ingenuity.

The *inclusion theory of Cohnheim* supposes that more embryonic cells exist than are needful to construct the fetal tissues, that masses of them remain in the tissues, and that these embryonic cells may, later in life, be stimulated into active growth perhaps by injury or irritations or hereditary tendency. In other words, Cohnheim believes that all tumors arise from embryonal cells which were included or imprisoned by adult cells during fetal life and were not used during development; or from cells which were "displaced from their proper relations during the process of cell differentiation in the embryo"

(Henry Morris, "Lancet," Dec. 12, 1903). The embryonic hypothesis seems to receive a certain force from the facts that exostoses do sometimes develop from portions of unossified epiphyseal cartilage, and that tumors often arise in regions where there was a suppression of a fetal part, closure of a cleft, or an involution of epithelium (epithelioma is usual at mucocutaneous junctions). This theory does not explain the origin of malignant tumors in scars or recent callus in parts subjected to injury or operation, etc. (Ibid.).

Durante's addition to Cohnheim's theory does explain them. Cohnheim taught that the matrix from which a tumor springs is always an antenatal embryonic area. Durante says a tumor may also spring from a postnatal embryonic area resulting from injury of the mature tissues, lessening their chemical and physiological activities (Morris) and causing them to revert to an embryonic condition.

Objection has been made to the Cohnheim theory on the ground that an embryonal matrix could not remain quiescent, but, as Henry Morris says, certain teeth, the female mammary gland, the larynx, and certain appendages of the skin may not develop until puberty ("Bradshaw Lecture," in "Lancet," Dec. 12, 1903). Branchial cysts which are known to have such an origin are seldom seen until after puberty, and the same is true of many dermoids.

Morris shows that congenital matrices have been shown to exist in the brain, tongue, eye, testicle, ovary, broad ligament, line of coalescence in the trunk, and other places, and such matrices constitute *fetal rests* or *vestiges*. The same author shows that postnatal matrices may arise in the healing of a wound or ulcer, fistula, burns, etc. Portions of epithelium are separated, get placed deeply in the newly forming tissue, become surrounded by connective tissue, and may later take on active growth. As Ribbert points out, any fragment of isolated and imprisoned tissue may become a tumor.

Heredity is an extremely uncertain influence, though not an influence to be denied. I believe that there is such a thing as a more or less complete immunity to cancer and that there is such a thing as a predisposition to cancer, and the predisposition as well as the immunity may be hereditary or acquired. Youth constitutes an almost though not quite certain immunity. Cancer is very rare in youth, and when it does occur in a young person it is always very malignant. Its occurrence means unnatural lack of tissue resistance or unusual vigor of cancer-cell. The retrogressive changes of age are predisposing causes. S. W. Gross found direct hereditary influence by no means frequent in cancer of the breast. From 25 to 37 per cent. of cases of cancer of the breast have or had cancerous relatives (see page 387). Heredity in cancer is affirmed by some, denied by others, and doubted by a number. At most, hereditary influence may only predispose. Nevertheless, cases have occurred which cannot be explained by the term "coincidence." In the celebrated "Middlesex Hospital case," a woman and five daughters had cancer of the left breast. A. Pearce Gould had charge of a woman for cancer of the left breast. The mother of this patient, the mother's two sisters, and two of the mother's cousins had died of cancer. Power reports a remarkable instance of family predisposition to cancer. A patient had his right breast removed for cancer in 1896. In 1897 cancerous glands were removed from the axilla. In 1898 he was seen again with an irremovable recurrent growth. His father died of cancer of the breast. He had two brothers, one of whom died of cancer of the throat when sixty-five years of age, the other having died of cancer of the axilla when he was only twenty-four years old. Of his eight sisters, four died of cancer of the breast, and the two who are living both suffer from cancer of the breast. One sister died when an infant and one died after giving birth to a child.[1] The Emperor Napoleon, his father, his brother Lucien, and his sisters Pauline and Caroline

[1] "Brit. Med. Jour.," July 16, 1898.

died of gastric cancer. That there is such a thing as predisposition is rendered probable by the fact that out of many exposed under like conditions a single one may develop cancer. I believe, with Murphy, that there may be such a thing as absence of resistance to the cause of cancer on the part of certain tissues and that such impairment of resistance may be hereditary.

Injury and *inflammation* may undoubtedly prove exciting causes. A blow is not infrequently followed by sarcoma; the irritation of a hot pipe-stem may excite cancer of the lip; the scratching of a jagged tooth may cause cancer of the tongue; chimney-sweeps' cancer (which used to be seen in the old days when "the sweep" was an institution) arose from the irritation of dirt in the scrotal creases; and warts often arise from constant contact with acrid materials.

Physiological activity favors the development of sarcoma, and *physiological decline* favors the development of carcinoma.

Parasitic Influences.—Many believe that parasites cause cancer. This theory does not maintain that the tumor is the parasite, but that it contains the parasite, although Pfeiffer and Adamciewicz did at one time assert that a cancer-cell is not a body-cell, but a parasite resembling an epithelial cell. Butlin in 1905 asserted his belief that the cancer-cells are parasites and act independently like protozoa. Most observers deny this contention because, were it true, there would be only one variety of cancer, because cases could only arise by direct contact, and because it would leave unanswered how the original growth arose, as it could not have come from a pre-existing cancer-cell (Brand, in "Lancet," Jan. 11, 1908). Some facts render a parasitic origin of malignant growths not improbable; as, for instance, the likeness of some tumors to infective granulomata, the tendency to secondary development in distant parts of the body, the resemblance of the secondary to the primary growths, and the tenacity of their persistence. A parasitic origin of cancer is possibly suggested by its geographical distribution, the disease being very common in low and marshy districts, and Haviland ("Lancet," April 27, 1894) and others maintain that certain houses become infected, the disease appearing in these houses among successive families inhabiting them. They speak of such abodes as *cancer-houses*.

Some surgeons believe that cancer is contagious, but most observers deny it. Hanau found a rat with a cancer and inoculated other rats from it. Moreau in 1894 inoculated mice from a mouse with cancer. Guelliott, of Rheims, believes that cancer is primarily a local infection. He believes this because Moreau and Hanau have inoculated it from one animal to another of the same species, and if this can be brought about experimentally he sees no reason why it cannot happen accidentally. This surgeon says that cancer is very unequally distributed, that genuine cancer-centers and "cancer-houses" exist, and that numerous cases of accidental infection have occurred.[1] Hahn apparently succeeded in grafting cancer from one part to another on the same individual. Jensen and Borrell have inoculated the disease in white mice. Mayet, of Lyons, holds that cancer can be reproduced by grafting or by injection of cancer-fluid. Graf could not find "cancer-houses" after a careful search.[2] Because several people, in the course of years, have died in the same house of cancer is not proof that the house was infected. If such a thing proves contagion there must be contagion in many things now thought free from it, and there must be broken-leg houses, and delirium-tremens houses, and heart-disease houses. Geissler claims to have produced the disease in a dog by planting fragments of cancer in the subcutaneous tissue and vaginal tissue, but Czerny, Rosenbach, and others dispute the claim. Plimmer tells

[1] "Amer. Jour. of Med. Sciences," June, 1895.
[2] "Archiv. f. klin. Chir.," 1895, l, p. 144.

us that an epidemic of cancer arose among the captive white rats in the Freiburg Pathological Institute, and in each case the growth was on the rear part of the body. Roswell Park believes that Gaylord has really produced adeno-carcinoma in the lower animals. Hauser disputes the assertion that cancer must be an infectious disease because it is followed by secondary growths. Secondary growths in an infectous disease are caused by the bacterium; secondary growths in cancer are caused by the transference of cells of primary growth.[1] Hauser says with truth that the close connection between innocent and malignant growths renders the parasite view untenable, because to hold it we would be forced to believe that every tumor has a special parasite or that one parasite may cause many kinds of tumors.

There seems to be no doubt that autotransference of cancer can occur, although it rarely does so. Sippel has reported a case in which vaginal carcinoma developed at the point where the vagina was in contact with a pre-existing cancer of the portio.[2] Cornil has seen cancer transferred from one of the labia majora to the other, and from one lip to the other. Geissler was unable to transplant cancer, and Gratia also failed in his attempts. Duplay and Bazin say that transmissibility is possible, but only under conditions which are not practically realized. The facts that transplantation can be sometimes carried out, and that contagion is a possible occurrence under exceptional circumstances, do not prove that cancer is a parasitic disease, but simply prove that it can be transplanted. It is not that the cancer carries a parasite which will cause the disease in sound tissues, but rather that the cells of the cancer may themselves take root and grow in sound tissues. The parasitic theory arose from observation of the metastasis which occurs during the progress of the disease, and received support from the fact that inoculation of another part of an individual suffering from cancer may be followed by the development of a tumor like the original growth. For instance, if a cancer is growing upon the lower lip, the upper lip may be inoculated (*contact cancer*). The same is true of the labia. Mr. Harrison Cripps reported the occurrence of cancer of the skin of the arm from contact with an ulcerating scirrhus of the breast. It has also been pointed out that carcinoma is especially common in regions predisposed by their situation to injury and infection, and that, "among the lower animals at least, tumors resembling carcinomata have been transplanted from one to another" ("Recent Studies upon the Etiology of Carcinoma," by Joseph Sailer, "Phila. Med. Jour.," June 7, 1902). But there is great doubt as to the cancerous nature of some of the tumors which have been successfully transplanted from one animal to another.

A transplanted mouse cancer may grow for a time and then completely disappear, and some observers (among them Gaylord) hold that when this occurs the mouse has become immune.

In 1908 the German Pathological Society met in Kiel and discussed various problems of cancer. In this meeting Sticker maintained that there is such a thing as natural immunity to tumors. He showed that a tumor arising spontaneously in an animal can never be transplanted into an animal of another species, and very seldom can a malignant tumor be transplanted into an animal of the same species. He quotes Metchnikoff's utter failure to transplant human tumors into anthropoid apes and reports his own failure to transplant human tumors into various domestic animals. He made over 400 trials and failed every time ("Jour. Am. Med. Assoc.," from Sticker, "Zeitschr. f. Krebsforschung," 1908, vii).

In successful transplantations there has been but slight effort to prove that epithelial cells were not transferred with the supposed parasites, and if they

[1] Hauser, in "Biolog. Centralbl.," Oct. 2, 1895.
[2] "Centralbl. f. Gynak.," No. 4, 1894.

were transferred the success of the experiment does not prove that cancer is due to parasites, but simply proves again what we knew before—that epithelial cells can be transplanted. Many parasites have been regarded as causative by different observers. Bacteria, yeast-cells, and protozoa have been found by different experimenters. It is not thought that bacteria are causative. Yeasts are regarded as causative by some. It is certain that they may exist in cancer, but it is by no means certain that they cause the disease. They may be only a contamination. Gaylord and others regard protozoa as causative, but this statement does not seem to be proved. Many of the supposed parasites of cancer have been shown to be cell degenerations or contaminations. We are justified in concluding that the parasitic origin is not as yet proved, and we agree with the elder Senn that it is improbable.

Tillmanns elaborately discussed the subject of cancer in the Congress of 1895. His conclusions are still most sound and scientific. He says there is no evidence of a bacterial origin of cancer. The parasitic origin has not been proved, and protozoa have not certainly been found. Cancer can be transferred from one part to another of the same individual, or from one individual to another of the same species, but never to one of a different species. It is possible that cancer can spread by contagion; this is very rare, but can happen (as when penile cancer is followed by cervix cancer in a wife). Because it is sometimes possible to transfer cancer, this does not prove that the disease is parasitic or infectious; it simply shows that *tissue* has been successfully transplanted.

Cancer à deux is cancer developing in people who live together. Such cases suggest, but do not prove, contagion. Behla collected 19 cases and Guelliot 103 cases. *Conjugal cancer* is classified as cancer à deux. A wife, for instance, may have cancer of the womb and a husband may develop cancer of the penis, supposedly from contact. Conjugal cancer is probably due to irritation or implantation and not to microbic inoculation.

Actinomycosis, long thought to be a true tumor, is now known to arise from the ray-fungus. Some think that psorosperms cause cancer. There can be no doubt that changes in the liver which practically constitute a new growth can arise from the growth of a cell called by Darier the "psorosperm." A disease due to psorosperms is called a "psorospermosis." It is affirmed by some that molluscum contagiosum, follicular keratosis, cancer, and Paget's disease are due to psorosperms. Some claim to find the parasite in all cases of cancer, while others can find it in only 4 or 5 per cent. of the cases.

Heneage Gibbes affirms[1] that dilatation of the bile-ducts of a rabbit's liver is caused by the chronic irritation arising from multiplication of the Coccidium oviforme in them, and not in the columnar cells of the bile-ducts, as has been stated; and, further, that the large majority of glandular cancers show nothing that can be considered parasitic, the suspicious appearances noted in some few cases being due to endogenous cell formation. The Coccidium oviforme is a genus of the sporozoa, class protozoa, the lowest division of the animal kingdom. To this case belong the monera and unfusoria. (For a further discussion of this subject see page 55.)

Malignant and Innocent Tumors.—Malignant growths infiltrate the tissues as they grow; benign tumors only push the tissues away; hence malignant tumors are not thoroughly encapsuled, while innocent tumors are encapsuled. Malignant tumors grow rapidly; innocent tumors grow slowly. Malignant tumors become adherent to the skin and cause ulceration; innocent tumors rarely adhere and seldom cause ulceration. Many malignant tumors give rise to secondary growths in adjacent lymphatic glands (cancer, except in the esophagus and antrum of Highmore, always does so; sarcoma rarely

[1] "Amer. Jour. of Med. Sciences," July, 1893.

causes them, unless the growth be melanotic or lymphosarcoma, or unless it arises in the testicle or tonsil). Innocent tumors never cause secondary lymphatic involvement; although the glands near the tumor may enlarge from accidental inflammatory complications. The malignant tumors, especially certain sarcomata and soft cancers, may be followed by secondary growths (metastases) in distant parts and various structures (bones, viscera, brain, muscles, etc.); innocent tumors are not followed by these secondary reproductions, although multiple fatty tumors or multiple lymphomata may exist. Malignant tumors destroy the general health, inducing anemia and cachexia; innocent tumors do not, unless by the accident of position. Malignant tumors tend to recur after removal; innocent tumors do not if operation was thorough. The special histological feature of a malignant growth is the possession by its cells of a power of reproduction which knows no limit, the cells of the tumor living among the body-cells like a parasite and invading and destroying the body-cells.

The Cachexia of Malignant Disease.—This condition arises sooner or later in every uncured case of sarcoma and carcinoma.

In sarcoma there is advancing anemia and there are often episodes of elevated temperature due to the absorption of toxic materials from the tumor. The blood examination gives results similar to those found in cancer, but leukocytosis is more frequent. Pain is far less prominent than in cancer unless a nerve is involved or squeezed. Ulceration occurs much later in sarcoma than in carcinoma.

In carcinoma (see page 382) the emaciation is rapid and decided, the loss of strength is significant and notable, and the anemia is marked and progressive. It is due to pain, sleeplessness, ulceration, impaired appetite and digestion, repeated hemorrhages, and the absorption from the tumor of toxic products, which are probably enzymes (especially isohemolysins). Loss of hemoglobin is early and is followed by decrease in the number of red cells. In many cases considerable amounts of sugar exist in the blood. Irregular fever may occur. In both sarcoma and carcinoma the development of secondary growths aggravates the anemia.

Classification.—Tumors may be classified as follows:

I. Connective-tissue tumors (those derived from the mesoblast).

1. Innocent tumors, or those composed of mature connective tissue:
   Lipomata, or fatty tumors; *fibromata*, or fibrous tumors; *chondromata*, or cartilaginous tumors; *osteomata*, or bony tumors; *odontomata*, or tooth-tumors; *myxomata*, or mucous tumors; *myomata*, or muscle-tumors; *neuromata*, or tumors upon nerves; *gliomata*, or tumors composed of neuroglia; *angiomata*, or tumors formed of blood-vessels; *lymphangiomata*, or tumors formed of lymphatic vessels. The term *lymphoma*, meaning a tumor of a lymphatic gland, was formerly applied to hypertrophy and hyperplasia of a lymphatic gland, no matter whether caused by syphilis, tubercle, Hodgkin's disease, or any other morbid impression. The term has been largely abandoned except as expressing enlargement of a gland, and does not convey any suggestion as to the cause. It is doubtful if there is such a thing as a true lymphoma, understanding by the term a neoplasm arising from and composed of lymphoid cells and resembling lymphatic structure. In the described cases the possibility of infection as a cause has not been eliminated.
2. Malignant tumors, or those composed of embryonic connective tissue:
   Sarcomata and adrenal tumors.
   Endotheliomata are regarded by some as constituting an independent group and by others as a variety of sarcomata.

II. Epithelial tumors (those derived from the epiblast or hypoblast).
  1. Innocent tumors, or those composed of mature epithelial tissue: *Adenomata*, or tumors whose type is a secreting gland; and *papillomata*, or tumors whose type is found in the papillæ of skin and mucous membranes.
  2. Malignant tumors, or those composed of embryonic epithelial tissue: *Carcinomata*, or cancers.

III. Cystomata are cystic tumors, the cyst-walls of which are new growths and the contents of which are produced by the cells of the newly formed cyst walls.

IV. Teratomata (tumors containing epiblastic, hypoblastic, and mesoblastic elements).

Innocent Connective=tissue Tumors.—These growths mimic or imitate some connective tissue or higher tissue of the mature and healthy organism.

Lipomata are congenital or acquired tumors composed of fat contained in the cells of connective tissue, which cells are bound together by fibers. If

Fig. 140.—Lipoma, wandered from axilla.

Fig. 141.—Diffuse lipoma.

the fibers are excessively abundant, the growth is spoken of as a *fibrofatty tumor.* A fatty tumor has a distinct capsule, tightly adherent to surrounding parts, but loosely attached to the tumor; hence enucleation is easy. Fibrous trabeculæ run from the capsule of a subcutaneous lipoma to the skin; hence movement of the integument over the tumor or of the tumor itself causes dimpling of the skin. An ordinary circumscribed lipoma is of doughy softness, is lobulated, of uniform consistence, and on being tapped imparts to the finger a tremor known as pseudofluctuation. A fatty tumor is mobile, although it may be attached to the skin at points by trabeculæ. Sometimes a fatty tumor gradually shifts its position or wanders (Fig. 140). This is due to gravity. Lipomata are most frequent in middle life, and their commonest situations are in the subcutaneous tissues, especially of the back or of the dorsal surfaces of the limbs; they usually occur singly, but may be multiple and sometimes symmetrical. Senn described the case of a woman who had a fatty tumor in each axilla. A lipoma may grow to an enormous size (in Rhodius's case the tumor weighed 60 pounds), and the growth may be progressive or may be at times stationary and at other times active. The skin over a fatty tumor

sometimes atrophies or even ulcerates; the tumor itself may inflame or partly calcify. When a lipoma has once inflamed, it becomes immovable. Subcutaneous lipoma of the palm of the hand or sole of the foot bears some resemblance clinically to a compound ganglion; it is apt to be congenital. Lipomata of the head and face are rare. In the subcutaneous tissues of the groins, neck, pubes, axillæ, or scrotum a mass of fat may form, unlimited by a capsule and known as a *diffuse lipoma* (Figs. 141 and 143). A diffuse lipoma may dip down among the muscles. Such masses attain large size. The typical diffuse lipoma is occasionally seen on the neck. It begins back of the mastoid process on one side or on both sides. When large, it completely surrounds the neck, a huge double chin forming in front, a great mass hanging on each side, and the posterior portion being divided into two halves by a median depression. A *nevolipoma* is a nevus with much fibrofatty tissue. A very vascular fatty tumor is called *lipoma telangiectodes*. If the tumor stroma contains large veins

Fig. 142.—Lipoma of submaxillary region.

Fig. 143.—Congenital diffuse lipoma of foot and leg. Child seven years of age, second and third toes amputated at thirteen months and large mass moved from sole of foot. Later a large fatty mass moved from calf of leg, surrounding gastrocnemius and soleus muscles and between them (Rugh).

the growth is called a *cavernous lipoma*. A tumor containing much blood can be diminished in size by pressure. Fatty tumors may arise in the subserous tissue, and when such a growth arises in either the femoral or inguinal canal or the linea alba it resembles an omental hernia and is spoken of as a *fat-hernia*. In the retroperitoneal tissues enormous fibrofatty tumors occasionally grow, and these neoplasms tend to become sarcomatous. Lipomata which arise from beneath synovial membranes project into the joints, being still covered by synovial membrane. Fatty tumors occasionally arise in submucous tissues, between or in muscles, from periosteum, and from the meninges of the spinal cord (Sir J. Bland-Sutton). A fatty tumor may undergo metamorphosis. The stroma may be attacked by a myxomatous process or a calcareous degeneration. The fat-cells themselves may become calcareous. Oil-cysts sometimes form. A *xanthoma* is a growth composed of fatty tissue in and about which

there is marked infiltration with small cells. Such a tumor is flattened and slightly elevated. Several or many of these growths occur in the same person. The eyelids are the most common seat of xanthoma. The tumor may undergo involution or may become sarcomatous.

Diabetics are liable to develop xanthomata.

Treatment.—A single subcutaneous lipoma should be extirpated. The capsule must be incised, when the tumor is torn out forcibly or, better, is enucleated by dissection; drainage is always employed for twenty-four hours, as butyric fermentation will be apt to occur, and necrosis of small particles of fat predisposes to infection. Multiple subcutaneous lipomata, if very numerous, should not be interfered with unless troublesome because of their size or situation, when the growth or growths causing trouble should be removed. It is difficult to extirpate entire a diffuse lipoma, and several operations may be needed to effect complete removal. Liquor potassæ, once recommended as possessing power, when taken internally, to limit the growth of multiple lipomata or diffuse lipoma, seems to be useless. Subperitoneal

Fig. 144.—Fatty tumor.

lipomata are rarely diagnosticated until the belly has been opened, sometimes not until the growth has been removed.

Fibromata are tumors composed of bundles of fibrous tissue. There are two forms, the hard and the soft. A *hard fibroma* consists of wavy fibrous bundles lying in close contact. Here and there connective-tissue corpuscles exist between the fibers. A fibroma has no distinct capsule, though surrounding tissues are so compressed as to simulate a capsule. Fibromata are occasionally congenital, are most usual in young adults, but they may occur at any period of life, and in any part of the body containing connective tissue. Pure fibromata, which are rare, are generally solitary, grow slowly, are of uniform consistence, have not much circulation, and are hard and movable. Fibromata may form upon nerve-sheaths, may arise in the mammary gland, may develop in the lobe of the ear, and may spring from various fibrous membranes, from the periosteum of the base of the skull (*nasopharyngeal fibromata*), and from the gums (*fibrous epulides*). A *soft fibroma* contains much areolar tissue, the spaces of which are filled with fluid, so that the tissue seems

edematous. Soft fibromata grow from the skin, mucous membrane, subcutaneous tissue, intermuscular planes, and periosteum. Soft fibromata possess distinct pedicles and are especially apt to arise from the skin of the scrotum, labia, inner surface of arm and thigh, and from the belly wall of a pregnant woman. They are not unusually multiple, grow slowly, but more rapidly than the hard fibromata, and may become quite large. Fibromata may become cystic, calcareous, osseous, colloidal, or sarcomatous, and may inflame, ulcerate, or even become gangrenous.

A *painful subcutaneous tubercle*, which is a form of fibroma commonest in females, arises in the subcutaneous cellular tissue, usually of the extremities. It is firm, very tender, movable, rarely larger than a pea, and the skin over it seems healthy. Violent pain occurs in paroxysms and radiates over a considerable area, of which the tubercle is the center. These paroxysms may occur only once in many days or many times in one day. Pain is always developed by pressure, and may be linked with spasm. Nerve-fibrillæ are now known to exist in these tubercles, a fact which was long denied.

A *mole* is a fibroma of the skin which is congenital or appears in the early weeks of life. It is rounded or flat, is usually pigmented and of a brown color, is slightly elevated above the cutaneous level, and has a few hairs or an abundant crop of hair growing from it, and varies in size from a pin's head to several inches in diameter, or may even occupy an extensive area of a limb or of the trunk. The tumor rarely grows after the thirteenth or fourteenth year. A mole may become malignant, melanotic carcinoma may arise from its epithelial structures, or melanotic sarcoma from its connective-tissue elements. A mole is an extremely vascular structure; it bleeds freely when cut or scratched, and it sometimes ulcerates. Occasionally several or many moles exist in the same individual. If a mole begins to increase rapily in size, operation is imperative, as rapid growth probably indicates malignant change.

Fibrous epulis is a fibroma arising from the gums or periodontal membrane (Sir J. Bland-Sutton) in connection with a carious tooth or retained snag; it is covered by mucous membrane, grows slowly, may attain a large size, and sometimes has a stem, but is more often sessile. It may undergo myxomatous change or may become sarcomatous.

Fibrous tumors may arise from the ovary, the intestine, the larynx, and the submucous tissues of the gastro-intestinal tract. Pure fibromata of the uterus are very rare, but fibromyomata are very common (see Myomata, page 361); hence the term "uterine fibroid" should be abandoned.

Desmoid tumors of the abdominal wall are cellular fibromata. A desmoid tumor has a strong disposition to become sarcoma. It has no real capsule. It takes origin from one of the abdominal muscles or muscular insertions or from fascia, particularly from the rectus muscle or its sheath. In most cases the growth is slow; in some it is rapid and the tumor may attain a great size. It may project either anteriorly or toward the abdomen. This form of tumor is vastly more common in women than in men and is especially common in women who have borne children. It may occur at any age, but is most frequent in those between twenty-five and thirty-five. It is a very rare tumor. (See Harvey B. Stone, "Annals of Surgery," August, 1908.)

Molluscum fibrosum is an overgrowth of the fibrous tissue of both the skin and subcutaneous structure. Senn excludes this form of growth from consideration with fibromata because of its supposed infective origin. It may be limited or widely extended; it may appear as an infinite number of nodules scattered over the entire body or as hanging folds of fibrous tissue in certain areas.

Keloid (Figs. 145, 146) is a fibroma of the true skin. It is a hard and fibrous vascular growth, with a broad base, arising in scar-tissue; it is crossed by pink, white, or discolored ridges, and is named from a fancied likeness to

the crab. It has rarely attacked mucous membrane. It is more common in negroes than in whites, and is most frequent in the cicatrices of burns, though it may arise in the scar of any injury, as the scar from piercing the ears, and in the scars of syphilitic lesions, tuberculous processes, smallpox, or vaccination. I believe that the scars of tuberculous lesions and the scars even of ordinary wounds in tuberculous individuals are particularly apt to become keloidal. It is very common in a person with keloid to be able to find some near or distant tuberculous lesion, or a history of former tuberculosis, or the record of the individual having tuberculous tendencies. The victim of keloid usually reacts to tuberculin. The growth seldom begins in early childhood or in old age. It grows slowly, lasts for many years, and may eventually undergo involution and disappear. The fact that keloid is especially common in the negro race (a race predisposed to tuberculosis) and that it is so frequently met with in the scars of known tuberculous processes, suggests the possibility of a tuberculous cause for the condition. The rapid return of keloid after operation suggests a near or distant infection which furnishes material to a point of least resistance which causes keloid to redevelop. Some cases of keloid

Fig. 145.—Keloid following a burn.

Fig. 146.—Keloid (case of Dr. L. L. Hill, Montgomery, Alabama).

have active tuberculous lesions, others have had them, in still others latent or distant lesions may be found by careful search. In many cases there is a family history of tuberculosis. I am at present investigating this important matter. It is certain that the keloid itself does not contain bacteria. Repeated examinations have failed to find them. It is quite possible that the growth contains toxins of tubercle bacilli, the toxins being the irritant cause. I am now seeking to determine if material from keloid introduced into tuberculous animals will cause a reaction. It is usually believed that it is almost useless to remove keloid by operation, as it will almost certainly return, yet a study of the growth removed shows no reason for the inevitable return. Charles A. Porter has reported a case of massive keloid of the face and hands notably benefited by many operations and skin-grafting. In this case, Porter says, "there has been a gradual but distinct abatement of the tendency to form keloid tissue" ("Annals of Surgery," July, 1909). The fibrous tissue of keloid

springs from the outer walls of the blood-vessels. The papillæ of the skin above the tumor are destroyed or replaced by fibrous tissue.

Morphea, spontaneous or true keloid, is a name used to designate a growth of this description which does not arise from a scar; but it seems certain that scar-tissue was present, though possibly in small amount from trivial injury.

Fibrous and papillomatous growths covered with endothelium may spring from any serous membrane. Such a growth of the choroid plexus calcifies early and constitutes a *psammoma* or brain-sand tumor. Such tumors are met with not only in the choroid plexus, but also in the conarium and the dura. All psammomata are not fibrous; some are gliomatous and some are endotheliomatous. A *cholesteatoma* is a fibrous growth covered with endothelium and containing layers of crystalline fat. It occurs especially in the pia mater, but may arise in either of the other membranes or even in the brain substance, and is called a *pearl tumor*.

Treatment.—Fibromata should not be let alone, because any fibrous tumor may become a sarcoma. When in accessible regions they should be enucleated. If a hard fibroma of the skin exists the skin is incised and the tumor is "shelled out. "A soft fibroma is removed by an incision carried around the base of its pedicle. A painful subcutaneous tubercle should be excised. If a mole shows the slightest disposition to enlarge, or if it is subjected to pressure or irritation, it should be removed, because if allowed to remain it might develop into a malignant growth. It is often desirable to remove a hairy or pigmented mole, not only because it may become malignant, but also because it is unsightly. A mole, if not too large, may be removed by a 30-second application of solid carbonic acid. This destroys hair and often causes pigment to disappear. Many moles are best treated by excision. Fibrous epulis requires the cutting away of the entire mass, the removal of the related snag or carious tooth, and sometimes the biting away of a portion of the alveolus with rongeur forceps. A nasopharyngeal fibrous polyp often contains sarcomatous elements or develops into a spindle-celled sarcoma. If the polyp is recent and has a pedicle it may be removed by the cautery loop. Most cases require extirpation, the surgeon cutting wide of the growth. In a severe case a part of the superior maxillary bone is removed by osteoplastic resection to permit of extirpation. Keloid should rarely be operated upon: it will almost certainly return, and will also develop in the stitch holes. Trust to time for involution, or use pressure with flexible collodion, by which method J. M. DaCosta cured a case following small-pox. It may be necessary to operate because of ulceration. If it is necessary to operate, remove the keloid and considerable adjacent tissue and fill the gap with Thiersch grafts. The administration of thyroid extract may be of benefit (a 5-gr. tablet three or four times a day). This drug must be given cautiously, as it may cause attacks characterized by fever, dyspnea, and rapid pulse. Thiosinamin hypodermatically has been used, it is claimed, with benefit. A 10 per cent. solution is made, and from 10 to 15 min. can be injected into the gluteal muscles every third day. I have seen two keloids cured by the use of the *x*-rays.

Chondromata (*enchondromata*) are tumors formed either of hyaline cartilage, of fibrocartilage, or of both. Chondromata are apt to arise from certain glands, the long bones, the pelvis, the rib cartilages, and the bones of the hands or feet, and often spring from unossified portions of epiphyseal cartilage. They may be single or multiple, and are most commonly met with in the young. They have distinct adherent capsules; they grow slowly, and if of osseous origin progressively hollow out the bones by pressure; they cause no pain; they impart a sensation of firmness to the touch, unless mucoid degeneration forms zones of softness or fluctuation; they are inelastic, smooth or nodular, immovable, and often ossify. A chondroma may grow to an enor-

mous size. A chondroma of the parotid gland or testicle practically always contains sarcomatous elements, and any chondroma may become a sarcoma. Chondromata are notably frequent in persons who had rickets in early life. *Ecchondroses*, which are "small local overgrowths of cartilage" (Sir J. Bland-Sutton), arise from articular cartilages, especially of the knee-joint, and from the cartilages of the larynx and nose. Loose or floating cartilages in the joints may be broken-off ecchondroses or portions of hyaline cartilage which are entirely loose or are held by a narrow stalk, and which arise by chondrification of villous processes of the synovial membrane; only one or vast numbers may exist; one joint may be involved or several; they may produce no symptoms, but usually produce from time to time violent pain and immobility by acting as a joint-wedge. An ecchondroma may arise within the medullary canal of a long bone, from foci of dormant cartilage, and may lead to the development of a *solitary cyst* of large size by softening of the tumor. The femur is the most usual site of solitary cyst. It begins very insidiously and progresses gradually. There are slight lameness, trivial pain, tenderness below the level of the trochanter, apparent shortening, and some bulging of bone. The bone may bend or at some spot may thin so that the cyst can be felt. Such a bone fractures from slight force, and after a fracture, when the effused blood and inflammatory exudate have been absorbed, a tumor can be distinctly detected. A solitary cyst of a long bone is apt to be regarded clinically as a sarcoma (Bergmann-Virchow).

Fig. 147.—Osteoma of femur.

Treatment.—Remove chondromata whenever possible, for, if allowed to remain undisturbed, they are apt to resent this hospitality by becoming sarcomatous. A chondroma of the testicle and of a salivary gland is sure to be sarcomatous. In an ordinary chrondroma incise the capsule and take away the growth, using chisels and gouges if necessary. Incomplete removal means inevitable recurrence. Amputation is very rarely demanded. In chondrosarcoma incision must be outside of the capsule. Loose bodies in the joints, if productive of much annoyance, are to be removed, the joint being opened with the strictest antiseptic care. Amputation is sometimes performed for a solitary cyst of a long bone, the surgeon having looked upon the growth as sarcomatous. If a correct diagnosis is arrived at, an attempt should be made to remove the cyst without amputation. Bergmann succeeded in extirpating such a mass from the femur.

Osteomata are tumors which are composed of osseous tissue. Sir J. Bland-Sutton says that osteomata are ossifying chondromata. Osteomata take origin from bone, cartilage, connective tissue, especially tissue near the bone, serous membrane, and certain glands and organs. Compact osteomata, which are identical in structure with the compact tissue of bone, arise from the frontal sinus, mastoid process, external auditory meatus, and other regions in those beyond middle life; they are small, smooth, round, densely hard, with small and occasionally cartilaginous bases.

Cancellous osteomata, which comprise the great majority of bone-tumors,

are similar in structure to cancellous bone. They spring from, and are crusted with, cartilage; they may have fibrous capsules, and are often movable when

Fig. 148.—Osteoma of humerus.

recent, but soon become fixed; they have broad bases, are angled, nodular, firm (but not so hard as are the compact osteomata), painless except when pressed, occur particularly at the ends of long bones (Figs. 147 and 148), may grow to large size, and are commonest in youth. Osteomata near joints become overlaid by bursæ, which in rare instances communicate with an adjacent joint.

Fig. 149.—Osteophyte of os calcis.

Osteomata do not tend to become malignant and do not recur after removal. The term *exostosis* or *osteophyte* has been used as being synonymous with osteoma, but wrongly so, as an exostosis is an irregular, local, bony growth which does not tend to progress without limit, and which is, hence, not a tumor. A true exostosis is seen in the ossification of a tendon insertion (Fig. 149), in a limited growth from one of the maxillary bones, and in a local growth from the last phalanx of the big toe, which latter form of growth is known as a *subungual exostosis*. *Osteophytes of the retrocalcaneal bursa* occasionally form when this bursa is inflamed. Inflammation of this bursa is

known as *Achillodynia,* or *Albert's disease.* The bony masses sometimes found in the brain, lungs, testicles, various glands, and tumors are not true osteomata. Osteophytes may arise in a joint in various forms of arthritis.

Multiple exostoses (Figs. 150, 151) are rare and depend upon some anomaly in and ossification of temporary cartilage. They arise during the period of active growth of bone. Volkmann and others assigned rickets as the cause. Virchow looked upon the condition as hereditary. Lippert traced the condition through four generations, but hereditary influence is not always evident. Tuberculosis has nothing to do with their development. One, several, or many of the growths may diminish in size or even disappear (Bruns, "Beiträge," xxxiv, 1902). In Oberndorf's case many tumors disappeared, but none after maturity ("New York Med. Jour.," March 5, 1910). This patient had syringomyelia and acromegalic symptoms, causing one to think of Charcot's statement that the gray matter of the cord contains the center for the nutrition of the bone. Exostoses within the cranium or spinal canal may cause symptoms from irritation or from pressure.

Treatment.—Osteomata which are non-productive of pain or trouble do not demand removal. If they produce pain by pressure, if they press upon important structures, if they cause annoying deformities, or if they grow rapidly, then remove them by means of chisels, gouges, or the surgical engine.

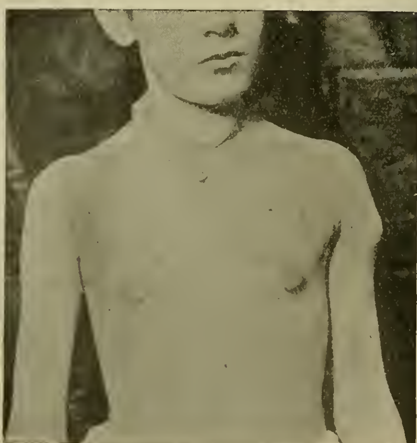

Fig. 150.—Multiple exostoses.

Fig. 151.—Multiple exostoses. Hundreds of them throughout the body.

Subungual exostosis should always be removed. The nail should be split and part of it taken away, and the bony mass be gouged away or be cut off with forceps.

Odontomata[1] are tumors composed of tooth-tissue. They spring from the germs of teeth or from developing teeth. Sir J. Bland-Sutton divides them into (1) those springing from the follicle; (2) those springing from the papilla, and (3) those springing from the whole germ.

[1] This section is abridged from Sir. J. Bland-Sutton's striking chapter upon Odontomes in his work on "Tumors."

Epithelial odontomes, or **multilocular cystic tumors,** arise from the follicle, occur oftenest in the lower jaw, dilate the bone, have capsules, and are made up of masses of cysts which are filled with brown fluid. These cysts are met with most frequently before the age of twenty. *Follicular odontomes*, or *dentigerous cysts* (Fig. 152), oftenest spring from the follicles of the permanent molars. In a dentigerous cyst there exists an expanded follicle which distends the bone, the follicle being filled with thick fluid and containing a portion of a permanent tooth. When a follicular odontome is discovered after the time of second dentition the patient is short one or more permanent teeth. The corresponding milk teeth may be retained. The position of the portion of the tooth is variable. It is usually just beneath the orbit. In a case operated on in the Jefferson Clinic the tooth was in this situation. A *fibrous odontome* is due to thickening of the tooth-sac, which prevents eruption of the tooth; fibrous odontomes are usually multiple, and are apt to occur in rickety children. A *cementome* is due to enlargement, thickening, and ossification of the capsule, the developing tooth being encased in cement. A *compound follicular odontome* is due to ossi-

Fig. 152.—Dentigerous cysts removed from upper jaw of a negro. Both in the right side. Contained portions of undeveloped teeth.

fication of portions only of an enlarged and thickened capsule, and the tumor contains bits of cementum, portions of dentin, or small misshaped teeth. A *radicular odontome* springs from the papilla and arises after the crown of the tooth is formed and while the roots are forming; hence it contains dentin and cement, but no enamel. *Composite odontomes* are formed of irregular, shapeless masses of dentin, cement, and enamel. All the above forms occur in man. They present themselves as hard tumors associated with teeth or in an area where teeth have not erupted. Occasionally an odontome simulates necrosis; it is surrounded by pus, and a sinus forms.

Treatment.—The diagnosis is now usually possible by the aid of the *x*-rays. Be in no haste to excise large portions of bone for a doubtful growth; incise first and see if it be an odontome, which usually requires only the removal of an implicated tooth, curetting with a sharp spoon, and packing with iodoform gauze.

Myxomata are tumors composed of mucous tissue. They are rare as independent growths, although myxomatous change is frequent in the stroma of other tumors. The tissue type of these tumors is found in the vitreous

humor of the eye and in the perivascular tissues of the umbilical cord (Wharton's jelly). Bowlby states that myxomata are, in reality, soft fibromata whose intercellular substance has been replaced by mucin. The myxomatous state may be a stage in the formation of a fibroma, a stroma not having developed. Myxomata may result from myxomatous degeneration of cartilage, of muscle, or of fibrous tissue. These tumors are soft, elastic, usually pedunculated, tremulous, and vibratory. The stroma is very delicate and carries minute blood-vessels. Cutting into a myxoma causes a straw-colored, clear jelly to exude. Myxomata grow slowly, are encapsuled, have but little circulation, and the diagnosis may be impossible before removal of the growth. Some pathologists place myxomata among the malignant tumors, but most consider them as benign tumors, though they tend strongly to become sarcomatous (*myxosarcomata*). A sarcoma may undergo myxomatous degeneration.

Myxomata may arise from the skin; from the mucous membrane of the nose, the frontal sinus, the antrum, the womb, the auditory meatus,' and the tympanum (*gelatinous polypi*); from the parotid and mammary glands; from the subcutaneous tissue, the nerve-sheaths, the intermuscular septa, the rectum, and the bladder (polyps). They may be congenital, but occur most often in young adults, as a result of inflammation. A sudden increase of growth indicates beginning malignancy (sarcomatous change). When a tumor begins to undergo myxomatous transformation we give to it a compound name; for instance, a chondroma undergoing myxomatous change is a chondromyxoma, a fibroma undergoing a like change is a fibromyxoma, etc. *Mucous polypi* grow from the mucous membrane of the nose, particularly from the outer wall near the middle turbinated bone, and often from the roof of the nares. Mucous polypi are soft and jelly-like, of a grayish color, and have stems or peidcles; they may be seen through the anterior nares, may project behind the veil of the palate, and may bulge out from the passages of the nose; they may be, and usually are, multiple; they may be present in one nasal fossa or in both; and they occur most commonly in youths and adults between the ages of fifteen and thirty-five years.

Hydatid moles of pregnancy are due to myxomatous changes in the chorion.

Treatment.—In treating myxomata, remove them promptly and thoroughly, because of the danger of sarcomatous change. Polypi of the bladder are removed by means of cutting forceps after suprapubic cystotomy has been performed. Nasal polypi may usually be twisted off or be removed by the wire snare or galvanocautery. Occasionally when the growths are numerous and recur rapidly after removal, the inferior turbinated bones should be removed with a saw (Rouge's operation). This operation secures ready access to the area of disease, which can be attacked radically. A very soft myxoma breaks up when removal is attempted, and the base must be cauterized.

Myomata are tumors composed of unstriped muscle-fiber mixed often with fibrous tissue. They are called *leiomyomata*. Tumors composed of striated muscle-fiber and spindle-cells are known as *rhabdomyomata*. They are very rare and are always sarcomatous. Leiomyomata are found in the womb, in the prostate gland, in the walls of the gullet, vagina, stomach, bladder and bowel, in the broad ligament, ovary and round ligament, in the scrotum, and in the skin. Myomata usually begin during or after middle age; they are encapsuled, they grow slowly, they are firm and hard, and produce annoyance by their size and weight or by obstructing a viscus or channel. A leiomyoma of the posterior portion of the middle of the prostate gland is known as a "middle lobe."

The so-called *uterine fibroid* is a myoma or fibromyoma. *Uterine myomata* may originate within the walls of the womb (intramural myomata), from the muscular structure of the mucous lining (submucous myomata), or

from the muscular tissue of the serous covering (subserous myomata). Intramural uterine myomata may be single or multiple and may grow to an enormous size. Submucous myomata project into the cavity of the womb (fleshy polypi), and may project into the vagina. They distend the uterus and are often accompanied by menorrhagia or metrorrhagia. In some rare cases the projecting tumor is detached by nature and the patient is cured; in some cases the myoma becomes gangrenous. A fleshy polyp may produce inversion of the fundus of the womb. Subserous uterine myomata cause trouble only by the inconvenience of weight or the discomfort of pressure. Uterine myomata are commonest in single women, and arise most frequently between the ages of twenty-five and forty-five. Negro women are especially prone to develop such tumors. They may never produce any symptoms. Some of these growths, by enlarging until they ascend above the pelvic brim, produce abdominal distention; some become jammed or impacted in the pelvis, and produce by pressure retention of urine, obstruction to the passage of feces, or hydronephrosis. Impaction may occur temporarily at each menstrual period. Many myomata produce uterine hemorrhage; some cause retroversion of the womb; some protrude from the cervical canal; some are so large that they cause disastrous pressure upon the colon (obstruction), upon the iliac veins (great edema), or upon the ureters (hydronephrosis). Uterine myomata usually shrink after the menopause. Pregnancy in a myomatous womb usually ends in abortion. Uterine myomata may undergo fatty, calcareous, or myxomatous change, and may be infected by septic organisms as a result of the use of a uterine sound or of infection of the pedicle after oöphorectomy. Infection of a uterine myoma causes great enlargement, elevated temperature, sweats, and exhaustion. Sarcomatous change may take place. Virchow pointed out this fact in 1863. Cullen found sarcomatous change in 17 cases out of 1400. If there be a carcinoma in some other part of the body metastatic deposit may occur in a uterine growth.

Uterine fibromyoma, if unoperated upon, often cause death. Noble claims that of cases denied operation or who refuse operation, 33 per cent. die and 28 per cent. become chronic invalids.

The symptoms of myomata of the alimentary canal are similar to or identical with the symptoms of malignant growths. Myomata of the skin are rare growths; they are encapsuled, firm or elastic, and painless.

Treatment.—Cutaneous myomata are removed in the same manner as fibrous tumors. A uterine tumor which causes symptoms should be operated upon. A tumor which causes no symptoms need not be operated upon if the patient can lead an easy life and can rest during the menstrual periods. Rest is an essential of the treatment. Ergot, thyroid extract, barium chlorid, and dilute sulphuric acid are recommended. In some cases the tumor shrinks, in some it disappears. If operation is required the form of operation chosen depends upon the case. In some cases the operation should be vaginal, and may be dilatation and curetment, torsion or incision of the pedicle, enucleation or hysterectomy. In other cases the operation should be by the abdominal route, and may be castration, ligation of vessels, myomectomy (cutting through the pedicle and closing with deep sutures), enucleation, shelling out growths from the wall, partial hysterectomy, or complete hysterectomy. Castration aims to create an artificial menopause, and so arrest hemorrhage and cause the shrinking of the growth. Sometimes it acts admirably, sometimes it fails, and it brings with it its own perils, for the sudden creation of the menopause is a great danger to the nervous system. For subserous myomata myomectomy is often the operation of choice. A very large tumor, a tumor which continues to enlarge after the menopause, and an infected tumor require partial or complete hysterectomy. If a myoma of the prostate causes severe obstruction, perform

a suprapubic cystotomy and remove the enlarged gland; or make both a suprapubic and a perineal opening, push the gland into the perineum and shell it out with the finger, or, if the condition is desperate, make permanent suprapubic drainage.

Neuromata.—A *true neuroma* springs from nerve-tissue (brain, cord, or nerve-trunks); it is composed of medullated or non-medullated nerve-fibers which form a plexus or network, and which are not continuous with the fibers of the nerve-trunk or other area from which the tumor grows. True neuromata are rare growths. They arise during middle life; are small in size, are due to injury or hereditary tendency, and may be single or multiple. There is usually around the tumor, rather than in it, severe neuralgic pain, which is greatly intensified by dampness, by blows, or by rough handling. The parts below a neuroma are cold, swollen, often anesthetic, and frequently present motor paralysis or trophic disorder. A *false neuroma* or *neurofibroma* is a fibrous tumor growing from a nerve-sheath, and is identical in structure with the sheath. False neuromata may be single, but they are often multiple; they may be as small as peas or as large as oranges; they are smooth and movable, and may cause great pain or may be painful only when pressed or struck; they may spring from roots, trunks, or branches, and they may be linked with the disease known as *molluscum fibrosum*. In *plexiform neuroma* some brances of a nerve enlarge and lengthen like an artery in a cirsoid aneurysm; the mass feels like beads or like a bag of worms; it is mobile, and no pain is felt on moving it; and it is generally congenital. In plexiform neuroma the nerve-sheath undergoes myxomatous change. *Malignant neuroma* is usually a primary sarcoma of a nerve-sheath, though any neuroma containing fibrous tissue may become sarcomatous.

Traumatic neuromata are false neuromata, and are occasionally well exhibited after nerve-section or amputation. After nerve-section the distal end shrinks and atrophies, the proximal end enlarges and becomes bulbous. A traumatic neuroma is composed of fibrous tissue which contains nerve-fibers. Such a growth is usually, but not always, painful on pressure or during dampness, and is most commonly seen in a stump which did not heal by first intention. In performing an amputation cut the nerves high up, and thus keep them out of the scar, permit them to remain mobile in their sheaths, and so prevent a tender stump. A tender stump may be due to anchoring of a nerve in a scar, the nerve ceasing to glide when the individual moves the extremity. The condition known as painful subcutaneous tubercle was discussed on page 355.

Treatment.—A false neuroma is to be removed, if possible, without destroying the nerve-trunk. If, in removing a neuroma, it is necessary to exsect a portion of a nerve-trunk, always proceed to suture the ends of the divided nerve so as to facilitate restoration of function. For multiple neuromata—at least should the number be large or should molluscum fibrosum exist—surgery can do nothing. Plexiform neuromata may often be removed, but amputation may be required. Painful neuromata in stumps should be excised.

Gliomata.—These tumors develop from neuroglia and more often from the white substance than from the gray. They are usually single, and arise not unusually in the brain, rarely in the cord, and very rarely in the cranial nerves. They may take origin in one of the cerebral hemispheres, in the cerebellum, in the pons, or in the medulla. Some gliomata are soft and bear a close relationship to sarcoma; others are hard and resemble fibroma.

A glioma is a circumscribed growth in contrast to a gliosis, which is a widespread and unlimited hyperplasia of the neuroglia. Syringomyelia is due to gliosis of the spinal cord.

"A glioma consists of cells containing rounded or oval nuclei with very

little protoplasm and fine protoplasmic extensions which interlace and form an intercellular reticulum" (Stengel).

A glioma passes almost insensibly into surrounding tissue, and there is no distinct edge; hence, because of the slight differentiation from brain substance, it may be overlooked during exploration. It is harder than the surrounding tissue, is vascular and of a pink or red color, and the normal shape of the part is often very little altered, although the tumor may reach the size of a lemon.

Hemorrhage may take place into a glioma, softening may occur, cavities may form, or the growth may become sarcomatous or psammomatous. The symptoms of a glioma of the brain depend on the situation.

Treatment.—When a glioma of the brain can be localized and is hard, removal should be attempted. No attempt should be made to remove a soft glioma.

Angiomata or Hemangiomata.—An angioma is a tumor composed largely of dilated blood-vessels. The older surgeons called such growths

Fig. 153.—Dr. Hansell's case of cavernous angioma of the eyelids.

Fig. 154.—Cavernous angioma of face.

erectile tumors. Some of the so-called angiomata are not genuine new growths, but are due to dilatation and elongation of blood-vessels.

Simple or capillary angiomata, nevi, or "mother's marks," which affect the skin or subcutaneous tissue, are composed of enlarged and twisted capillaries and of anastomosing vessels surrounded by fat. These growths are congenital or appear in the first few weeks of life; they are flat and slightly raised, and are of a bright-pink color if composed chiefly of arterioles, and are bluish if composed mainly of venules; they are but little elevated; they can be almost completely emptied by pressure; they occasionally pass away spontaneously, but usually grow constantly and may become cavernous; they may ulcerate and occasion violent or fatal hemorrhage. One or several large vessels connect a nevus to adjacent blood-vessels. **Port-wine** or **claret stains** are pink or blue discolorations due to superficial nevi of the skin; they may be small in extent or they may involve a very large area, are not elevated, and do not usually spread. *Telangiectasis* is a form of nevus involving the skin and subcutaneous tissue in which many arterioles and venules exist. Simple angiomata are common on the forehead, the scalp, the face, the neck, the back, and the extremities. They may appear on the labia, the tongue, or the lips.

Cavernous angiomata, or venous nevi (Figs. 153 and 154), resemble in structure the corpora cavernosa of the penis; there are large endothelial lined spaces with thin walls carrying blood, and there may be distinct vessels as well. Arteries send blood into the spaces, and veins receive it from the spaces. These channels and sinuses are enormously distended capillaries. Cavernous angiomata arise in the skin and subcutaneous tissues; they are usually congenital, but may develop from simple angiomata; they are purple or blue in color; are more distinctly elevated than the capillary nevi; may be either cutaneous or subcutaneous; swell when the child cries, and are apt to pulsate; they may be emptied by pressure, and often look like cysts with very thin walls. Cavernous angiomata may arise in the breast, the tongue, the lip, the cheek, the gums, the subcutaneous tissues, or the muscles. If an angioma contains an excess of fat, the growth is called a "nevoid lipoma."

Plexiform angiomata are known as "cirsoid aneurysms" or aneurysms by anastomosis (see page 434).

Angiomata noticed soon after birth may disappear completely or may enlarge progressively.

Treatment.—A capillary nevus can often be quickly cured by touching it with fuming nitric acid. A second application of acid may be required. The

Fig. 155.—Cavernous angioma: Subcutaneous tissue of leg.

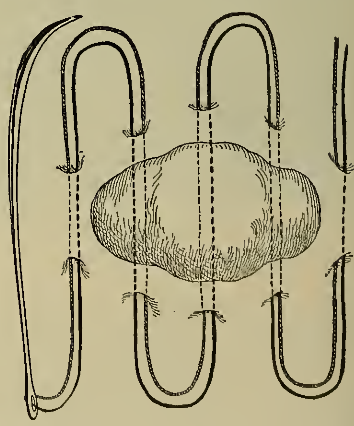

Fig. 156.—Method of applying Erichsen's suture.

growth may be destroyed by heat—"a knitting-needle at a dull-red heat or the galvanocautery" (Wharton). The application of ethylate of sodium or the employment of electrolysis will destroy the growth. Solid carbon dioxid is valuable to destroy capillary nevi. Often but one application is necessary, but in some cases two or more are required. Astringent injections are dangerous unless the base of the nevus is ligated, because they may lead to the formation of emboli.

Small port-wine stains may be removed by electrolysis or multiple incisions, but extensive stains are ineffaceable. Solid CO_2 may be used. Two or three applications are made in the same place and then another spot is selected. It

usually fails to cure. Small nevi may be ligated under harelip pins, larger nevi may be strangulated in sections by the Erichsen suture (Fig. 156), or may be completely excised. Excision is usually the best plan for the cure of angiomata. It is rapid, thorough, and leaves but a trivial scar. Excision should always be employed if we feel sure that the edges of the wound can be subsequently approximated and that there will not be a dangerous loss of blood. It is sometimes justifiable to excise an angioma even when approximation of the wound will obviously be impossible. In such a case the raw surface should be covered with Thiersch grafts.

Most superficial nevi and some cavernous angiomata can be treated by solid CO_2, and, if this fails, by excision. The incisions must be beyond the dilated vessels. In large angiomata involving the skin and also deeper parts, or involving a structure like the lip, which it is undesirable to remove, electrolysis should be employed. The operation should be carried out with aseptic care, and if the tumor is large an anesthetic should be given.

The positive pole produces a firm and hard clot. One or more needles connected with the positive pole are inserted into the tumor, the needles being insulated to within about $\frac{1}{4}$ inch of their points. A flat moist pad is placed upon the skin near the tumor and is attached to the negative pole, and the pad is moved from time to time during the operation.

Fig. 157.—Cavernous angioma and lymphangioma.

Fig. 158.—Cavernous angioma, lymphangioma, and lymphangiectasis, also beginning cancer.

From 25 to 75 milliampères is the proper strength, and the current is passed for ten minutes. The current is increased for a moment before withdrawing the needles, otherwise they will stick to the tissue and cause bleeding when torn loose. After the withdrawal of the needles the nevus will be found to be hard, but the hardness will gradually disappear. It may be necessary to repeat the operation a number of times at intervals of ten days.[1]

[1] Cheyne and Burghard's "Manual of Surgical Treatment."

When solid CO_2 is applied it subjects the tissue to a temperature of 79° F. below zero. It is called carbonic-acid snow. It is applied to nevi with pressure. This drives out the blood. It is held against the part for thirty or forty seconds. It drives the color out of the part, but a few minutes after the cessation of the action color returns, reaction occurs, the surface becomes moist, and fibrinous inflammation takes place (E. R. Morton, "Lancet," May 7, 1910).

Necrosis seldom arises. Within an hour a vesicle forms, which should be opened aseptically. A crust forms, which drops off in about two weeks, leaving "a soft and elastic scar," the color of the normal skin (Morton, Ibid.).

Lymphangiomata are tumors composed of dilated lymph-vessels and are often, though not invariably, congenital (Fig. 158). A *lymphatic nevus* is a colorless or faintly pink elevation; if it is punctured with a needle, lymph flows from the puncture. One or several nevi may be present in the same individual. The dilatation is due to blocking of the lymph-channels. Local lymphangioma of the tongue is manifested by a cluster of papillary projections containing lymph. *Macroglossia* is a congenital enlargement of the anterior portion of the tongue, which enlargement grows more and more marked, until finally the tongue is forced far out of the mouth. This condition of tongue enlargement is due to lymphangioma of the mucous membrane. *Lymph scrotum* is due to a similar growth. A collection of these warty-looking dilatations is called *lymphangiectasis*. Just as cavernous angiomata constitute a variety of blood-vessel tumors, so *cavernous lymphangiomata* constitute a variety of lymph-vessel tumors, and the spaces of the latter are filled with lymph instead of with blood (Figs. 157 and 158). Areas affected with lymphangiectasis are liable to repeated attacks of erysipelas-like inflammation. Whether this inflammation is causative or secondary is not known. In tropical countries blocking of lymph-channels may be brought about by the Filaria sanguinis hominis, a parasite which lurks in the lymph-vessels during the day and is found in the blood only at night. Lymphangiectasis is often the first stage of elephantiasis.

Treatment.—A lymphatic nevus requires excision. In macroglossia the bulk of the mass should be removed by a V-shaped cut, the mucous membrane being sutured so as to cover the stump. In conditions due to the filaria, anilin-blue has been given internally.

Malignant Connective-tissue Tumors, or Sarcomata.—The sarcomata are composed of embryonic tissue-cells, the intercellular substance being very scanty, and they *resemble* a process of chronic inflammation. They develop from connective tissue, rarely have a definite stroma, and the constituent cells, as a rule, proliferate with great rapidity. If a sarcoma has a stroma of connective tissue, this stroma contains lymphatics and such a sarcoma infects adjacent glands. In most cases there is no connective-tissue stroma and no lymphatics. In a sarcoma without a definite stroma the blood-vessels are not surrounded by lymph-spaces and are quickly invaded by cells (B. H. Buxton). The rapidly growing forms are very vascular, the blood flowing in vessels whose walls are very thin or running in canals lined by endothelium and bounded by sarcomatous cells. Such a tumor may pulsate and have a bruit, and hemorrhage often takes place into its substance. A rapidly growing soft sarcoma with dusky skin above it (Fig. 161) may be mistaken for an abscess. A slow-growing sarcoma has but few vessels. Sarcoma tends strongly to infiltrate adjacent parts. The growth disseminates by means of the blood and the vessel walls, particles of the tumor being carried by the venous blood to the heart, and from this organ to the lungs, where they lodge and form secondary growths. Emboli from these secondary foci are sent out by the arterial blood to various portions of the body, as the bones, kidneys, brain, liver, etc. This process is known as *metastasis*. In some cases sarcoma

is disseminated widely throughout the body, almost all the tissues showing minute white spots of secondary sarcoma which resemble tubercles. Such widespread dissemination is called *sarcomatosis*. Sarcoma follows the vein walls for considerable distances and builds elongated masses of tumor substance inside the veins. The primary tumor may possess a capsule when it is in an early

Fig. 159.—Sarcoma of antrum.

Fig. 160.—Sarcoma of antrum.

stage, but soon loses this except in very slow-growing varieties or in mixed forms growing by central proliferation, but secondary sarcomata are often encapsuled. Sarcomata may arise at any age from birth to extreme senility, but

Fig. 161.—Small round-celled fungating sarcoma of neck.

they are commonest during youth and early middle age. They are not hereditary. They often follow traumatism and inflammation. A number of observers maintain that they are due to parasites (the question of the parasitic origin of malignant disease is discussed on page 348). A sarcoma may be primary or

may arise from malignant change in an innocent connective-tissue growth (chondrosarcoma, fibrosarcoma, etc.). A sarcoma rarely affects adjacent lymphatic glands unless it contains lymphatics, and the great majority of sarcomata do not contain them. Occasionally sarcoma cells are carried to adjacent glands by the vein walls rather than by the lymph-stream. Sarcoma of the tonsil, sarcoma of the testicle, melanotic sarcoma, and lymphosarcoma do affect the glands. The skin over the tumor may give way, a bleeding fungous mass protruding (fungus hæmatodes) (Figs. 161, 162, and 163), and suppuration may cause septic enlargement of adjacent glands. In the course of growth of a sarcoma there may be irregular episodes of elevated temperature (see page 351). After removal of a sarcoma the growth tends to recur, and the recurrent tumor may be either more or less malignant than its predecessor, the degree of malignancy being in direct ratio to the number and smallness of the cells. A sarcoma is malignant by local tissue infection and by dissemination. Sarcomata rarely cause pain when they are not ulcerated. They are commonest in the skin and connective tissue of the extremities, but they arise also

Fig. 162.—Small round-celled sarcoma of neck. Skin has given way and a bleeding mass is exposed.

Fig. 163.—Sarcoma of neck (Horwitz).

from bone, neuroglia, periosteum, the lymphatic glands, the breast, the testicle, the eyeball, the parotid, and other parts. A pigmented mole may become sarcomatous. Hemorrhages into a sarcoma often occur, with the result of suddenly increasing the size of the mass and formation of blood-cysts. Sarcomata are subject to partial fatty degeneration, to myomatous changes which produce cavities filled with fluid, to calcification, and occasionally to necrosis of large masses.

Varieties of Sarcomata.—The following species of sarcomata are recognized:

1. *Round-celled sarcoma* is a tumor composed of round or spherical cells and resembling a chronic inflammatory area. The intercellular substance is scanty, the mass is soft and vascular, and grows with great rapidity. It often softens, and may become cystic. The cells may be small or large. The smaller the cells, the more malignant the growth. A growth composed of small round cells is the most malignant form of sarcoma (Fig. 166). *Lymphosarcoma* is a form of round-celled sarcoma which arises from lymphatic

glands, lymphoid tissues, the thymus gland, the spleen, and some other structures. The structure of a lymphosarcoma resembles the structure of a lymph-

Fig. 164.—Dr. W. R. Bishop's case of small-celled sarcoma of the antrum.

Fig. 165.—Osteosarcoma of eighteen months' standing of right side of superior maxilla. Note bony lump on left side of lower jaw.

gland in the fact that it has a reticulum which looks like lymph-adenoid structure. *Chloroma* is a form of lymphosarcoma arising particularly from the periosteum of the bones of the cranium and face. The cells contain greenish pigment, hence the name. What is known as *glioma* of the eyeball is not a true glioma, but is really a sarcoma composed of small round cells.

Fig. 166.—Small round-celled sarcoma of the neck.

Fig. 167.—Spindle-celled sarcoma of sheath of flexor tendon of finger.

2. *Spindle-celled sarcoma* is a tumor composed of large or small spindle-shaped cells lying in a matrix, which may be homogeneous, but which may

show some attempt at fiber formation. Angular cells and stellate cells are often present. The cells may be placed in columns, which are at some places nearly parallel and which at others diverge or interlace. Often there is no orderly arrangement. Spindle-celled sarcomata are usually harder than round-celled growths, but are sometimes quite soft. Cystic changes may occur. If there is a large amount of intercellular substance the growth is known as a *fibrosarcoma.* A *rhabdomyoma* is really a spindle-cell sarcoma containing striated muscle-cells. The spindle-cell sarcomata often contain cartilage. Spindle-cell growths are by no means as malignant as round-cell tumors. Often they do not show any tendency to metastasis. The greater the amount of intercellular substance and the fewer the cells, the less the malignancy. Bloodgood points out that in one group of cases (the least malignant) the spindle cells exhibit a disposition to form fibroblasts (*fibrospindle-cell sarcoma*). In another group (the most malignant) there are no fibroblasts and round cells are distributed among the spindle cells (*mixed spindle-cell* and *round-cell sar-*

Fig. 168.—Melanotic sarcoma. Observe the pigmentation of the face.

coma). Spindle-cell growths constitute the majority of sarcomata met with in practice.

3. *Giant-cell*, *myeloid*, or *medullary sarcoma* is characterized by the presence of numerous very large cells with many nuclei, looking exactly like the myeloplaques of bone-marrow. Such a growth is maroon colored on section. It arises usually from bone, especially from the interior of a long bone, hence is often called *osteosarcoma.* It is almost invariably single, but Rehn reported a case of multiple giant-cell sarcoma of bone, and Crile and Hill reported another. It may, however, arise from other structures than bone. It is the least malignant form of sarcoma. Metastases do not occur and the growth often admits of complete extirpation and cure. Some surgeons do not class these growths with sarcomata. Bloodgood regards their malignancy as very slight. Friedländer looks upon them as benign angeiomata in which giant cells have been formed by endothelial cells budding into spaces lined with endothelium.

4. *Alveolar sarcoma* is a tumor containing both round cells and spindle cells, and characterized by the formation of acini, filled with round cells of

large size resembling epithelioid cells. The walls of the acini are formed of spindle cells and fibrous tissue, and in these trabeculæ are the blood-vessels. The collection of the cells in the alveoli makes the structure resemble that of a cancer. Such growths are often pigmented. Alveolar sarcomata arise particularly from moles of the skin, but may arise from lymphatic glands, serous membranes, the testicle, and other parts. Such growths are very malignant.

5. *Melanotic or Black Sarcoma* (Fig. 168).—The color of such a tumor is due to pigment in the cells or matrix. These growths are usually composed of round cells, but may consist of spindle cells, and they are sometimes alveolar. Melanotic sarcomata spring from parts which contain pigment (for instance, the skin and the choroid coat of the eye), pigmented moles, and pigmented nevi; they are very malignant; they implicate related lymphatic glands, undergo early metastasis, and during their existence the urine contains pigment.

Malignant growth from a congenital pigmented mole used to be regarded by most observers as melanotic sarcoma, but Bloodgood would place these growths in a group by themselves. He says that the weight of opinion is on the side of those who maintain that the cells are of epithelial origin misplaced early in embryonic life, and that the tumor is a cancer. Many surgeons still regard such a tumor as sarcoma.

Fig. 169.—Hansell's case of cystic myxosarcoma of the orbit.

6. *Hemorrhagic sarcoma* is a sarcoma containing blood-cysts which result from parenchymatous hemorrhages.

7. *Angeiosarcoma* or *hemangeiosarcoma* takes origin from the outer coat of a blood-vessel. The growth is often very vascular, and when the blood-vessels are notably dilated the tumor is called a *telangiectatic sarcoma*. The ordinary forms of angeiosarcoma are only moderately malignant, but alveolar and melanotic forms occur which are highly malignant. Angeiosarcoma may arise in the skin, in a serous membrane, in intermuscular structure, in bone, or in a salivary gland. It most frequently takes origin from a nevus.

8. *Cylindroma, or Plexiform Sarcoma.*—In this variety the sarcoma cells adjacent to vessels have undergone hyaline or myxomatous degeneration; the cells distant from vessels are unchanged. Section shows the sarcoma cells apparently contained in spaces with hyaline walls. These degenerative changes occur most often in the angiosarcomata. Cylindromata arise from the brain, salivary glands, lacrimal glands, and rarely from the subcutaneous tissue. The growths are only moderately malignant.[1]

9. *Mixed tumors* consist partly of mature and partly of embryonic tissue, the cellular elements exceeding the adult elements in amount. Among these mixed tumors are *fibrosarcoma* or the *recurrent fibroid tumor*, *myxosarcoma* (Fig. 169), *chondrosarcoma*, *gliosarcoma*, and *osteosarcoma*.

[1] Stengel, "Text-Book of Pathology."

10. *Endotheliomata* are tumors springing from endothelium, and the name is retained no matter what changes the growths ultimately undergo. Many writers include under the term "endothelioma" *psammoma*, myxosarcoma, angiosarcoma, and plexiform sarcoma. Others consider endothelioma a special and characteristic form of sarcoma. Some would not consider it with the sarcomata at all. The growth may take origin from the "endothelium of the blood-vessels and of the perivascular lymph-spaces, of the lymph-vessels, and of the great serous cavities (peritoneum, pleura, meninges)."[1] The characteristic cell is the endothelial cell, usually known as the epithelioid cell. The structure of these tumors is very variable and depends upon the origin; some tumors "recalling the original vascular network" ("American Text-Book of Pathology"), others being distinctly alveolar. Many pathologists consider a *psammoma* of the dura to be an endothelioma with a fibrous stroma. A psammoma contains calcareous particles. In appearance an endothelioma strongly resembles cancer, and such a growth is often spoken of

Fig. 170.—Recurrent sarcoma of the sternum.

Fig. 171.—Periosteal sarcoma of the femur.

as endothelial cancer. Such growths can arise in many different situations, but are particularly common in the peritoneum, pleural membrane, membranes of the brain, ovary, and testicle. I have removed an endothelioma of the tonsil, one of the mammary gland, two of the nasopharynx, one of the superior maxillary bone, and two of the carotid gland. The proliferating endothelial cells lie in lymph-spaces. Many endotheliomata grow rapidly, secondary growths form, and metastases are apt to pass to the serous membranes. Certain endotheliomata grow slowly, do not infiltrate adjacent structure, and do not produce secondary growths. In the brain and cord endothelioma may produce no symptoms for a long time. It is not as yet possible, clinically, to distinctly recognize endotheliomata from ordinary sarcomata.

11. *Mycosis* or *granuloma fungoides* is a disease which resembles sarcoma in many particulars and may perhaps be a form of sarcoma. It attacks the skin and subcutaneous tissues. It is preceded for months or years by an eczematous or urticarial condition. The skin becomes red and swollen; numerous pinkish or reddish nodules or flat areas of induration form; the nodules become distinct tumors, soften at their centers, usually ulcerate, and fungation

[1] "An American Text-book of Pathology," edited by Hektoen and Riesman.

occurs. When ulceration occurs the mushroom-like growths form. Microscopically, the tumor resembles a lymphadenoma. Mycosis fungoïdes is considered by some pathologists to be multiple cutaneous sarcoma. It is very chronic and lasts for months or even years. It was first described and was named by Alibert.

Treatment of Sarcomata.—Remove a sarcoma at once if it is in an accessible spot. Never delay removal, and always cut well clear of it. If affecting a part where amputation is impossible, the rapidly growing sarcomata will almost inevitably return, and the very malignant variety, if uninterfered with, may ter-

Fig. 172.—Central sarcoma of humerus.

minate life in six months; but even in such case operation postpones the evil day and renders it possible that death will occur from metastatic growth in an organ, and that the patient will escape the horrors of ulceration and hemorrhage from the original tumor. Slowly growing and hard tumors offer better prospects of cure. The mixed tumor (as a recurrent fibroid) may repeatedly recur, and yet the patient may be cured at last by a sixth, an eighth, or a tenth operation. In a case of spindle-cell sarcoma of the breast the younger Gross performed 22 operations in the course of four years, and eleven years later the woman was well. In a case of recurrent fibroid of the neck the younger Gross operated five times. Three years after Prof. Gross's death I

operated upon the same patient, and again two years later. Nine years after the last operation she was alive and well. In sarcoma of a long bone (though not in giant-cell sarcoma) amputation should, as a rule, be performed. Bloodgood proves that in some of these cases extensive excision is just as useful. In giant-cell sarcoma incision and curetting may be employed, or, if this is insufficient, subperiosteal excision. Bloodgood has reported the cases of giant-cell sarcoma from Halsted's clinic. The reports show that excellent results follow this plan of treatment. If the soft parts are involved, they must be removed wide of the growth. Amputation is necessary only when the removal of soft parts must be so extensive as to hopelessly mutilate the limb. In sarcoma of either jaw-bone, excision; of the eye, enucleation; of the testicle, cas-

Fig. 173.—Central sarcoma of the fibula.

tration is demanded. Sarcoma of the ovary in adults demands removal, but in children the operation is generally useless. Sarcoma of the kidney in adults calls for nephrectomy, but in children the operation is usually of little avail. In my experience, in the cases of sarcoma of the kidney which survived operation the growth always appeared in the other kidney. In melanotic sarcoma extirpate the growth widely and remove anatomically related lymph-nodes, or in some cases amputate far away from the tumor and remove lymph-nodes. In very malignant sarcoma even amputation does not often cure. Removal of a sarcoma when there is no hope of a cure is often justifiable to prolong life, to relieve the patient of a foul, offensive, bleeding mass, and to permit of an easier road to death by means of metastasis to an internal organ. In an inoperable case the ligation of the vessel of supply may do good. In sarcoma of

the tonsil Dawbarn advises the extirpation of the external carotid artery and the ligation of its branches. The operation is performed first on the side occupied by the tumor and in a week or so on the other side. I employed it in 7 cases with distinct but temporary benefit. Occasionally, though very rarely, suppuration cures a sarcoma. Wyeth, of New York, reported a case of sarcoma of the abdominal wall. It was found possible to remove only part of the growth; suppuration followed and the tumor disappeared, and ten years later had not returned. A study of statistics seems to indicate that more cases of sarcoma are cured after operation if the wound suppurates than if it remains aseptic, and it has been proposed to deliberately infect the wound with pus germs to lessen the danger of recurrence. If the wound is large, it should not be infected until it is nearly healed. If it is small, it may be infected at the time of operation or soon after. After amputating for sarcoma, Wyeth waits until the wound is nearly healed and then infects it by inserting a gauze drain saturated with cultures of pure Streptococcus pyogenes (Wyeth's "Surgery"). After removing a sarcoma from any region the patient should be given courses of injections of Coley's fluid (see below).

Fig. 174.—Inoperable sarcoma of the back.

It has been observed that an attack of erysipelas occasionally greatly benefits a sarcoma, causing large masses of the growth to soften or to slough and exposing a granulating surface. Busch noticed this in 1866, but the fact had been observed in the seventeenth century. Interest was decidedly awakened by Billroth's case of sarcoma of the pharynx which was cured by an attack of facial erysipelas. It was suggested that in inoperable cases of sarcoma erysipelas might be established artificially. Fehleisen inoculated tumors with cultures of erysipelas. Lassar in 1891 employed the toxins (cultures rendered sterile by heat and filtration). In 1892 Coley began his observations. The first plan was as follows: a bouillon culture was made of the streptococci; this culture was filtered through porcelain and an injection was given once a day into and about the sarcoma. The first dose was 10 min. and it was progressively increased. The effect was to cause a febrile reaction, and sometimes the injections were followed by softening or suppuration. Coley's present method is as follows: Make cultures of erysipelas cocci in cacao broth; after three weeks inoculate them with the Bacillus prodigiosus, and cultivate the mixed growth for four weeks. The mixed cultures are maintained at a temperature of 136° F. until they become sterile. This sterile fluid contains the toxins. The usual dose for an adult is from 1 to 8 min. Coley has given as high as 24 min. I have never given over 18 min. Most cases will show reaction at 4 to 6 min. The first dose for an infant is $\frac{1}{10}$ min. If in an adult the fluid is injected remote from the tumor the initial dose should be 1 min. If the fluid is injected into the tumor the initial dose is $\frac{1}{4}$ to $\frac{1}{2}$ min. (Coley, in "Amer. Jour. Med. Sci.," March, 1906). Some cases are treated purely by distant injections (gluteal or pectoral regions), others by alternately injecting the tumor and some distant point. The latter plan combines local action

and systemic effect. The dose should be gradually increased until a chill occurs in from one-half an hour to two hours after the injection, followed by a temperature of 101° to 104° F. In some cases there is so much depression after reaction that injections are given every other day, but if safely possible they should be given every day. The object is to obtain a reaction with each injection. The more vascular the tumor, the more severe the reaction (Coley). If an area softens during treatment Coley advises us to open and drain the softened area. If improvement is going to occur it usually begins in from one to four weeks. If there is no improvement within four weeks there will not probably be any. In most cases as injection is continued susceptibility diminishes, in some few it increases. It seems definitely proved that cases are occasionally cured by Coley's fluid. Spindle-celled sarcomata are influenced most favorably. Round-celled sarcomata are very refractory and so are cancers. The method is not entirely free from danger, but the danger is very slight if treatment is begun with the minimum dose. The toxins seem of value in postoperative cases to prevent recurrence. For this purpose the fluid is used twice a week for several months and at greater intervals for a long period of time. During the autumn of 1910 I brought before my class in the Jefferson Hospital a colored woman (Fig. 175) with an inoperable spindle-cell sarcoma of

Fig. 175.—Huge sarcoma of buttock cured by partial extirpation and Coley's fluid.

the thigh and groin. A portion of the growth was removed and the remainder completely disappeared from injections of Coley's fluid. She remains well over three years after treatment was suspended. This patient had a violent reaction every day for weeks. She was given as much as 7 min. at a dose.

How the toxins act is uncertain. They produce some change in the blood-serum, and the valuable effect is systemic. Nearly always they cause leukocytosis. Probably they cause the formation of antibodies, which are antagonistic to the sarcoma cells. The treatment, as Coley insists, is not a substitute for operation. The fluid is used in inoperable cases, a trial of it is made in sarcoma of long bones before advising operation, it is given after all operations for cancer or sarcoma to combat recurrence, and it may be tried in inoperable cancer. Coley ("Surg., Gynec., and Obstet.," August, 1911) has had 65 cases of inoperable sarcoma in which the tumor disappeared from the treatment: 7 are alive and well at the end of fifteen to eighteen years; 7 alive and well at the end of ten to fifteen years; 17 alive and well at the end of five to ten years; 10 alive and well at the end of three to five years. The others could not be traced.

Emmerich and Scholl claim good results in inoperable sarcoma from the injection of erysipelas serum. A sheep is injected with cultures of erysipelas, the blood is drawn, the serum separated, filtered to remove cocci, and injected

about the sarcoma. Results are not definite. Among other agents which have been used to inject inoperable sarcomata we may mention alcohol, chlorid of zinc, arsenic, corrosive sublimate, thiosinamin, pepsin, alkalis, etc. The injection of anilin products into the sarcoma, which once received qualified commendation from some observers, has been abandoned by most surgeons. The x-rays are sometimes of benefit, but are not so serviceable as in carcinoma, and possess a certain danger, for occasionally after using them dissemination rapidly occurs. Abbe and others have obtained some remarkable results by radium, but such results are exceptional and not the rule.

Hypernephromata, or Adrenal Tumors.—Some of the tumors bear a strong resemblance to adenomata and carcinomata. Some adrenal tumors are benign, and among such tumors we note fatty and fibrous growths and growths resembling glioma. Another benign growth imitates the structure of the cortex of the adrenal. Malignant tumors occur, and many of them are identical or almost identical with sarcoma. One form is composed of epithelioid cells and resembles endothelioma. An adrenal tumor may arise from the adrenal body proper or from "rests" in ectopic portions of adrenal within the kidney, ovary, testicle, solar plexus, renal plexus, liver, mesentery, or some other part. Some of these tumors attain a large size. Metastases are late, but tend to occur eventually even in hypernephromata which seem benign, and may occur even when the primary growth has given rise to no symptoms. The metastases are lodged particularly in the bones, the lungs, and the liver. In a case from which I removed a goiter and death resulted from reactionary hemorrhage the tumor (which I had considered to be adenoma) was found to be composed of adrenal tissue. Unfortunately, an autopsy was not permitted.

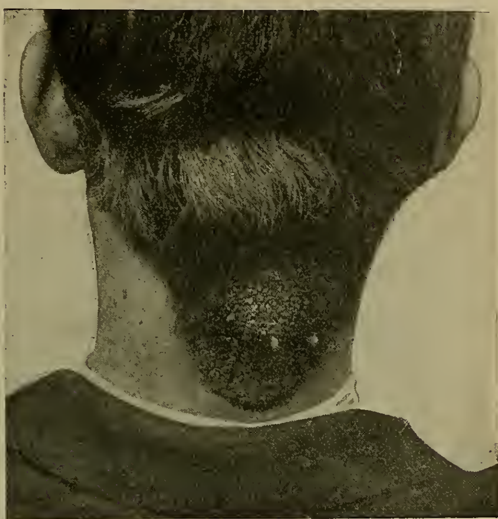

Fig. 176.—Keen's case of papilloma with angioma.

Accessory adrenals are common. They are known as *adrenal rests.* "They are found oftenest in the connective tissue about the main adrenals, but also in the kidneys, the right lobe of the liver, along the renal vessels and spermatic veins, in the inguinal canals, and in the broad ligaments" ("American Text-Book of Pathology").

Innocent Epithelial Tumors.—These growths imitate an epithelial tissue of the mature and healthy organism.

Papillomata, or Warts (Fig. 176).—Papillomata are formed upon the type of cutaneous and mucous papillæ. A papilloma consists of a fibrous stroma, which contains blood-vessels and lymphatics and is covered by epithelium of the variety appertaining to the diseased part. Papillomata grow from the skin and from mucous membranes; they may be single or multiple; many may form in one region or various distant parts may be affected; they may be painless or may be ulcerated or bleeding; they vary in color from light pink to deep brown or black. Papillomata of the skin are usually hard; papillomata of mucous membranes are soft. A skin-wart may be smooth and rounded,

or may look like a small cauliflower, the epidermis upon it being very rough. A papilloma of a mucous membrane looks like a small cauliflower. Papillomatous masses may gather around the anus, the vagina, or the penis during the existence of a filthy discharge (*venereal warts*, Fig. 177), and crops of warts may appear on the hands of those who work in irritant material (as petroleum). Papillomata are apt to arise in mucous membrances about carcinomata or chronic ulcerations. A large crop of warts may disappear in a single night; hence the popular belief in the efficacy of charms. Warts are particularly common on the skin of the back of the hands and fingers, the skin of the back, and the skin of the neck and scalp. A single skin-wart may reach the size of a walnut and become pigmented. The squamous epithelium covering a skin-wart may become horny (*a wart-horn*). Other cutaneous horns arise from the nails, from the scars of burns, or from ruptured sebaceous cysts.

Villous papillomata grow chiefly from the bladder, but they may also grow from the stomach and intestine. A papilloma of mucous membrane covered with squamous epithelium looks like a wart of the skin. Papillomata of the

Fig. 177.—Venereal warts.

larynx are formed of squamous epithelium. Villous papillomata form tufts like the villous processes of the chorion; they may be single or multiple, and may be sessile or pedunculated; they are very vascular, and are apt to bleed freely. Papillomata may arise in cysts of the paroöphoron, in cysts of the mammary gland, from the choroid plexuses of the ventricles of the brain, and from the spinal membranes. Papillomata may give rise to hemorrhage or may impair the function of a part. Any papilloma may become a cancer.

Treatment.—Venereal warts are treated by repeatedly washing with peroxid of hydrogen, drying with cotton, and dusting with a powder composed of borated talcum or of equal parts of calomel and subnitrate of bismuth, or of oxid of zinc and iodoform. If they do not soon dry up, cut them off with scissors and burn with the Paquelin cautery. Ordinary warts may usually be destroyed in a short time by daily applications of lactic or chromic acid. Most warts are easily destroyed by solid CO_2. It is held in contact with the wart for thirty or forty seconds. In a few days the warts drop off or can be easily picked off. In multiple warts of the face Kaposi applies daily for several days a portion of the following combination: sublimed sulphur, 5 dr.; glycerin,

$1\frac{1}{2}$ dr.; acetic acid, $2\frac{1}{2}$ oz. Keeping a wart constantly moist with castor oil will usually cause it to drop off. Warts, and even extensive callosities, may be removed by painting once a day for five days with pure carbolic acid and covering with lint kept wet with boric acid. A convenient plan is to paint a wart daily with a solution containing 1 part of corrosive sublimate to 30 parts of collodion (hydrarg. chlor. corros., $\frac{1}{2}$ dr.; collodion, 15 dr.). Large warts should be excised. Villous papillomata of the bladder, if not cured by fulguration, demand the performance of a suprapubic cystotomy in order to remove them. A papilloma of the larynx may be removed by the cautery or may be destroyed by sparking.

Adenomata are tumors corresponding in structure to normal epithelial glands. They have a framework of vascular connective tissue, and they may contain acini and ducts like racemose glands or tubes like tubular glands. The acini or tubules contain epithelium of either the cylindrical or polyhedral variety. Adenomata grow from secreting glands; either they cannot produce the secretion of the glands from which they spring, or they do secrete, but the fluid is retained and not discharged by the gland-ducts. Adenomata occur in the mammary gland, the parotid, the ovary, the thyroid gland, the liver, the sweat-glands, the sebaceous glands, the kidney, the pylorus, and the prostate; and they may spring as pedunculate growths from the mucous lining of the intestine and uterus. They are encapsuled, are usually single, but may be multiple, are of slow growth, but may attain a great size; they do not tend to recur after thorough removal, do not involve lymph-glands, and do not disseminate; they are firm to the touch; they tend to become cystic (especially in the thyroid gland), the fluid which distends the ducts being formed by mucoid liquefaction of the proliferating epithelium. If cysts form, the growth is spoken of as a *cystic adenoma*. If the framework of an adenoma contains considerable fibrous tissue, the tumor is named a *fibro-adenoma*. Adenomata are particularly liable to become carcinomatous.

In the breast a fibro-adenoma has a distinct capsule; it is elastic and movable, is usually superficial, and one occasionally exists in each gland. They are most common before the age of thirty, and are often painful, especially during menstruation. Cystic adenomata of the breast attain a large size; they are encapsuled and grow slowly, are most common after the thirtieth year, and are rarely painful. Both fibro-adenoma and cystic adenoma may arise in the male breast. Young unmarried women not unusually develop in the breast small, very tender, and painful bodies, most usually around the edge of the areola, which bodies increase in size and become more tender during menstruation; they are only cysts of the mammary tissue.

Adenomata of the thyroid gland usually begin before the fifteenth year. They may arise in the prostate if that gland be already the seat of senile hypertrophy. Adenomata of mucous glands may arise in the young or middle aged. Adenomata of mucous membranes often cause hemorrhage and interfere with function.

Treatment.—Adenomata should be extirpated. To let them alone exposes the patient to the danger of cancerous change. By confusing adenomata of the mammary gland with small areas of chronic mastitis an erroneous belief has arisen that the former as well as the latter may sometimes be cured by the local use of iodin, mercury, ichthyol, and the internal use of iodid of potassium. The treatment in the breast, as elsewhere, is excision.

Malignant Epithelial Tumors, Carcinomata, or Cancers.—Cancers are tumors taking origin from epithelial structures and composed of embryonic epithelial cells which are clustered in spaces, nests, or alveoli of fibrous tissue, and which proliferate enormously, extending beyond normal anatomical boundaries and as an invading host entering into connective tissue by way of the lymph-spaces. Certain cells "pass out of somatic coördination"

with the other body cells and become as parasites (Walker, in "Lancet," May 13, 1911). Such cells constitute cancer. The unrestrained and unlimited reproduction of epithelial cells and the assumption by them of parasitic properties are the characteristics of cancer. The healthy epithelium has a strictly limited power of reproduction, as is illustrated by a skin-graft. Cancerous epithelium has an unlimited power of reproduction. The alveoli of cancer are distended lymph-spaces filled with proliferating cells. The cells of a cluster are not separated by any stroma, and the walls of the alveoli carry blood-vessels and lymphatics. The growth may have been cancerous from the start, or may have begun as an innocent epithelial tumor which became cancerous. Cancers are always derived from epithelium (of glands, of skin, of mucous membrane, etc.), and if found in a non-epithelial tissue must be secondary, or must have arisen from a depot of embryonal epithelial cells of prenatal origin or from a dermoid cyst lying in the midst of a non-epithelial tissue, or epithelial cells must have been displaced by inflammation or injury so as to be among mesoblastic elements. For instance, the bone does not normally contain epithelial cells. If osteomyelitis arises operation is performed, and a lot of skin may be buried in the bone cavity or an epithelial graft may adhere. Such an epithelial area may become cancerous. Carcinomata have no capsules, rapidly infiltrate surrounding tissues, and are firmly anchored and immovable. In the beginning a cancer is a local lesion, but it soon attacks adjacent tissue and related lymph-glands, and by means of the lymph-cells are carried to other structures, producing secondary tumors and diseases and enlargement of more distant lymph-glands. Finally, lymph containing cancer-cells reaches the blood by the lymph-vessels and passes to distant parts, and secondary tumors or metastatic deposits form. When lymphatic vessels are obstructed, lymph filled with cancer-cells may flow in a direction the reverse of that pursued in health. Widespread or general dissemination may be due to carcinomatous thrombosis of a vein, or perforation of the wall of a vein, multiple emboli forming. Strange to say, emboli composed of cancer-cells may be surrounded with blood-corpuscles and move against the blood-current. A secondary growth (Fig. 178) consists of cells identical in character with and similar in arrangement to those of the parent growth. It may be clinically more or less malignant than the parent growth. The cells of the secondary growth were transported from the primary growth and multiply in their new situation. For instance, the cells of a primary carcinoma of the liver may secrete bile, and the cells of a metatastic area may do the same. Fütterer has reported a case of carcinoma of the thyroid the pulmonary metastases of which secreted colloid. Stewart reported a case of cancer of the lungs and liver secondary to cancer of the pancreas. The secondary growths were of a structure similar to the pancreas and contained trypsin. Metastases from a columnar-celled rectal cancer are composed of columnar cells. Metastases from a squamous-celled epithelioma are composed of squamous cells. In rare cases metastasis of carcinoma of the stomach has occurred in the rectum. Schnitzler reported 11 cases ("Mitth. a. d. Grenzgeb. der Med. u. Chir.," 1908, xix, No. 2).

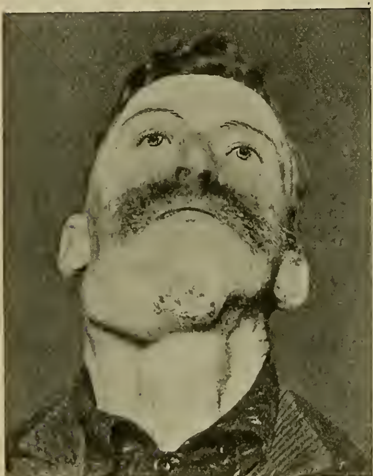

Fig. 178.—Secondary carcinoma of the submental and submaxillary lymphatic glands following carcinoma of the lip (Senn).

Such a condition is probably due to implantation. Contact cancer has already been referred to (see page 349). We often speak of lymph-nodes enlarging when affected with cancer. The enlargement certainly occurs, but is not due to growth of the cells of the lymph-node. It results from multiplication of the carcinoma cells deposited in the gland. As Henry Morris says ("The Bradshaw Lecture," "Lancet," Dec. 12, 1903), the parenchyma of the involved part does not undergo transition into cancer. After the growth of epithelium has lasted for a length of time the patient becomes poisoned by materials absorbed from the seat of disease, and finally dies from cachexia and exhaustion or some complication. These materials are probably enzymes. During the progress of cancer irregular fever may arise from time to time (see page 351). Cancer is rare before the age of forty, although occasionally it is met with in younger persons. Cancer of the rectum is sometimes met with as early as the twenty-fourth year. I have operated on a woman of twenty-six for cancer of the breast, on a man of twenty-four for cancer of the stomach, and on a man of twenty for epithelioma arising in the old scar of a burn (see Fig. 82). Karsner ("Proc. Path. Soc. Phila.," Feb., 1910) reports 10 cases of carcinoma occurring before the age of twenty-four: 1 was seven; 1, ten; 1, eleven; 1, fourteen; 1, nineteen, 1, twenty-one; 1, twenty-two, and 3, twenty-three. In De la Camp's collection of 9906 cases of cancer only 19 were under twenty years of age. *X*-ray cancer usually occurs in young people. When xeroderma pigmentosum exists in children cancer may arise in areas of the disease. If cancer appears in a young person, growth is apt to be extremely rapid and early recurrence is common. A carcinoma is often the seat of pricking pain; the growth tends strongly to recur after removal; is prone to ulcerate, causing pain, hemorrhage, and cachexia; makes rapid progress, and is often fatal in from one to two and a half years. It is more common in women than in men, and rarely exists in association with tubercle. After a cancer has existed for a time in an important structure, or after a superficial cancer has ulcerated and become hemorrhagic, there are noted in the individual evidences of illness and exhaustion. We speak of this condition as the *cancerous cachexia*, and in it the muscles are wasted, the body-weight is constantly diminishing, the complexion is sallow, the face is sunken, pearly white conjunctivæ contrast strongly with the yellow skin, the pulse is weak and rapid, and night-sweats occur. The above condition is due to the absorption of toxic products from the diseased tissues, which products damage the blood-corpuscles, and also to pain, loss of sleep, deprivation of exercise, malassimilation of food, and perhaps bleeding. It is held that cancer cells contain an enzyme which disintegrates the body cells; hence the wasting. From the disintegrating body cells poisons also come, hence some of the toxemia. Perhaps the materials from disintegrating body cells favor the proliferation of cancer cells. Mental depression is not believed by many surgeons a cause of recurrence. As J. D. Bryant says, it is simply expressive of a condition of nutritive failure which may favor recurrence. We must remember, however, that the great name of Paget is associated with the belief that not uncommon antecedents of the disease are "deep anxiety, deferred hope, or disappointment" ("Lectures on Surgical Pathology," 1863). Victims of rheumatoid arthritis are particularly liable to cancer. Recurrence after operation is due to the growth of cells which were not removed at the operation. Cancer may kill by obstructing a canal, by destroying the functions of a viscus or organ, by hemorrhage, by anemia, by sepsis, or by exhaustion. The duration of life varies in different forms of cancer and in different situations of the growth. After the first symptoms appear, cancer of the gall-bladder, as a rule, causes death in about four months; cancer of the stomach, in less than a year; cancer of the face, in from three to three and one-half years. Billroth's case of carcinoma mastitoides killed the patient in six weeks.

Serum Reaction in Cancer.—Kelling in 1906 pointed out that the blood-serum of a cancer patient has a hemolytic action on the red corpuscles of the lower animals. It has been known for some time that the serum of persons affected with certain diseases is able to destroy the red blood-corpuscles of normal individuals; in other words, such sera are hemolytic to the red blood-corpuscles of healthy human beings. The agents in a serum which hemolize the red corpuscles in other sera are called isohemolysins. Isohemolysins are contained in the sera of syphilis, tuberculosis, and cancer. Freund and Kaminer pointed out that normal serum dissolves carcinoma cells, but the serum of a victim of carcinoma does not, and suggested that this fact might be employed diagnostically. In about two-thirds of cancer cases the reaction is positive, but in one-third it is negative. The test is not conclusive and is unreliable. Cobra poison contains hemolysins and has been used as a test for carcinoma (Weil's reaction). The results are positive in about 80 per cent. of cancer cases. Weil pointed out that the serum of a dog suffering from advanced lymphosarcoma destroys the red corpuscles of normal dogs, but is resisted by the red corpuscles of animals that are victims of the same disease. Attempts are being made to utilize the serum reaction for diagnostic purposes. Different observers employ different technic and differ widely in their conclusions. Crile ("Jour. Am. Med. Assoc.," Dec. 12, 1908) is disposed to think highly of the diagnostic value of the serum reaction. Janeway ("Annals of Surgery," May, 1909) obtained positive results in 48.5 per cent. of the 35 cancer cases examined. Janeway's conclusions are wisely cautious. He states that a negative reaction is not proof positive that cancer is absent. A positive reaction makes the existence of malignant disease probable, especially if advanced tuberculosis and syphilis are absent.

The fact that the serum of a cancer patient contains agents destructive to red corpuscles explains the anemia and cachexia of cancer. Janeway points out that the serum of sufferers from benign tumors never exhibits the reaction.

Some Theories as to Cause of Carcinoma.—Heredity is discussed on page 347.

1. *Contusion and Irritation.*—As Dennis says, clinical evidence points strongly to the view that inflammatory changes following irritation are responsible for cancer. Individuals with phimosis are particularly prone to cancer of the penis. Those who smoke a short-stemmed clay pipe, which grows hot when in use, are most liable to cancer of the lower lip. In the old days chimney-sweeps often developed cancer of the scrotum, which was always irritated by soot in the cutaneous folds. Cancer of the gall-bladder may arise if gall-stones exist. Cancer of the skin of the hands may arise in x-ray workers. Cancer of the skin may be induced by the influence of light (James Nevins Hyde, in "Amer. Jour. Med. Sciences," Jan., 1906). Aniline workers are rather liable to cancer of the urinary bladder. An ulcer may be the irritating focus which leads to the development of cancer at its edge (see Marjolin's Ulcer, page 159). So may a scar. As is well known, certain innocent tumors may become cancerous. The believers in the parasitic theory maintain that irritation and inflammation simply open the gates to the real cause, which they assert is a parasite.

In certain regions of the body, notably the tongue and lip, we regard prolonged chronic inflammation as very apt to eventuate in cancer, and if an ulcerated area is not soon cured by ordinary means we advise operation. A condition persisting in spite of ordinary treatment, prone to eventuate in cancer, but not as yet demonstrably cancerous, is called the *precancerous* stage of cancer. It probably is already cancer, although so early as to lack the positive signs.

A wart is the result of inflammation and a wart may become a cancer.

The edge of a gastric ulcer may become cancerous. Cancer may arise from a scar (see Fig. 85) or the edge of an old ulcer of the skin, the lip, the cheek, or the tongue.

Certain benign tumors tend to become cancerous, especially if irritated by injuries, caustic applications, or inefficient attempts to remove them surgically. Any papilloma and any adenoma may become cancerous. A benign epithelial tumor is always a menace and is to be regarded as a possible or potential carcinoma.

Whereas chronic inflammation or irritation of epithelial structures is not infrequently followed by carcinoma, a single traumatism, as a blow, seldom is. Nevertheless well-established cases are on record of cancer due to a single trauma (Coley, in "Annals of Surgery," April and May, 1911). A woman with cancer of the breast is apt to lay the blame upon a blow, but very seldom can the surgeon regard the blow as causal. In many cases cancer was present when the injury was received, and the injury drew attention to the tumor.

2. *The Inclusion Theory of Cohnheim.*—This theory was set forth on page 346.

3. *The Thiersch Hypothesis.*—This maintains that normal, healthy connective tissue has a restraining influence on the growth of adjacent epithelium; when connective tissue degenerates (as in advancing years or after prolonged irritation) its control over epithelium is weakened, and the epithelium grows more rapidly than it does normally, and from the moment it invades the connective tissue cancer exists. This theory assumes that the connective tissue is a police force and the epithelial cells the criminal class. When the first is weakened or corrupted, the second becomes active and uncontrolled.

Fig. 179.—Epithelioma of right temporal region. Paralysis of right side of face. Papule noticed by patient two years prior to admission.

4. *The Parasitic Theory.*—Various agents have been described as causes, viz., bacteria, protozoa, and yeast fungi.

This theory was discussed on page 348. We do not regard it as proved, and even Plimmer, warm advocate as he is of the theory of contagion, admits that as yet there is no clearly demonstrated case of contagion of cancer from one man to another. I can find no authenticated case on record of a surgeon having been infected by cancer during an operation. Transplantation has been carried out from one animal to another of the same species, although attempts to do so usually fail. Tyzzer, of Harvard, succeeded in nearly 46 per cent. of his inoculation experiments with the Jensen tumor and he has kept up the tumor formation for ten generations. (See "Fourth Report from the Harvard Medical School of the Caroline Brewer Croft Fund Cancer Commission.") It is a serious question, however, if mouse cancer is really cancer at all. Mouse cancer is far more strongly hereditary than human cancer; spontaneous cure is by no means uncommon; metastasis is rare;

the disease may occur as an epidemic in a laboratory. It has been asserted that mouse cancer may revert to sarcoma (Apolant, in "Münch. med. Wochenschr.," 1907, liv), and it may revert to adenoma (Ibid.). These tendencies separate mouse cancer very positively from human cancer. It is said that epidemics of fish cancer may occur in a hatchery. Cancer has not been transplanted from an animal of one species to an animal of another species. If a portion of human cancer is implanted in the tissues of an animal, the cells of the growth retain their vitality for a very few days and then perish. If a piece of mouse cancer is transplanted into a rat the same thing happens. In any case, even a successful transplantation of cells is a very different thing from contagion. The late Prof. Nicholas Senn deliberately implanted a piece of cancer in the tissues of his own forearm without result ("Jour. Am. Med. Assoc.," April 28, 1906). Recently advocates of the contagion theory claim that mouse cancer can be reproduced after transplantation even when the cells in the inoculated matter have been first killed by exposure to the intense cold induced by liquid air (Salim, Moore, and Walker, in "Lancet," Jan. 25, 1908). If these observations should be sustained, they would indicate that the element responsible for growth of a graft is not cellular and might be microbic. Alibert carried out similar experiments and claims to have obtained like results. Most observers believe that transplantation cancer is due to cell transplantation.

Fig. 180.—Carcinomatous horn.

5. *The Biological Theory.*—In a unicellular organism the function of reproduction is, of course, possessed by the cell. In a multicellular organism certain cells are set apart for the performance of the function of reproduction, but all the cells possess the potentiality for reproduction, but fail to exercise it. If cells undergo atavistic reversion they may again assume the reproductive function. If they do, unrestrained growth will result, and such unrestrained growth is cancer.

N. F. MacHardy ("Lancet," Oct. 24, 1903) states that if a unicellular organism has not sufficient reproductive energy it fuses with another cell and is thus stimulated to produce numerous daughter-cells. In multicellular organisms cells may also fuse, take on active reproductive power, and produce hosts of new cells. When cells are persistently irritated, MacHardy affirms that they become worn out by making repeated attempts at repair, undergo atavistic reversion, and actively assume the power of reproduction. According to this theory cancer is expressive of atavistic reversion of epithelial cells.

The Prevalence and the Alleged Increase of Carcinoma.—Crile estimates that at the present time there are probably 80,000 cases of cancer in the United States, and states that in hospital autopsies cancer is found in 1 case out of 12 ("Med. Record," June 6, 1908). In the United States cancer causes 5 per cent. of the annual deaths. Kellogg ("N. Y. Med. Jour.," Sept. 2, 1911) claims that there are 300,000 cancerous people in the United States, that 75,000 die of it each year, and that in 1909, of women who died between the ages of forty-five and fifty-five, 1 in 6 died of cancer. In England in 1909 there were over 34,000 deaths from cancer. In France in 1908 there were over 30,000 deaths from cancer. It has been stated that of persons living

above the age of thirty-five, that 1 woman in 8, and 1 man in 12, will die of cancer (Copeman, quoted by Brand, in "Lancet," Jan. 11, 1908). Is cancer increasing? Of course, the number of cases increases with the increase of population. The apparent death-rate from cancer increases year by year. It is pointed out by W. Roger Williams that in England and Wales the mortality from cancer has increased from 1 to 5646 in 1840 to 1 to 1306 in 1896, and the proportion to deaths from other causes has risen from 1 to 129 in 1840 to 1 to 22 in 1896 ("Lancet," Aug. 20, 1898). Roswell Park comments on the increasing number of deaths from cancer in New York State, and says if it continues for the next ten years the disease will kill more persons annually than phthisis, small-pox, and typhoid combined. Kellogg ("N. Y. Med. Jour.," Sept. 2, 1911) believes that the increase is enormous, and claims that in the United States the disease has increased 500 per cent. in sixty years. Bertillon, of the Statistical Department of Paris, believes that cancer is increasing in all countries. The increase is greater among men than women. Such statements are truly alarming, and yet the reality of all of this apparent increase is doubtful. A part of the apparent increase is due to the greater frequency of exploratory operations for diagnostic purposes, to the greater frequency of postmortem examinations, to more correct diagnoses of obscure internal conditions, and to greater accuracy than was once either usual or expected in filling up death certificates. Neusholme says that just as deaths certified as due to old age grow apparently fewer every year, so other non-specific certifications grow fewer, and cancer gains as they lose. The diminution in infant mortality also causes a relative rise in the apparent cancer mortality. Further, more people than formerly live to reach the cancerous age, and people in general live longer than formerly, and in the later years of life cancer is common. The above facts certainly account for a portion of the alleged increase, but we must also remember that we are curing many more cases by operation than we used to be able to, and hence that the death-rate from cancer is not the real and final measure of the incidence of cancer. The experience of most practical surgeons is that there is a real increase in cancer, but the extent of the increase cannot be ascertained with any accuracy.

Hereditary Influence.—This was referred to on page 347. It can be at most only tissue predisposition or a diminution of tissue resistance to the real cause of cancer, whatever that may be. Some previously quoted cases are too impressive to be regarded as coincidences. Williams ("Brit. Med. Jour.," May 9, 1908) points out that 24.2 per cent. of women with cancer of the breast have or had relatives with a history of cancer. Williams states that Butlin's estimate is 37 per cent.; Leaf's, 23 per cent.; and Nunn's, 29.3 per cent.

Immunity.—This was referred to on page 347.

It is known that mouse tumors which follow transplantation in some cases retrogress and undergo spontaneous cure, and that animals in which this has occurred are found to have become immune to a re-inoculation of a like tumor. Crile and Beebe present some studies on this interesting subject in the "Journal of Medical Research," June, 1908. Gaylord and Clowes found that the serum of an animal thus rendered immune tends to destroy tumor cells, and experimented with the transfusion of the blood of immune animals into animals with active tumors; 7 animals out of 10 were cured. The blood of an animal naturally immune to tumor inoculation is said to act similarly to that of an animal which has acquired immunity, as shown by retrogression of a tumor.

Sex.—Cancer is more common in women than in men. If we leave out of consideration cancer of the uterus and breast, men suffer from cancer more often than women. Men are most apt to get cancer of the lip, tongue, and digestive canal.

Distribution of Cancer.—It occurs in all climates and probably all races, although it has been asserted that Eskimos are not liable to it. It is much more common among civilized than barbarous people. It is rarer among the black and yellow races than the white race. The American Indians seldom suffer from it. It occurs in the lower animals far less often than in man, is more common in domestic than in wild animals, and in captive wild animals than in those free and at large. It can even occur in cold-blooded animals. Cancer is most common in the temperate zone. It is usually asserted that the disease is rare in the tropics, but Dudley denies that this statement is true of the Philippine Islands ("Jour. Am. Med. Assoc.," May 23, 1908). Cancer is certainly less common in India than in England, and it is very rare in Greenland. It is almost unknown among the natives of Algeria. It is usually believed that cancer is most prevalent in low and marshy districts. It is less common at high altitudes and among the dwellers on soils of chalk and lime.

Cancer Regions and "Cancer Houses."—Some regions show a remarkable frequency of cancer. In Bookfield, New York, during five years nearly 10 per cent. of the deaths were due to cancer.

Tynes (Ibid., March 21, 1908) reports that in Fisherville, Pennsylvania, in 265 families there were 105 deaths, and 18 of them were due to cancer. It is maintained by Haviland and others that certain houses become infected and that cancer appears in such houses again and again among successive families inhabiting them. Such houses are called "cancer houses," and many remarkable facts have been collected relating to them, facts which to some observers seem to prove contagion, but which to others merely serve as interesting examples of coincidence.

Leeson ("Practitioner," Feb., 1909) is of the latter opinion and shows that there was not a cancer house in his district. He studied 248 cases of cancer and all but 4 of them were in different houses. As this author says: "If we are to accept such evidence as that on which the belief in 'cancer houses' is founded, we must believe in 'apoplexy houses,' 'liver houses,' etc."

Influence of Diet.—Some blame meat, some tomatoes, etc., for the development of cancer. Vernueil and Reclus, commenting on the fact that carnivora are much more prone to cancer than herbivora, suggested that the increase of cancer during recent years might be due to the increased consumption of meat by the poorer clasess. There is no proof of the truth of this suggestion. In fact, Prof. Senn points out that the Eskimos seem immune to tumor formation, yet they live on an exclusive animal diet and, furthermore, are the healthiest people in the world.

Arsenic Cancer.—Sir Jonathan Hutchinson pointed out in 1887 that the administration of arsenic may lead to cancer. Dubreuilh, of Bordeaux, has collected 19 cases ("Annales de Dermatoses," Feb., 1910). It will be highly important to find out if salvarsan can ever be responsible for malignant growth.

X-ray Cancer.—A number of *x*-ray operators who worked with the rays soon after Röntgen's discovery developed cancer. An *x*-ray operator in Philadelphia died of carcinoma of the hand. It led to axillary and mediastinal growths. I operated on him twice in vain. Another Philadelphia operator submitted to amputation of the arm and subsequently died. The cells are repeatedly injured by the rays and, finally, normal repair becomes impossible.

Recurrence After Operative Removal.—This is usually due to the fact that all of the cells were not removed. It may be due to a new growth. Recurrence may be due to cutting across lymph-tracts and flooding the wound with carcinoma cells, which lodge and grow. The growth of cancerous nodules in the abdominal scar resulting from an exploratory operation for cancer of the stomach is observed every now and then. It is probably due to contact invasion of the scar area, which area has lessened vital resistance to cancer cells.

Murphy thinks that the same explanation holds when the stitch cicatrices become cancerous ("General Surgery," in "Practical Medicine Series for 1909").

Extension of Cancer.—It spreads by the lymphatics and rapidly involves the anatomically associated lymph-nodes. In the nodes the migrating cancer cells are imprisoned for a time, and in this incarceration lies the hope of surgery. The adjacent glands are involved much more rapidly than we used to think. They are usually involved within a few weeks of the start of the growth, except in superficial epithelioma, in which cases they are not involved at all.

In a structure devoid of capsule (as the tongue, the mammary gland, etc.) Lockwood points out that involvement of related lymph-nodes is practically immediate.

Lymphatic involvement may result in the formation of a mass much larger than the parent growth. The ducts between the primary cancer and the involved glands are filled with carcinoma cells and their walls become infiltrated. Hence in an operation the ducts should not be cut across or the wound would be flooded with fluid rich in cancer cells. The ducts should be extirpated as well as the glands. To flood the wound with fluid containing embryonic cells is very dangerous, for some of them may adhere, multiply, and reproduce the disease. After a time the capsules of cancerous nodes rupture and periglandular tissue becomes involved. The cells are held in the first glandular stopping-place (the anatomically related glands) for a time, but sooner or later other and more distant glands become involved. In certain abdominal cancers (stomach, rectum, and uterus) the thoracic duct may become obstructed by cancer cells. Large glands may cause much trouble by pressure. When they soften and break down the skin becomes involved and dreadful sores form, oozing foul matter and blood. Death may be due to hemorrhage from a large vessel which has become infiltrated.

Several times I have been consulted by patients on account of glandular enlargements of the neck, the patients never having noticed a small primary lesion in the mouth, and yet the entire glandular disease was secondary to the limited oral trouble.

Dissemination or Metastasis.—These terms mean the formation of secondary growths. These growths are formed by small fragments of cancer being broken off and carried to lodgment in distant structures. Such small fragments are called *cancer emboli*. Cancer emboli may be carried by lymph or blood. When cancer emboli lodge in a region favorable to their growth their constituent cells multiply and produce secondary growths. A secondary growth is the histologic counterpart of the parent growth, and an examination of a secondary growth gives us accurate information as to the nature of the primary growth. In cancer of the rectum there may be secondary deposits in the liver or in bone containing structure like rectal glands. In cancer of the stomach secondary nodules in the skin may contain structure resembling the gastric glands. Secondary deposits are by no means as common in cases of squamous-celled cancer as in glandular cancer.

Another method of dissemination is observed in the abdomen. When cancer of a viscus breaks through the peritoneal coat the cells are spread widely by peristaltic movements and peritoneal fluid, and the peritoneum becomes extensively involved. This involvement is a form of contact cancer. Any structure may be the seat of a secondary growth. The lung is frequently affected, so is the liver, so are the bones. Any organ or tissue may become the host for secondary deposits of carcinoma.

Spontaneous Disappearance of Cancer.—This is an excessively rare event in human beings, but it does occasionally occur. Gaylord has collected 11 cases which he considers authentic, viz., 2 epitheliomata (1 of the tongue and

1 of the lip), 1 scirrhous cancer of the breast, 1 malignant adenoma of the rectum, and 7 cases of chorion carcinoma ("Seventh Annual Report of the Cancer Laboratory of New York State Department of Health"). The same author also notes the spontaneous disappearance of two sarcomata. Spontaneous disappearance of Jensen tumors successfully inoculated in mice is quite common. It occurred in 23 per cent. of Gaylord's animals. Whereas it is common in mouse tumors resulting from inoculation, it is rare in spontaneous mouse tumors. Bushford finds spontaneous healing in less than 1 per cent. of the latter group. Spontaneous disappearance is not due to the fatty degeneration and necrosis so often found about the center of a carcinoma, but to deprivation of the epithelial cell of some or all of its vitality by an utterly unknown process. Some observers think spontaneous cure is brought about by the stimulation of an immunizing force. When spontaneous cure occurs cancer cells are gradually replaced by scar tissue, and the resulting scar may contain cancer cells immeshed in it. Hence, after apparent retrogression, growth may begin anew.

Fig. 181.—Carcinoma of the auricle.

Besides the apparently positively authenticated cases reported by Gaylord, there are numerous cases on record in which it is highly probable cancer disappeared spontaneously. These cases are collected in the appendix to the previously cited report of Gaylord.

Blood Changes in Cancer Cases.—In early cases there is no notable change in either erythrocytes or hemoglobin. In more advanced cases as cachexia begins secondary anemia develops, fall of hemoglobin antedating diminution in erythrocytes.

The anemia may become so profound that it resembles pernicious anemia; in fact, some observers have asserted that pernicious anemia may arise. The anemia of cancer is not benefited by medical treatment.

In gastric cancer, because of vomiting and diarrhea, blood concentration may occur, the red corpuscles being 6,000,000 or even 7,000,000 per cmm.

The leukocytes may be normal, but are often increased. It has been claimed by Macalister and Ross ("Lancet," Jan. 16, 1909) that the blood of a patient with cancer contains a material in its plasma which is an excitant for the leukocytes of healthy persons. As previously stated (see page 384) the serum of the blood of a person with cancer contains agents destructive to the red corpuscles of healthy blood.

Classification of Carcinomata.—Carcinomata are classified as follows: (1) Epithelioma; (2) rodent ulcer, or Jacob's ulcer; (3) spheroidal-celled cancer; (*a*) schirrous; (*b*) encephaloid; (*c*) colloid, and (4) cylindrical-celled cancer. Clinically, we speak of *cuirass cancer*, a condition sometimes arising when the mammary gland is cancerous and due to the infiltration of the cutaneous lymphatics with cancer cells; *chimney-sweeps' cancer* and *paraffin worker's cancer*, if either of these occupations seems to have been causative; *cancer à deux*, a phrase used in France to signify that carcinoma has occurred in two persons of a household who are not blood relations, but have been in close contact; *contact cancer*, when cancer appears in an area which was in close

contact with a cancerous area in the same or in another individual—for instance, when a cancer of the upper lip follows a malignant growth of the lower lip; when a carcinoma of the face follows a like growth of the hand; when a cancer appears on the penis of a husband whose wife has cancer of cervix uteri or vagina. A *melanotic carcinoma* is a form of encephaloid in which the cells contain melanin. Scirrhous cancer contains much fibrous tissue and is densely hard. An encephaloid is very soft or brain-like. *Marjolin's ulcer* is an epithelioma which arises from the epithelial edge of a chronic ulcer, a scar, or a sinus (see page 159). Figures 82, 83, 84, and 85 show a Marjolin ulcer arising in the scar of a burn.

Epitheliomata.—An epithelioma arises from surface epithelium, and may arise from squamous cells or cylindrical cells, according to the location.

Squamous-celled epithelioma (see Fig. 179) takes origin from the skin or from a mucous membrane covered with pavement-epithelium. It is especially apt to appear at the junction of skin and mucous membrane (as the lips) or the point of juxtaposition of different kinds of epithelium. Such a growth may arise in the anus or vagina; on the penis, scrotum, lips, or tongue; in the mouth or nose; on the skin, and other situations. There is an ingrowth of surface epithelium into the subepithelial connective tissue, colonies of cells growing inward and forming epithelial nests. It may arise without discoverable cause, it may follow prolonged irritation, or it may arise in a wart or fissure. In the nipple it is not very unusually, and in the scrotum and nose it is occasionally, preceded by a persistent dermatitis due possibly to psorosperms, and known as *Paget's disease.* Paget's disease is not true eczema, but is rather malignant dermatitis. A crust gathers on the part, and beneath this crust is a raw, red, and moist surface, the edge of which is slightly elevated and somewhat indurated. In the beginning there is a strong resemblance to eczema. The nipple is apt to retract. The parts are the seat of a constant itching and scalding sensation. The area may become cancerous in a few weeks, but may not for years. I have seen two cases of Paget's disease of the glans penis. Squamous epithelioma generally begins as a warty protuberance which soon ulcerates. A malignant or *true cancerous ulcer* (see Fig. 179) has a hard, irregular base, uneven edges, a foul, fungus-like bottom, and gives off a sanious or ichorous discharge. This ulcer is the seat of sharp, pricking pain, sometimes bleeds, and extends over a considerable area, embracing and destroying every structure. Epithelioma usually affects lymphatic glands early, but such infection may be long delayed. Epitheliomatous glands break down in ulceration, making frightful gaps and often causing fatal hemorrhage. Dissemination is not nearly so common as in other forms of cancer, but it does sometimes occur.

Cylindrical-celled Epithelioma.—This form of growth takes origin from structures covered with or containing cylindrical epithelium, and it contains cylindrical or columnar cells. It is composed of a stroma of fibers between which lie tubular glands lined with columnar epithelium and containing masses of epithelial cells. Such tumors are found in the uterus and gastro-intestinal tract, and may begin from the surface epithelium or from the cells of tubular glands. In these tumors there is an acinus-like structure and the spaces are filled with proliferating epithelium. Cylindrical-celled cancers may also arise from the mammary gland, liver, and kidney. One of the most common seats of cylindrical-celled cancer is the rectum. Cancer of the rectum may occur at an earlier age than cancer elsewhere, being not uncommon between the ages of twenty-eight and forty. Cylindrical-celled epitheliomata are at first covered with mucous membrane, but they soon ulcerate and involve the submucous and muscular coats in the growth. They may grow rather slowly, usually but not always cause lymphatic involvement, and finally disseminate widely. They require in some regions from five to six years to cause

death. In the rectum, however, growth is much more rapid and few victims of cylindrical-celled carcinoma of the rectum, if unoperated upon, live beyond two years, and many of them die long before this period.

A *rodent* or *Jacob's ulcer, epithelioma exedens* or *cancroid* (Fig. 182), was called by the older surgeons *noli me tangere,* because they found that surgical interference (incomplete removal as we now know) was sometimes followed by very active growth. A rodent ulcer is scarcely ever met with except upon the face, though Jonathan Hutchinson saw one upon the forearm, and James Berry met with one upon the arm. It is especially common upon the nose and forehead. It begins after the age of forty as a little warty prominence which ulcerates in the center, the ulceration progressing at a rate equal to the new growth. The ulcer becomes deep; it is not crusted; its edges are irregular, hard, and everted; the floor is smooth and of a grayish color; the discharge is thin and acrid; and the parts about the sore contain numbers of visible vessels. Jacob's ulcer grows slowly, may last for years, does not involve the lymphatics, produces no constitutional cachexia, and is rarely fatal. In some cases, although growth is very slow, destruction eventually becomes very great because of ulceration, there is great loss of tissue and horrible deformity. A rodent ulcer is usually considered to be a malignant epithelial growth which springs from a sweat-gland, a sebaceous gland, or a hair-follicle, but Kanthack asserts that before ulceration the rete and the sweat-glands are normal, but the sebaceous glands are destroyed. The base and edges of the ulcer are hard, which differentiates it from lupus; and, further, the bacilli of tubercle may perhaps be cultivated from the discharge of an area of lupus (see page 247). Rodent ulcer begins below the skin, ordinary epithelioma begins in the skin, and a rodent ulcer contains no cell-nests. A rodent ulcer very rarely undergoes cicatrization, a fact which differentiates it from lupus. Occasionally, but very rarely, a small portion of the growth sloughs out and a temporary scar forms at this point.

Fig. 182.—Rodent ulcer. Case in the author's wards in Philadelphia Hospital.

Adenocarcinoma or Glandular Carcinoma.—Glandular carcinomata in structure resemble racemose glands. They consist of a stroma of connective tissue and alveoli filled with proliferating epithelial cells. If the proportion between the fibrous stroma and the cellular elements is about the same as in a normal gland, the growth is called simple. When the cellular element is in excess the growth is soft (medullary), and when the fibrous stroma is in excess the growth is hard (scirrhous).

1. *Scirrhous carcinoma* is a white and fibrous mass which has no capsule, which infiltrates tissues, and which, by the contraction of its outlying fibrous processes, draws in toward it adjacent soft parts, thus producing dimpling, or, as in the breast, retraction of the nipple. It is composed of spheroidal cells in alveoli formed of connective-tissue bands. The commonest seat of

scirrhus is the female breast. It occurs also in the skin, vagina, rectum, prostate, uterus, stomach, and esophagus. It is most frequent in women after forty. It begins as a hard lump which is at first painless, but which after a time becomes the seat of an acute, localized, pricking pain. This lump grows and becomes irregular and adherent, causing puckering of the soft parts. After the skin or mucous membrane above it has become infiltrated ulceration takes place and a fungous mass protrudes which bleeds and suppurates. The adjacent lymphatic glands usually become cancerous in from six to ten weeks, and constitutional involvement is rapid and certain.

2. *Medullary* or *encephaloid carcinoma* is a soft gray or brain-like mass. It is a rare growth, it has no capsule, and it may appear in the kidney, liver, ovary, testicle, mammary gland, stomach, bladder, and maxillary antrum. An encephaloid cancer often contains cavities filled with blood, and this variety is known as a "hematoid" or a "telangiectatic" carcinoma. These growths are soft and semifluctuating, they infiltrate rapidly and soon fungate, and they terminate life in from a year to a year and a half. If the cells of encephaloid become filled with melanin, the condition is called "melanosis" or "melanotic cancer."

3. *Colloid cancer* is extremely rare. It arises from either a scirrhus or an encephaloid, when the cells or the stroma of such a growth undergo colloidal degeneration. On section there will be seen in the center of the growth a series of cavities filled with a material resembling honey or jelly; the periphery is frequently an ordinary scirrhus or encephaloid cancer. Colloid degeneration is most prone to attack carcinomata of the stomach, mammary gland, and intestine. The name colloid cancer is often given to glistening, gelatinous, malignant growths springing from the ovary, testicle, mammary gland, or gastro-intestinal tract. The condition is due to mucous degeneration of the connective tissue or of the epithelial tissue of a carcinoma. Only a portion of the tumor may degenerate or the entire mass may become gelatinous.

Syncytioma Malignum.—By this name is meant a malignant epithelial growth arising from the site of the placenta during pregnancy or the puerperal state. It resembles placenta in appearance and rapidly causes metastases by way of the blood-vessels. It is quickly fatal.

Treatment.—Cancer is so prevalent, is so dreadful in its nature and inexorable in its progress, tends so strongly to cause death in from two to five years, people are so afraid of it, and so many physicians are hopeless of curing it that multitudes seek relief from the obsessed Christian scientists or from the vulgar criminal quacks. It cannot be too strongly insisted that in the beginning cancer is a local disease curable by early and radical operation, that early diagnosis should be made, and that prompt operation is imperative. Delay is not only disastrous, it is usually fatal. Certainly at least 50 per cent. of the cases of cancer I see are beyond operation when they are first brought to the hospital, they having sacrificed the golden moments during which cure was possible. Carcinomata demand early and wide excision, with removal of implicated glands. Anatomically related lymph-nodes must be removed even if they show no evidence of involvement. If operation is early and thorough, and if certain regions are involved, a considerable proportion of cases can be cured. Carcinomata of the lip, the skin, and the mammary gland can often be cured. The operation must be radical. That the tumor is small and recent is no justification for minimizing the extent of operation. That is the sort of case which may be cured by radical removal. Anything short of radical removal is bound to fail. Recurrence almost certainly means that cancer cells have been left behind. Unless a wide area is removed cancer cells are sure to be left. During removal the parts should be handled as little as possible so as not to squeeze malignant cells into the wound. Cancer cells in a wound soon become

fixed and multiply. For the same reason tumor and glands are removed in one piece. The surgeon avoids cutting across lymph-vessels and planting cancer cells in the wound. After operation the x-rays should be used in hope of destroying cancer cells which may have remained in the tissues. To use the rays lessens the danger of recurrence. Czerny ("Deutsche Med. Wochen.," Nov. 2, 1912) is so impressed with the necessity of special effort to prevent recurrence that he leaves the operation wound open for two or three months, uses radium, the x-rays, or fulguration in the wound, and then, if everything seems to be going on well, he closes the wound by a plastic operation. A recurrent growth may be removed as a palliative measure to lessen pain and to relieve the patient from ulceration and hemorrhage, but such an operation is rarely curative. If a growth does not recur within five years after removal, a cure has very probably been attained; in fact, if there is no recurrence within three years, the case is probably cured. The three-year limit has been usually accepted since Volkmann's paper on the subject. A rodent ulcer should be excised or else be curetted and cauterized with the hot iron or the Paquelin cautery. In cancer of the lower *lip*, remove the growth by Grant's operation (*q. v.*), or, if necessary, cut away the entire lip. In every case remove the glands beneath the jaw. In cancer of the *tongue*, excise this organ and also the lymph-nodes from beneath the jaw and in the anterior carotid triangles. In cancer of the *breast*, remove the breast, the pectoral fascia and the pectoral muscles, and take away the fat and glands of the axilla. In cancer of the *rectum*, if near the surface, excise the rectum from below; if above 5 inches from the anus, do the sacral resection of Kraske and then remove the growth. In cancer of the *esophagus*, perform gastrostomy; in cancer of the *pylorus*, perform pylorectomy or gastro-enterostomy; in cancer of the *bowel*, do resection, side-track the diseased area by an anastomosis, or make an artificial anus; in cancer of the *penis*, amputate the organ and remove the glands of the groin.

Treatment of Inoperable Cancer.—Erysipelas toxins are seldom of any service in carcinoma. In very rare cases they do good. It is justifiable to try them. Claims have been made that cancer can be benefited by the injection of material expressed from carcinomatous tumors. There are suggestions of the value of such treatment. The late Dr. Hodenpyl had charge of a case in which a cancer of the liver was undergoing spontaneous retrogression. When a cancerous individual was injected with ascitic fluid from this case a local reaction was observed in the tumor (swelling, redness, diminution in size, necrosis). It was assumed that the fluid contained a specific material which might cure cancer. The results of the study of such fluid have been negative (Richard Weil, "Jour. Med. Research," August, 1910). Serum from animals suffering from cancer is without therapeutic value. Pyoktanin, thiosinamin, trypsin, and many other materials have come upon the scene as remedies. They were like plausible confidence men, but each was soon exposed. There is no drug and no serum at present known to be capable of curing cancer. Honest investigators have at times been lead into error by forgetting that at times the rate of growth of a cancer may temporarily lessen or that growth may for a time actually cease. (See Lewis S. Pilcher's address before the Surgical Society of Brooklyn in Feb., 1909.)

Fulguration has of late excited much interest. By this term we mean bombarding a part from a metal electrode with sparks flashed from a high-tension current. It was introduced as a treatment for cancer by De Keating-Hart in 1907. The sparks have no specific action on cancer cells. All the surface cells of an ulcerated growth are converted into an eschar and the connective tissue under and around the sore is stimulated to cicatrize. Sometimes after fulguration healing occurs over cancerous nodules. Fulguration cannot act through the unbroken skin. It is not a real cure, though it may retard the

progress of a case or aid in preventing recurrence after extirpation of a growth. Application of sparks may be followed by grave or fatal sepsis. The early enthusiasm for fulguration in cancer has largely waned. No operable growth should be treated by it, as, at best, it has only a local effect and cannot act upon the involved lymph-nodes. The *x*-rays are of distinct value in certain cases of carcinoma. Surface growths may be apparently cured, although, unfortunately, they are apt to return even after total disappearance. Deeper growths are seldom lessened in size and practically never cured, but the rate of growth may be diminished and pain be abated or abolished. The knife is to be preferred to the *x*-rays, except in very superficial skin cancer about the eyelid or nostril, and in inoperable cancer. The real curative power of radium is as yet undetermined. The *x*-rays and radium have a decided influence in lessening the horrible pain of recurrent or inoperable cancer. In lymphatic recurrence after operation thyroid extract may perhaps be of some value. In some cases of recurrent cancer ligation of the artery of supply or extirpation of the artery, as suggested by Dawbarn, notably retards growth. I have been able to confirm this statement. In cancer of the breast, oöphorectomy occasionally produces great benefit (Beatson's operation). In inoperable cases palliative operations may be justifiable to relieve some urgent discomfort or get rid of a foul or bleeding mass. Gastro-enterostomy, gastrostomy, and colostomy are palliative operations. In a malignant growth of the nasopharynx tracheotomy may be required, and in a malignant growth of the bladder it may be advisable to perform suprapubic cystostomy. In an inoperable case it may be necessary to relieve the pain by opium, giving as much as may be required to secure ease. Opium so used seems not only to relieve pain, but to retard the growth of the tumor and to favor the development of fibrous tissue in the stroma.

Chemotherapy of Cancer.—Wassermann has been able to cause mouse cancer to disappear by injecting into the veins of the animal negrosin, and also by injecting eosin and selenium. This proves that a chemical, as well as a parasite, may have an affinity for certain cells. The chemicals used by Wassermann attacked the cells of mouse cancer, and did not attack or only slightly influenced the other cells of the body. The world is seeking for a chemical agent to destroy cancer.

Wassermann desired to introduce selenium into the cancer cells. He found eosin (an aniline dye) to be the helping hand to put selenium into the cells. When the pink solution of eosin-selenium is thrown into the blood of a mouse the skin at once becomes pink. The pink color of the skin disappears in a few hours; the tumor remains deeply stained. Numerous injections will kill the mouse or cause the tumor to disappear, and the action is just as positive in spontaneous as in transplanted tumor.

This material is too dangerous to use in man, but the investigation suggests splendid possibilities for the future (E. F. Bashford, in the "Lancet," Jan. 13, 1912).

Malignant Growth from Congenital Pigmented Mole (Fig. 183).—As previously stated, the embryonic origin of the pigment-producing cells is uncertain. Some regard a malignant growth of a congenital pigmented mole as epithelioma, others as alveolar pigmented sarcoma. Bloodgood thinks it is probably carcinomatous.

Malignant change seldom occurs before the fiftieth year, the growth rarely attains a large size, metastasis takes place very rapidly by the blood and lymphatics, and the patient seldom lives more than a year after malignant change begins. (See Bloodgood, in "Progressive Medicine," Dec., 1907.)

Because of the danger of subsequent malignant change it is wise to remove large pigmented moles. Every pigmented mole which is irritated or begins to

enlarge must be removed, and the associated lymph-nodes should also be removed. Bloodgood knows of no definite cure on record of a malignant tumor arising in a pigmented mole. Prevention is easily secured by extirpation before the onset of malignancy.

Cystomata.—A cystoma is a benign cystic tumor in which the cells of the cyst wall constitute the new growth. The cyst contents are derived from the cells of the wall. The tumor is the cyst wall; the cells of this wall are derived from the epiblast, the hypoblast, or the mesoblast, and are either epithelial or endothelial. The cells of the cyst wall adhere to connective tissue which seems to constitute a part of the wall. A thick wall contains much connective tissue, a thin wall very little. The nature of the contents is dependent on the character of the cells which constitute the tumor. Cysts lined by endothelium contain serous fluid; a cyst of the thyroid gland usually contains colloid material; a cyst lined by flat epithelial cells contains matter resulting from fatty degeneration, etc.

Fig. 183.—Melanotic growth, secondary to pigmented mole.

Cystomata may be congenital or acquired, and an acquired cystoma may arise after injury or follow inflammation. The cyst may increase in size progressively or its growth may be halted. The wall may become calcareous or even bony. When a cyst has one cavity, we call it monolocular; when there are several or many cavities it is called multilocular.

Varieties of Cystomata.—The chief varieties are: Traumatic epithelial; atheromatous; mucous; mesoblastic.

Traumatic Epithelial Cystomata.—These growths have been called traumatic dermoids. Such a growth may arise after an injury which carries and deposits epithelial cells or a bit of skin deep into the connective tissue. For instance, a punctured wound of the hand may be followed by an epithelial cystoma (Fig. 185). It may arise after a scalp wound or in the scar of a burn. The cyst grows only to a certain size and then remains stationary. It is lined by pavement-epithelium and it contains products of the fatty degeneration of epithelial cells.

Treatment.—Extirpation of the wall of the cystoma.

Atheromatous Cystomata.—These growths, according to Senn, are met with particularly in the ovaries, in the orbital region, and at the base of the tongue, but they can arise almost anywhere. They may remain small or may attain a great size. Such a cystoma contains columnar epithelial cells which have undergone fatty degeneration and sometimes contains oil. An atheromatous cystoma is deep seated and is not connected with the skin, in contrast to a sebaceous cyst, which is superficial and is a part of the skin. An atheromatous cystoma is lined with epithelium, but not with skin. A dermoid cyst is lined with skin or other definite structure. An atheroma is due to the displacement of a mass of epithelial cells, which mass was the matrix of the cystoma. "The displacement of the matrix of an atheroma occurred at a time prior to the differentiation of the epiblastic cells into the organs representing the appendages of the skin, while the matrix of a dermoid cyst points to

a later displacement of the matrix" ("Pathology and Surgical Treatment of Tumors," by Nicholas Senn). Atheromatous cystomata may be congenital, but may not appear until puberty or even much later.

Treatment.—Extirpation of the wall of the cystoma.

Mucous Cystomata.—A mucous cystoma, like an atheromatous cystoma, is due to the displacement of epithelium, but in the former condition it is pavement-epithelium and in the latter it is columnar epithelium. The latter is filled with a mucoid material and the former with a fatty débris. Such a mucous cystoma must not be confused with a retention cyst of a mucous membrane. Mucous cystomata are found particularly about the lips, mouth, and pharynx. They rarely attain any considerable size. Cystomata lined with ciliated epithelium may arise in the testicle, the liver, and the brain.

Treatment.—Incise, cauterize, and drain. The wall is so delicate that excision is rarely possible.

Mesoblastic Cystomata.—They are lined with endothelial cells. They contain serous fluid, often grow to a large size, and sometimes disappear spontaneously. Mesoblastic cystomata are probably distended lymph-spaces. They are congenital and are most common in the neck, axilla, and perineum.

Fig. 184.—Hydrocele of neck in boy nine weeks of age.

In one case seen by the author such a cystoma of the neck appeared late in life, but it is probable that it had existed in childhood, and after disappearing for a long time had reappeared. The most common form of mesoblastic cyst is known as *hydrocele of the neck* (Fig. 184).

Treatment.—Excision is very difficult. In 1 case in which I assisted Professor Keen it was successfully accomplished. The usual treatment is to tap frequently, after each tapping washing out with carbolic acid (2 to 5 per cent.) and applying pressure.

Cystomata of bone, of the thyroid gland, of the mammary gland, etc., are considered in the sections on Regional Surgery.

Teratomata.—The teratomata contain tissues or higher structures derived from two or all of the blastodermic layers. The tumors we previously considered are derived from only one of these layers. The elder Senn, in his work on "Tumors," thus defines a teratoma: "A teratoma is a tumor composed of various tissues, organs, or systems of organs which do not normally exist at the place where the tumor grows. The highest type of a teratoma is a fetus in fetu. In the simpler varieties the tumor is composed of heterotopic tissue, such as bone, teeth, skin, mucous membrane, etc. All teratoid tumors are congenital; that is, the tumor either exists at the time of birth or

the patient is born with the essential tumor matrix. A teratoma never springs from a matrix of postnatal origin." Any human structure may be found in a teratoma. Various fetal malformations belong to this group, as do also double monsters, in which one of the embryos is rudimentary. Teratomata are divided into *external* and *internal*. To the external teratomata belong the parasitic fetus and the suppressed fetus. A *parasitic fetus* is the result of fusion of two embryos, one having gone on to complete development, and the other developing partially, and obtaining nutrition from the fully developed embryo to which it is attached. A *suppressed fetus* is an irregular mass attached to the posterior surface of the sacrum, to the chest, or to the abdomen. It contains a conglomeration of tissues and fragments of organs, for instance, bone, cartilage, lung tissue, kidney tissue, a piece of intestine, or a portion of liver. In a case pictured by Sir J. Bland-Sutton a leg projects from the sacral region.

An *internal teratoma* may be found within the cranium, chest, abdomen, or pelvis. The internal teratoma consists of a conglomeration of the tissues and visceral fragments of a suppressed fetus, but, unlike the external teratoma, it is surrounded by a cyst wall. The members of this group most often seen by the surgeon are *dermoid cysts*.

Dermoid Cysts.—These cysts were first studied and described by Lebert. The name "dermoid" implies that the cyst contains skin, and it does contain skin or mucous membrane, the chief mass of the tumor being derived from proliferation of the cells of a portion of displaced epiblast or hypoblast, but it also contains mesoblastic derivatives. There are two varieties of true dermoid: *sequestration dermoid* and the *tubulodermoid*. In this section we speak of the first form. The second form is considered on page 401. A superficial dermoid is formed by the inclusion in mesoblastic tissues of a portion of the epidermis or mucous membrane. Superficial non-traumatic dermoids are situated in regions where the blastodermic layers were in contact. A deep dermoid is formed from a collection of epithelial cells completely separated from the epiblastic tissue from which they originated. When a cyst originates from epiblastic cells so immature that the skin appendages have not as yet been formed, it will contain only atheromatous material like that found in a sebaceous cyst. When a cyst arises from epiblastic cells after they have so matured that the appendages of the skin have been formed, it will contain atheromatous matter, sweat, sebaceous matter, and hair. The first form is known as an *atheromatous cystoma;* the second, as a dermoid. A deep-seated dermoid may contain also such structures as prove it must have taken origin from "a displaced matrix representing different tissues and organs" (Senn). Such a dermoid may contain portions of organs, bone, cartilage, and teeth. A dermoid cyst may be defined as a heterotopic cyst, the wall of which is composed of connective tissue lined with epithelium and containing material formed by the proliferation of epithelium and often hair, teeth, or even bone. An injury may displace a bit of epithelium and lodge it in connective tissue and from this a traumatic dermoid may arise (Fig. 185). Traumatic dermoids are not true dermoids. Garrè called them *traumatic epithelial cysts*. They are most often encountered in the palmar surface of the hand or fingers. The skin above such a cyst is not adherent to it and often a scar is visible. The cyst wall is composed from without inward of connective tissue and epithelial cells, the stratum corneum being the inner layer (Leo Buerger, in "Annals of Surgery," August, 1907). The cyst contains desquamated epithelium and often cholesterin. The causal injury is usually a puncture, but may be a laceration, a contused wound, or a bite. Sometimes a cyst arises in the track of a healed sinus. Pietzner collected reports of 73 cases ("Ueber Traumatische Epithelcysten. Dissert. Rostock.," 1905).

True dermoid cysts are most commonly found in the ovary and in regions where, during bodily development, the blastodermic layers come in contact; for instance, in the neck, the eyelids, the orbital angles, the lumbosacral region, the root of the nose, and the floor of the mouth. Such cysts are also found in the ovary, testicle, brain, eye, mediastinum, lung, omentum, mesentery, and carotid sheath.

A dermoid of the lumbosacral region may be mistaken for a spina bifida. Sarcoma may form from the connective-tissue elements of the wall of a dermoid cyst. A dermoid cyst may become cancerous, or innocent epithelial tumors may originate from the cyst lining. The epithelial cells may become fatty and an oil-cyst may actually form. If the cyst epithelium was derived from mucous membrane, mucus may gather in the sac. A dermoid cyst may inflame or even suppurate. It is free from pain unless it suppurates, inflames, or develops into a malignant tumor; it grows slowly and rarely attains any considerable size unless it arises in the ovary. A subcutaneous dermoid may or may not fluctuate. It is not in the skin as is a sebaceous cyst, but the skin can be moved over it. A sebaceous cyst moves with the skin. Subcutaneous dermoids about the orbit are adherent to the underlying periosteum. The matrix of a true dermoid is congenital, but the cyst often does not appear until puberty or later. Teratoids and dermoids connected with the rectum require special consideration (see page 1165).

Fig. 185.—Traumatic dermoid cyst.

Treatment.—Complete extirpation. If any of the epithelium of the cyst-wall is left, the cyst will re-form. A superficial dermoid should be removed in the same manner as a sebaceous cyst, and if it is adherent to underlying periosteum the portion of this membrane to which it adheres should also be removed. A deep dermoid ought to be removed as a tumor would be, if operation is feasible.

Branchial Cysts and Fistulæ.—When a branchial cleft fails to become completely obliterated, a branchial cyst may form. The branchial clefts are the analogues of the gill-slits of a fish. There are four of these clefts on each side of the neck. They are called clefts, but they are really grooves, and each groove on the skin has its counterpart in the mucous membrane of the pharynx. Each pharyngeal groove is covered with hypoblastic epithelium; each cutaneous groove is covered with epiblastic epithelium, and the two grooves are separated by mesoblastic structures. When the sides of a cleft do not unite and an opening forms in the mucous membrane, a *complete branchial fistula*

(*complete congenital cervical fistula*) results. When the sides of a cleft fail to unite and, although the mucous membrane is not perforated, the skin does not cover the cleft, a *branchial sinus* or an *incomplete branchial fistula* (*incomplete congenital lateral cervical fistula*) results. When the sides of a cleft toward the pharynx fail to coalesce, a *pharyngeal diverticulum* is produced. When the pharyngeal surface and the cutaneous surface both close, but the deeper part of a cleft remains open and epithelial cells are caught in mesoblastic elements, a *branchial cyst* is formed. Sinuses are more common than complete fistulæ or cysts.

The essential cellular element of a branchial cyst is epithelium, derived either from the skin or pharynx; hence the branchial cyst is not a true dermoid, because its histologic elements are derived from only one of the blastodermic layers. Branchial cysts are most common in the triangle of election of the left side. They are round, smooth, often fluctuating, and are very deeply situated, being in close relation with the great vessels. Some cysts contain mucus, others serous fluid, others fatty débris. An abscess may form. The origin of a cyst or fistula is usually from the second branchial cleft, but I have operated on two cysts of the first branchial cleft, and my colleague, Dr. Nassau, also operated on one of like origin. There may be one, two, or three openings of a fistula. Not unusually the openings are bilateral. Hereditary tendency is often manifest. The cutaneous openings are always along the anterior margin of the sternocleidomastoid muscle. At the external orifice there is often an irregularly shaped bit of skin and cartilage, which is called a *cervical auricle*.

Treatment.—In old children and in adults it may be possible to extirpate a cyst or a fistula, although this is very difficult and often impossible. Other methods employed are incision, cauterization with the Paquelin cautery, and packing with gauze; frequent tapping and injection with iodin; incision and drainage, every antiseptic care being observed. In all young children and in some older persons with deep cysts the latter plan is the only one advised, and it will often fail, but may sometimes produce a cure.

Cysts.—A cyst is a cavity, abnormal or pathological in character, lined by a membrane and containing material usually fluid or semifluid. It is necessary to bear in mind the distinction between a cystoma and a cyst. Hektoen and Riesman, in the "American Text-Book of Pathology," insist on this distinction. They say: "A *cystoma* is a true tumor, arising from active proliferation of a matrix destined to form cystic spaces; whereas a cyst is a secondary formation not primarily due to tissue proliferation." Cysts are divided into the following classes: Retention-cysts; cysts from softening; tubulo-cysts; and parasitic cysts (Ibid.).

Retention-cysts.—A retention-cyst is formed by blocking of the duct of a gland or by failure in the absorption of the proper amount of the secretion of a ductless gland. A few characteristic forms of retention-cysts will be described.

Sebaceous Cysts (Wens).—A sebaceous cyst arises when the excretory duct of a sebaceous gland is blocked by dirt or occluded by inflammation. The orifice of the duct is often visible as a black speck over the center of the cyst. They are very common in the scalp, being known as *wens*, and upon the face, neck, shoulders, and back. Arising in the skin, and not under it, the skin cannot be freely moved over a sebaceous cyst. A sebaceous cyst is lined by epithelium and is filled by foul-smelling sebaceous material. A sebaceous cyst may suppurate. When a cyst ruptures and the contents become hard, a *horn* is formed. Another form of horn has been previously alluded to as due to horny transformation of a wart.

Treatment.—To treat a sebaceous cyst, incise the portion of skin above it and dissect the sac entirely away by scissors or a dissector, trying to not

rupture the delicate wall. If even a small particle of the wall is left, the cyst will re-form. If it ruptures during removal and it is feared that some portion may remain, cauterize the interior of the wound by pure carbolic acid. If acid is not used, close without drainage; but if acid is used, drain for twenty-four hours. If an abscess forms in a sebaceous cyst, open it, grasp the edges of the cyst lining with forceps, dissect out this lining by scissors curved on the flat, cauterize by pure carbolic acid, and drain for twenty-four hours.

Mucous Cysts.—A mucous cyst is due to the blocking of a mucous gland or a mucous crypt. Mucous cysts occur particularly in the mucous membrane of the mouth and genito-urinary organs, and are filled by thick, adhesive mucus containing numerous epithelial cells. Such a cyst is of spherical outline, and the epithelial membrane which lines it is strongly adherent to tissues beyond.

Treatment.—Incision, curetment, cauterization by pure carbolic acid, and packing or extirpation of a considerable part of the cyst, and curetment and cauterization of the part remaining.

Fig. 186.—Dr. Weatherby's case of multiple sebaceous tumors of the scrotum.

Oil Cysts.—An oil cyst is due to fatty degeneration of the epithelial lining of a sebaceous cyst, or a milk cyst of the breast. As previously noted, a dermoid may become an oil cyst.

Treatment.—Extirpation, as for sebaceous cysts.

Salivary Cysts.—A retention-cyst of a salivary gland is known as a *ranula* (*q. v.*). These cysts are most common in the submaxillary or sublingual gland.

Lacteal or Milk Cysts (Galactoceles).—Such a cyst occasionally arises in the mammary gland during lactation, and is the result of blocking of a lactiferous duct (see Cysts of Mammary Gland).

Among other forms of retention-cysts, most of which are discussed in special sections of this book, we mention *hydrosalpinx*, a cyst due to blocking of a Fallopian tube; cysts due to obstruction of the bile-ducts (the most common form is known as *hydrops*, which is a dilated gall-bladder the result of obstruction); cyst of the thyroid gland; cyst of the pancreas; and *hydronephrosis*, a condition produced by obstruction of the ureter.

Cysts from Softening.—These cysts are formed by the disintegration of degenerated tissues. For instance, after a hemorrhage into the brain, softening may follow and a cyst arise. Cystic changes of this sort are frequently observed in sarcomata and carcinomata. A cyst from softening has a wall of connective tissue, but there is no endothelial or epithelial layer.

Tubulocysts.—This name was given by Sir J. Bland-Sutton to cysts formed in certain remains of embryonal ducts, which vestiges ought to have been destroyed in the developed body. A small cavity is left unobliterated, and in this space fluid gathers. The source of the fluid is usually the lining cells of the cavity. Branchial cysts are frequently considered under this heading. Among the commoner tubulocysts are cysts of the vitello-intestinal

duct, cysts of the urachus, and thyroglossal cysts. Thyroglossal cysts and sinuses are considered on page 926.

Mesenteric cysts, not hydatid and not due to carcinoma, are embryonic developments from remains in the mesentery of the vitelline duct, the Wolffian ducts, the Wolffian bodies, and the Müllerian ducts (Moynihan).

What are called "chyle cysts" of the mesentery are embryonal cysts placed in such close adjacency to lacteals that chyle enters into them (E. P. Baumann, in "Lancet," May 7, 1904).

Cysts of the Vitello-intestinal Duct.—Such a cyst presents itself as a small, bright red, globular mass, which appears to arise from the umbilicus of a baby or a young child, and which usually has a distinct pedicle, but may be sessile. A cyst of this character forms when the vitello-intestinal duct atrophies from the gut toward the umbilicus, but a remnant at the umbilicus escapes obliteration, and from this remnant a cyst forms. The wall of such a cyst contains unstriped muscular fiber and is lined by mucous membrane. Occasionally the duct in the process of involution is not destroyed—its caliber is simply lessened—and the duct remains open in the navel and feces come from it. If the duct fails of obliteration at the intestinal end, a diverticulum remains at this point (*Meckel's diverticulum*).

Treatment.—A pedunculated cyst at the navel is treated by ligating its base and dividing the stalk beyond the ligature. A cyst with a thick base is dissected out. The surgeon must be careful to avoid confounding an umbilical hernia with a cyst of the navel.

Urachal Cysts.—The urachus is the obliterated allantois, and is a cord running from the summit of the bladder to the umbilicus. This structure is in the middle line of the abdomen and in front of the peritoneum. A portion of the allantois may not be obliterated at birth, and in consequence of this failure a cyst forms. It grows to a considerable size, may push the peritoneum away and reach the pelvis, may communicate with the bladder, may break through the umbilicus, or grow backward toward the spine.

Treatment.—Extirpation of the lining membrane, partial closure of the cavity by suture, and packing the unobliterated part. Complete extirpation of the cyst is seldom attempted. W. R. Weiser ("Annals of Surgery," Oct., 1906) collected 86 cases of cyst of the urachus. In 8 of these complete extirpation was performed, and Macdonald has since reported a successful complete extirpation (Ibid., August, 1907).

Parasitic cysts are due to the development of certain parasites in the tissues. The form most often encountered is known as hydatid cysts.

Hydatid cysts are especially common in Iceland, and are frequent in Australia and South America, but are very rare in the United States. In the United States 91 per cent. of cases occur in foreigners (Lyon). Hydatid cysts are due to echinococci. The adult echinococcus is the tapeworm of the dog (Tænia echinococcus), and its ova or larvæ gain access to man's body by accompanying the food he eats and passing into the alimentary canal, from which situation they are transported to various organs by the blood. Osler says the embryo (which has six hooklets) burrows through the wall of the bowel and enters the peritoneal cavity or muscles; it may enter the portal vessels and reach the liver, or may enter the systemic circulation and pass to distant parts. The danger depends on two factors: "the situation and the liability of the cyst to suppurate" (Sidney Coupland). The organs most usually attacked are the liver and lung. In 60 per cent. of cases the liver suffers, and in 12 per cent. the lung (Thomas). Lyon estimates that the liver is the seat of disease in 73 per cent. of cases. Cysts sometimes arise in the intestine, genito-urinary passages, brain, or spinal canal. When the embryo lodges, the hooklets disappear and a cyst is formed. This cyst is composed

of two layers, an outer capsule (cuticular membrane) and an inner layer (endocyst). The cyst contains clear saline fluid. As the cysts grow, daughter-cysts bud out from the wall of the mother-cysts, the structure of the daughter-cysts being identical with that of the mother-cysts. From the lining membrane of all the cysts, after a time, growths arise known as scolices, which represent the head of the echinococcus and exhibit four sucking disks and a row of hooklets (Osler).

The fluid is not albuminous, is occasionally saccharine, is thin and clear, and may contain scolices or hooklets.

A hydatid cyst may calcify, may rupture, or may suppurate. These cysts are very firm, but usually fluctuate. Palpation with one hand while percussion is practised with the other gives a persistent tremor (*hydatid fremitus*). If the cyst can be safely reached, some fluid should be drawn and examined for diagnostic purposes. When a cyst suppurates, positive constitutional and local symptoms arise. Hydatid cysts of the brain and cord tend to produce death in the same manner as do tumors. A cyst of the liver may rupture into the pleural sac, into the belly cavity, into the stomach, or into the bowel, producing shock, hemorrhage, and probably death. In rare cases hydatid cysts rupture into the pericardium or into a great abdominal blood-vessel, or externally. Rupture into the bile-passages is usually followed by suppuration of the cyst. Suppuration of a cyst may follow uncleanly tapping. It has been pointed out that eosinophilia is noted in most persons suffering from hydatid disease.

Treatment.—An unruptured hydatid cyst of a superficial structure should be incised and the sac wall should be dissected out. Hydatids of the brain have been successfully removed in Australia. A cyst of the kidney is removed through a lumbar incision. Omental cysts should be radically removed if possible; if this is not possible, open the abdomen, surround the cyst with gauze, evacuate through a trocar, stitch the cyst wall to the wound, incise, irrigate, and drain by gauze. Bond advocated evacuating the cyst, closing it by sutures, and dropping it back in the abdomen. Gardner says tapping is dangerous, as it may cause rupture of the cyst. In a hydatid of the liver the abdomen should be opened, the cyst should be surrounded by gauze pads, and tapped by a trocar and cannula. When the cyst is emptied of fluid it is grasped by forceps and pulled to the incision in the abdominal wall; it is sutured to this incision, the trocar opening is enlarged, and the endocyst is removed by irrigation.[1] This operation is called *marsupialization.* If the cyst is on the summit of the liver, it may be reached by a transpleural hepatotomy. If aspiration is performed to settle a diagnosis, operate at once after doing it, because of fear that the cyst may leak and disseminate the disease throughout the peritoneal cavity. If hydatid fluid is disseminated throughout the peritoneal cavity, it may or may not lead to the development of new cysts, but it is almost certain to cause a febrile condition accompanied by urticaria and known as *hydatid toxemia*. Brewer ("Annals of Surgery," April, 1908), in operating on a case of hydatid cyst of the liver, wounded the portal vein and was obliged to tie it. The patient recovered. That there was no failure of nutrition Brewer attributes to the fact that the vein had been long pressed upon and the collaterals were dilated when ligation was performed.

XIX. DISEASES AND INJURIES OF THE HEART AND VESSELS

Rupture, Wounds, and Injuries.—Rupture.—The heart may rupture and cause instant death, but rupture may not be instantly fatal. Curtin reported a case in which death did not occur for over twenty-four hours. Elsner reported a case of rupture in which life was prolonged for ten days. One case lived eleven days. In cases in which death does not occur rapidly the rupture must be so small that very little blood escapes. Rupture occurs in a damaged heart, a heart in which the muscular fiber is fatty, is fibroid, or is necrotic from suppuration. It may be traumatic, resulting from a fall or a blow upon the chest, or non-traumatic, following a great effort or strain. If death does not at once take place the pulse becomes very rapid, there is precordial pain, dyspnea, cyanosis, feeble heart-sounds, rapid respiration, great restlessness, collapse and syncope, and the development of a triangular area of dulness on percussion. Positive diagnosis is impossible. Meyer collected 36 cases of rupture of the heart reported since 1870. Death occurs from accumulation of blood in the pericardium. This acute compression of the heart due to blood escaping from the heart is called **heart tamponade.** It is held by Franke, of Berlin, and others that in heart tamponade the pressure within the pericardium comes to exceed the pressure within the auricles, that the pressure within the pericardium causes the symptoms of the injury, and finally death. Some would treat heart tamponade by puncture or aspiration. It would seem that either must be useless, as fresh blood is bound to replace what is withdrawn. Suturing must fail in non-traumatic cases because of the badly diseased myocardium. In traumatic cases it may possibly succeed.

Wounds of the Pericardium and Heart.—Severe wounds usually, though not always, produce death, but slight wounds may not prove fatal. It is a popular impression that the expression "stabbed to the heart" is another way of saying that instant death has occurred. This view was accepted even by surgeons during many centuries. During the sixteenth century sportsmen found now and then bullets and arrow-tips healed in the heart walls of animals they had slain. At this time the famous case of a duelist was published by Paré: a man received a sword thrust in the heart, but was able to run after his opponent many hundred feet before falling down in death. (See "An Experimental Investigation of the Treatment of Wounds of the Heart," by Charles A. Elsberg, in "The Journal of Experimental Medicine," Sept. and Nov., 1899.) From Paré's time until our own it has been recognized by surgeons that a wound of the heart does not of necessity produce immediate death, and may even be recovered from.

In 1867 G. Fisher published a study of 452 cases of wound of the heart, and pointed out the surprising fact that from 7 to 10 per cent. of such cases recover. In more recent years Rosenthal, Block, Del Vechio, and others proved by animal experimentation not only that cardiac wounds are not of necessity instantly fatal, and that in some cases they may be recovered from, but that the suturing of such wounds is possible and greatly enhances the chance of recovery. L. L. Hill ("Med. Record," Nov. 29, 1902) shows that although 90 per cent. of heart-wounds are penetrating, only 19 per cent. are immediately fatal. Sudden death occurs when Kronecker's coördination center is damaged. Several times during postmortem examinations on human beings healed scars have been found upon the heart. The heart has been punctured a number of times accidentally or intentionally, and death has not ensued. John B. Roberts,[1] of Philadelphia, suggested in 1881 that it would be proper to try to suture wounds of the heart.

[1] The author, in "Progressive Medicine," vol. i, 1899.

Symptoms.—A wound of the heart causes hemorrhage, which is usually copious, but owing to the interlocking of muscular fibers the hemorrhage may be slight. Bleeding may take place into the pericardial sac in some cases where the pericardium has been injured and the heart has escaped. Such an injury is occasionally inflicted by the sharp end of a fractured rib. The wound is rarely at or near the apex of the sac. In most heart wounds the pleural cavity is also opened and severe hemothorax occurs. The lung may or may not be injured. A wound of the pericardium or heart causes profound shock, irregular or very weak pulse, sighing respiration, dyspnea, and, it may be, the signs of hemopericardium, pneumopericardium, or hemothorax. In hemopericardium splashing sounds are heard with the heart-beats and the heart-sounds are very feeble. In pneumopericardium there is a tympanitic percussion-note in the area which should exhibit the cardiac dulness. There may or may not be serious external bleeding. Fatal concealed hemorrhage may occur. Pain is constant, and attacks of syncope are the rule. The position of the wound and the evidences of hemorrhage may aid in making the diagnosis. Death is apt to occur suddenly from shock, hemorrhage, inability of the heart to contract because of the severed fibers, or inability of the heart to dilate because of the pressure of blood in the pericardial sac (heart tamponade). If a wound of the pericardium or heart does not cause death during the first day or two, inflammation follows (traumatic pericarditis or carditis) and the patient may die of suppurative pericarditis or of empyema.

Treatment.—Wounds of the pericardium and heart should be sutured. We should explore if, from the location of the wound and the symptoms, we suspect a cardiac wound. I agree with Vaughan, that if there is a wound in the cardiac region and if the symptoms threaten life, exploration should be performed at once. In a doubtful case exploration should be made by enlarging the wound, and this may be done under local anesthesia. In operating for a heart-wound the cutaneous surface should be rapidly disinfected, and every effort be made to antagonize shock during the operation. The patient should be wrapped in hot blankets and surrounded with hot bottles or hot-water bags, or should be placed upon a table composed of pipes in which hot water circulates. The foot of the bed should be raised. Hot saline fluid containing adrenalin chlorid should be infused into a vein, or, in desperate cases, into an artery. The extremities, except the one selected to infuse salt solution in, should be bandaged (autotransfusion), an enema of hot coffee and whisky should be given, and atropin should be injected hypodermatically. It is wiser, in most cases, to give a general anesthetic than not to give it. Local anesthesia is slow and unsatisfactory. Without an anesthetic the patient will probably struggle, and struggling is very dangerous, as it loosens clots and permits hemorrhage to begin again (L. L. Hill, in "Med. Record," Sept. 19, 1908). Chloroform is the anesthetic used. If the patient is unconscious and the corneal reflex is abolished, no anesthetic should be given. The heart is exposed by resecting several ribs. In a knife-wound of the right pleural cavity and right side of the pericardium, Barth, of Danzig, removed 1 inch from each of three right costal cartilages (fifth, sixth, and seventh), close to the side of the sternum, and removed also the ensiform cartilage and 1 inch of the sternum. The same surgeon, in the case of a man stabbed in the fourth left intercostal space, removed the fourth and fifth left costal cartilages and part of the sternum ("Deutsche Zeitschrift für Chirurgie," Bd. lxix, No. 1). Schwerin, of Berlin, in a stab-wound of the chest exposed the heart by resecting the fourth and a portion of the fifth left ribs ("Proceedings of German Surgical Congress," 1903). Wilms ("Centralblatt f. Chirurgie," Leipzic, vol. xxxiii, No. 22), in a case of gunshot-wound, obtained access to the anterior and posterior surfaces of the heart by a simple intercostal incision. Parrozzani makes a trap-door in the

chest, the hinges of the door being the rib cartilages. In exposing the heart Giordono enters along the wound, removing any obstacles that intervene. It is needless to try to avoid opening the pleura if a flap with an internal hinge is used; it has usually been opened by the accident, and in any case can very seldom be avoided. Matas advises Spangaro's intercostal incision. The mammary vessels are tied and the width of the intercostal space is greatly increased by strongly retracting the ribs and cartilages. If more space is needed, the incision is carried upward at the junction of the cartilages and sternum. The heart is exposed, clots are removed from the pericardial sac, and the sac is irrigated with hot saline fluid. The bleeding may be furious. A non-penetrating wound of the ventricle may bleed so profusely during systole as to resemble a penetrating wound (Sherman). A penetrating wound may bleed most during diastole. The motions of the chest make manipulation difficult. It is wise to insert two traction sutures in order to lift the heart toward the operator. A wound in the heart is sutured with interrupted sutures of catgut, which are passed by means of a round, curved needle, and if a cavity of the heart is open each suture includes the whole thickness of the heart wall except the endocardium. It has been said that the sutures should be tied during diastole, otherwise they are apt to cut out, but Profs. Gibbon, Stewart, and Nassau tell me that in their cases such a procedure was impossible because of the very rapid action of the heart. As few stitches are used as will efficiently close the wound. Numerous stitches cause extensive degeneration of muscular fiber and stitch-holes may permit leaking. The pericardium is sutured with silk or, as was done in 1 successful case (Rehn), the sac is packed with iodoform gauze. It is not absolutely necessary to drain the pericardial sac. Clots are removed from the pleural sac by irrigation with hot saline solution, pulmonary bleeding is arrested by the suture or by packing, and a wound in the lung, especially if it communicates with the air-passages, is sutured if the patient's condition justifies prolonging the operation.[1]

After such an operation the patient is in great danger and every effort should be made to save him from shock. In performing operations upon the heart the pleura is almost always opened, and if it is open there is always pneumothorax and grave danger of pulmonary collapse and overwhelming shock. It is a great advantage in such cases to have at hand an apparatus which will prevent or amend pulmonary collapse (see page 896).

Frazier ("Progressive Medicine," March, 1913) collects 218 cases of operation for heart-wounds. The mortality in the series was 55.5 per cent. This estimated mortality is probably much too low. Many operators have reported a single successful case each. It is reasonable to believe that many unsuccessful cases have not been reported. It is eminently desirable to have the reports of a number of consecutive cases. We have here such a record. Hesse (Bruns's "Beiträge," 1911, lxxv) reports 21 cases with a mortality of 71 per cent. We believe this represents about the average mortality of heart-wounds subjected to operation. In 1881 Dr. John B. Roberts, of Philadelphia, suggested that heart-wounds should be sutured. In 1887 Dr. Harvey Reed sutured a wounded pericardium and the patient recovered. In 1891 Dalton, of St. Louis, obtained recovery by a similar operation. The first operation on a wounded human heart was performed in 1896 by Farina, of Rome. The patient had been stabbed in the right ventricle. The wound was sutured, but he died of pneumonia on the sixth day. Rehn, of Frankfort, in 1896 sutured a wound of the heart and packed the pericardium with gauze, and the patient recovered. Among others reporting cases are Cappelan, Peyrot, Williams, Barth (in this case the internal mammary artery was also injured), Wilms, Hill, Sherman, Harte, Gibbon, Stewart, Guinard, Sultan, Cumming and Beattie, Wolff,

[1] The author, on "Suture of the Heart," in "Progressive Medicine," 1899, vol. i.

Picqué, Lenormand, and Parrozzani. There have been 12 cases of heart suture in Philadelphia and 7 recoveries. Stewart had 5 cases and 3 recoveries; Gibbon, 2 cases and 1 recovery; Nassau, 1 case, which recovered. I have never operated for a wound of the heart. According to Hill, the right ventricle is most often, the left auricle least often, injured; wound of the auricle is generally considered to be more dangerous than wound of the ventricle; and wound of the apex is less dangerous than either. Peck points out, however, that there are 11 reported cases of auricle wounds with 4 deaths, a mortality of 36.3 per cent., while the general mortality of heart-wounds is about 64 per cent. ("Annals of Surgery," July, 1909). Wounds of the left ventricle give a better prognosis than of the right ventricle; wounds of the right auricle a better prognosis than of the left auricle. A needle puncture rarely causes serious bleeding from a ventricle, but is very apt to cause severe bleeding from an auricle. A wound received during diastole is less dangerous than one received during systole. Wounds of the right heart bleed more than wounds of the left heart. Wolff points out that ligation of one coronary artery can be done and recovery follow; wounds of the left ventricle give the best prognosis because the wound is closed by thick edges of muscle. In 37 operations for heart-wounds the left pleura was opened, in 3 the right pleura, and in 2 the pleura was uninjured. In bullet-wounds death usually occurs before operation can be done (Wolff, "Deutsche Zeitschrift für Chirurgie," Bd. lxix, No. 1). Bircher reports a case of gunshot-wound of the heart in which there was no operation, yet the patient recovered. He believes that a gunshot-wound by a small bullet should not be operated upon, but he would operate for wounds by large bullets and for stab-wounds ("Arch. klin. Chir.," 1912, xcvii). Manteuffel reported 7 cases, occurring during the war in Manchuria, in which recovery followed gunshot-wounds of the heart which were treated expectantly. Without operation the mortality of heart-wounds will be at least 90 per cent.; with operation it will be about 60 to 70 per cent.

Matas ("Southern Med. Jour.," August, 1908) discussed 160 cases of heart-wounds with 43.83 per cent. of recoveries. In 134 cases the wound was sutured, with 49 recoveries. In 11 cases it was exposed, but was not sutured, and 5 recovered. In 5 cases foreign bodies were removed with success.

In Peck's table ("Annals of Surgery," July, 1909) there are 69 wounds of the right ventricle with 48 deaths (69.6 per cent.); 74 of the left ventricle with 45 deaths (60.8 per cent.); 5 of the left auricle with 2 deaths (40 per cent.); 6 of the right auricle with 2 deaths (33.3 per cent.); and 7 miscellaneous cases with 5 deaths (71.5 per cent.), a total of 160 cases with 58 recoveries and 102 deaths, a mortality of 63.7 per cent.

The immediate dangers of the operation are hemorrhage, shock, and the entrance of air. The late dangers are pericarditis, empyema, and pneumonia (Vaughan). Traumatic carditis or pericarditis is treated in the same way as idiopathic cases. Pus in the pericardial sac should be evacuated by resection of the fourth left costal cartilage and incision of the pericardium (von Eiselsberg's case). Pool reviewed the subject of heart-wounds in the "Annals of Surgery," April, 1912.

Pericarditis is an infectious condition that may be traumatic or non-traumatic. If pericarditis follows an open wound, it is obvious how the infection must have entered; if it follows a bruise or a contusion, the injury has rendered the pericardium a point of least resistance. In some few cases, which are known as primary pericarditis, it is impossible to determine how the micro-organisms gained entrance. The ordinary form appears as a complication of certain infectious diseases, such as septicemia, pneumonia, rheumatism, and tuberculosis. It may be secondary to some adjacent infection, such as an empyema. A tuberculous abscess may break into the pericardium,

and an abscess, even from a considerable distance, may burrow into it. It may arise secondary to a distant infection, as a suppurating wound, osteomyelitis, middle-ear suppuration, abscess of the mastoid, tonsillitis, abscesses anywhere, peritonitis, and gastric ulcer. It sometimes follows gastro-enterostomy and may arise in an individual with Bright's disease. In a recently born child infection of the stump of the umbilical cord may cause pericarditis. A pericardial effusion in a newborn child is invariably purulent and in a young child it is usually purulent. In children the condition is usually associated with pulmonary disease (Poynton, in "Brit. Med. Jour.," August 15, 1908). A great variety of bacteria may be responsible for pericarditis. The exudation may be serofibrinous; this is an evidence of its being a mild infection, and such an exudate may undergo absorption. On the other hand, the exudate may become purulent, and in such a case cure will never be obtained by absorption of the pus. In pericarditis there is usually some pain in the region of the heart, and this pain is apt to extend into the left arm. Epigastric pain is a common symptom. The heart is overacting, the heart-sounds are indistinct, the pulse is strong and very rapid, there is an increased area of cardiac dulness, and the patient complains of dyspnea. The temperature is elevated and a double friction-sound may be made out upon auscultation.

Treatment.—Ordinary pericarditis, without pus-formation or extensive effusion, is managed by the physician; but when there is extensive effusion with symptoms of dangerous compression it is advisable to open the pericardium, and if there is purulent effusion the pericardium must be opened. The procedure usually practised in the past to relieve pericarditis with marked effusion was puncture or aspiration. This, however, is dangerous. The heart is not, as was formerly taught, pushed back and up by the pericardial effusion, but is lifted upward and forward, and may be pushed to the right or left if there are adhesions between the pericardium and heart; and it is impossible to select any place for aspiration that assures us that there will be no danger of puncturing the heart. A coronary vein may be injured, the pleural cavity may be entered, and a dry tap is usual from blocking of the needle. Brentano has shown that tapping cannot completely empty the sac. Many surgeons, however, do not fear puncture, and explore by inserting a fine needle in the fourth or fifth space of the left side close to the sternum. In cases of extensive pericardial effusion, and also in cases of suppuration within the pericardium, I believe that *pericardiotomy* should be performed. An inch or more of the cartilage of the fourth rib of the left side should be removed or 2 inches of the fourth rib itself, and the pericardial sac should be exposed and, after exploratory puncture, formally incised. In this operation it may be necessary to tie the internal mammary artery. In pyopericardium the pleural cavity is very seldom invaded, because the pleural space in front of the pericardium has usually been obliterated by the spread of the inflammation. The pericardial sac is opened as directed above, is cleared of purulent material and fibrinous masses by irrigation, the edges of the pericardial wound are sutured to the edges of the superficial wound, and gauze drainage is introduced. Incision is safer and more certainly curative than aspiration; for whereas aspiration might be curative in pericardial effusion, it cannot be so if the effusion is purulent. In 41 cases of purulent pericarditis (Roberts's table of 35 cases and Ljunggren's 6 cases) operated upon, 16 recovered. Local anesthesia is safer than general anesthesia.

Phlebitis, or Inflammation of a Vein.—**Acute Phlebitis.**—Phlebitis may be *plastic* or it may be *infective.* Plastic phlebitis, while occasionally due to rheumatism, to gout, to advanced phthisis, to a febrile malady, or to some other constitutional condition, usually takes its origin from a wound or other injury, from the extension to the vein of a perivascular inflam-

mation, or, in the portal region, from an embolus. Varicose veins are particularly liable to phlebitis. When phlebitis begins a thrombus usually forms (see Thrombosis, page 184) because of the destruction of the endothelial coat of the vessel, and this clot may give rise to emboli, may be absorbed, or may be organized. An aseptic clot organizes and the vein becomes permanently narrowed or blocked. A septic clot is apt to soften and break up. In the lower extremities *paraphlebitis* is common with slight involvement of coats, and a clot may not form. Clot-formation causes edema. Infective phlebitis is a suppurative inflammation of a vein arising by infection, perhaps from suppurating perivascular tissues (*infective thrombophlebitis*), perhaps from the blood-stream or in the portal system, perhaps from infective embolism. It is not unusually met with in cellulitis or phlegmonous erysipelas, may arise in the lateral sinus as a result of mastoid suppuration, or in the liver from appendicitis or from phlebitis of the rectal veins. Sometimes as the convalescence from pneumonia begins, phlebitis due to pneumococci arises. If a septic thrombus forms, the vein wall suppurates, is softened and in part destroyed, and the infected clot softens and gives rise to emboli. No bleeding occurs when the vein ruptures or is opened, as a barrier of clot keeps back the blood-stream. The clot of suppurative phlebitis cannot be absorbed and cannot organize. Septic phlebitis causes pyemia, and the infected clots are disseminated.

Postoperative phlebitis of the iliac, femoral, or saphenous veins is not uncommonly the result of a mild or attenuated infection, toxins in the blood probably attacking the vein. As a rule, the toxins are non-pyogenic. It may follow an abdominal operation when there is no evidence of infection. According to Cordier, it occurs in 2 per cent. of abdominal operations. It is called, as is the like puerperal condition, *milk-leg*, or *phlegmasia alba dolens*. Nearly always the femoral vein is the one which suffers. Strange to say, it is most apt to attack the left iliac, femoral, or saphenous veins; it matters not upon which side the operation was performed. In over 90 per cent. of cases the left femoral or left saphenous veins are attacked (Cordier, in "Jour. Am. Med. Assoc.," Dec. 9, 1905). One theory regards the pressure of the right common iliac artery upon the left common iliac vein as a predisposing cause. Another theory attaches importance to the pressure of a loaded sigmoid. It is most common in anemic subjects, especially when anemia results from blood loss. It may be due to toxins damaging the inner coat of the vein, but feeble circulation is a powerful factor in its production. I believe, with Clark, that powerful traction on the sides of an abdominal wound may be responsible for it (see Thrombosis after Abdominal Operations, page 187). Vanderveer reported 4 cases in which sepsis was positively absent ("American Medicine," July 13, 1901). It occurred in the left iliac vein of a woman on whom I had operated for carcinoma of the left breast six days before. There was no obvious infection of the wound. I have seen it occur in the left iliac vein after an interval operation for appendicitis. Phlebitis may arise in the vein of one extremity, a clot may form, and this may be absorbed or may organize. The other extremity may be involved afterward or simultaneously (horseshoe form). It may come on seven or eight days after operation, many days, or several weeks. It usually is ushered in by chilly sensations or slight chills and elevated temperature. There is always pain in the limb. The pain may be dull or acute; it is made worse by motion and by pressure over the involved vein. The entire extremity swells from edema. It is probable that marked edema signifies associated lymphangitis or an extensive clot running into many venous branches. The edema is seldom characterized by very distinct pitting on pressure. The skin is white and looks stretched and shiny. The inguinal glands are usually enlarged. Sensation is impaired except over the vein. Paresthesia is common. The involved veins come to feel like cords to the touch.

In mild cases the symptoms disappear in a few days. Severe cases continue for several or many weeks or even months. Involvement of the deep veins causes prolonged swelling. There is seldom any disposition to gangrene.

In some cases there is extensive muscular atrophy, in some there are trophic disturbances, in some muscular contractures. Postoperative phlebitis is sometimes responsible for embolic pneumonia and cerebral embolism. Many postoperative pneumonias are due to this cause.

The *symptoms* of plastic phlebitis are pain, tenderness in and around a vein, discoloration over it, and edema below the seat of the disease. Suppurative phlebitis, besides these conditions, causes the constitutional symptoms of pyemia (see page 197). Any thrombus, if it loosens, forms emboli. It is said that the clot resulting from pneumococcic phlebitis forms so rapidly that it adheres slightly and is peculiarly apt to loosen and give rise to emboli (Pierre, in "Gazette des Hôpitaux," Sept. 3, 1904). Septic thrombi are apt to cause septic pneumonia.

Fig. 187.—Varicose veins.

The *treatment* of plastic phlebitis of an extremity comprises rest in bed for from four to six weeks, slight elevation of the part, the use of cold for the first twenty-four hours, and then the application of external heat and a flannel bandage. If the patient is gouty or rheumatic, appropriate remedies should be given. A clot does not always form in an inflamed vein, but if one forms there is danger of embolism; hence massage and both active and passive movement are dangerous until the clot becomes firm. When a vein is involved in a suppurative process and septic thrombophlebitis exists, we should operate when the situation makes operation possible. Ligate the vein (compress a sinus by packing) above and below the clot, open the vessel, and wash out the infected clot, or, if dealing with an accessible vein, extirpate the involved portion. This plan of treatment is always to be applied in infective thrombophlebitis of the lateral sinus and of the internal saphenous vein. The constitutional treatment is that of pyemia.

Chronic Phlebitis.—This rare condition is known as *phlebosclerosis*, and it is a chronic inflammation of the wall of a vein, producing a fibrous change in the vascular coats. It may arise in a part the seat of chronic venous engorgement, but its most frequent cause is syphilis. It is often associated with arteriosclerosis.

Varicose Veins; Phlebectasis, Phlebectasia, or Varix (Figs. 187 and 188).—**Definition and Causes.**—Varicose veins are unnatural, irregular, and permanently dilated veins which are elongated and pursue a tortuous course. This condition is very common, and 20 per cent. of adults exhibit it in some degree in one region or another. Some facts indicate hereditary predisposition. In over 80 per cent. of cases the trouble begins before the age of twenty-five. The causes of varicose veins are said to be obstruction to venous return and weakness of cardiac action, which lessens the propulsion of the blood-stream. A. Pearce Gould says obstruction is not a cause, because in pregnancy varicose veins may be seen early, before the

womb is much enlarged. The real cause is probably a predisposition to the growth of vein-tissue, which leads to valve failure and a regurgitation of blood from the deep veins into the superficial venous channels (A. Pearce Gould, in "Lancet," March 1 and 15 and June 7, 1902). As Billroth said over thirty years ago, sudden obstruction causes edema and gradual obstruction a free collateral circulation. Neither sudden nor gradual obstruction causes true varicosity unless the veins are predisposed by a tendency hereditary or acquired.

Varicose veins may occur in any portion of the body, but are chiefly met with on the inner side of the lower extremity, in the spermatic cord, and in the rectum. Varix in the leg is met with most commonly during and after pregnancy and in persons who stand upon their feet for long periods. It is especially common in the long saphenous vein, which, being subcutaneous, has no muscular aid in supporting the blood-column and in urging it on. The deep as well as the superficial veins may become varicose. Verneuil maintained that varix of the superficial veins is almost always secondary to varix of the deep veins, a radical view which seems improbable. It is certain, however, that after contusions of the leg it is not unusual for the deep veins to become filled with clot and for the superficial veins to dilate notably. By the term "*caput medusæ*" is meant dilated veins radiating from the umbilicus. The veins of the esophagus may become varicose, and this malady is commonly unrecognized clinically. Varicose veins are in rare instances congenital, but they are most often seen in the aged, and usually are first observed between the ages of twenty and forty. They are more common in women than in men, owing, it is believed, to the influence of pregnancy.

Fig. 188.—Varicose veins.

Varix of the spermatic cord is known as *varicocele*. It is apt to appear about the time of puberty, and most adult men have at least a slight varicocele. Varix is more likely to appear in the left spermatic vein than in the vein of the right side, because the left spermatic vein has no valves (see page 1400).

Varicose tumors of the rectum constitute *hemorrhoids* or *piles*. Piles are caused by obstruction to the upward flow in the hemorrhoidal veins, either by obstructive liver disease, enlargement of the uterus or prostate, or the presence in the rectum of fecal masses in a person habitually constipated (see page 1177).

A vein under pressure may dilate more at one spot than at another, the distention being greatest back of a valve or near the mouth of a tributary.

The valves become incompetent and the dilatation becomes still greater. Callender has pointed out that varix of the lower extremity is apt to begin where the deep vessels join the superficial veins. At this point Treves says three forces meet: the blood column above, the valve below, and the force of the blood-current. At the spot where the pressure is greatest the vein wall dilates, and from this dilatation the blood-current is deflected and causes another dilatation higher up and on the opposite side of the vessel. The blood is again deflected and causes another dilatation, and so on. The vein wall may become fibrous, but usually it is thin and sometimes it ruptures. The veins not only dilate, but they also become longer, and hence do not remain straight, but twist and assume a characteristic form. It seems probable that the first step in the process is a growth of new venous tissue (A. Pearce Gould), and then follow lengthening, tortuosity, incompetence of the valves, and dilatation of the vessel.

Delbet[1] points out that varicose veins of the leg, which begin in the thigh, result from valvular incompetence; varicose ulcers arise from variations of venous pressure due to valvular incompetence. The incompetence of the valves does harm by allowing the intravenous pressure to equal the pressure in the arterioles, a condition which arrests capillary circulation, causes congestion, and greatly lowers tissue resistance. Incompetent valves also favor ulceration by developing a *vicious venous circle*, first described by Trendelenburg. Blood passing through this circle loses nutritive elements. Trendelenburg has described the vicious circle as follows: Blood in the saphenous vein flows toward the periphery instead of toward the center, because of incompetent valves—it passes into the veins which connect the superficial veins with the deep veins and then enters the tibial and peroneal veins. It passes from the tibial and peroneal into the popliteal and femoral veins, and some blood leaves the femoral vein and again enters the saphenous.

The skin over varicose veins in the leg is often discolored by pigmentation due to red blood-cells having escaped from the vessel and broken up. The tissues around a varicose vein become atrophied from pressure, and it is not unusual to meet with a very large vein whose thin walls are in close contact with skin. In this condition rupture and hemorrhage are probable. When the vein wall forms a pouch-like dilatation the condition is spoken of as a *vein cyst*. Varicose veins are apt to inflame, and thrombosis frequently occurs. When a thrombus forms, emboli may be broken off and carried into the circulation, especially if the patient walks about. The formation of emboli is not nearly so common as a result of thrombosis in a varicose vein as in thrombosis in an undistended and unelongated vessel. In varicose veins of the thigh, however, the chance of embolism following thrombosis is much greater than when the veins of the leg alone are involved. In some elderly people thrombus actually effects spontaneous cure. When a thrombus organizes, more or less calcification is apt to ensue, and a *vein-stone* or *phlebolith* is formed. After middle life many varicosities remain stationary or cease to give trouble. The chief complications of varicose veins of an extremity are thrombosis, edema, violent hemorrhage from rupture, phlebitis, eczema, and chronic ulceration.

Treatment of Varix of the Lower Extremitiy.—The treatment of varix of the leg may be *palliative* or *curative*, but whichever plan is followed, the surgeon should endeavor first of all to remove the exciting cause. An essential part of palliative treatment is to attend to the general health, to keep up the force and activity of the circulation, and to prevent constipation. Massage is useful, especially alcohol frictions, if eczema is absent. *Cold* baths are always forbidden (Bennett). The patient should exercise regularly in the

[1] Delbet, "Sem. méd.," Oct. 13, 1897.

open air and should lie down for a time, if possible, every afternoon. Instead of lying down for a time during each day, he may sit down and elevate the legs, resting them on a table, and thus assuming a position supposed to be peculiarly American. If there is no pain, distinct discomfort, or edematous swelling, a support is unnecessary, but if these conditions exist it is needed. If a support is required in varix of the leg, use a flannel roller or a perforated rubber bandage applied over a long stocking. Such a bandage supports the veins and drives the blood into the deeper vessels, which have muscular support. The use of a rubber pad filled with glycerin and applied over the saphenous vein, so as to support the blood column and act as a valve, has been recommended. A purely local varix should be excised, because there is always danger of injury, and consequently of hemorrhage or thrombosis. If the superficial veins have dilated because of thrombosis of the deep veins and edema exists, ligation or excision is contra-indicated, as its performance might lead to permanent edema. In such a case it would perhaps be proper to incise the deep fascia the length of the thigh, place the vein beneath it, and suture the fascia. The vein would then be supported, but not blocked. If the disease involves the leg only, operative treatment is rarely required and may even do harm. Such cases are operated upon if there are cyst-like dilatations, if thrombi form, and, as Bennett points out, if a thin-walled vein crosses the tibia, and is thus exposed to the danger of injury and thrombosis.[1]

If the leg is involved in the process, and the saphena in the thigh is also varicose, operation should be performed.

If a thrombus forms in a superficial varicose vein, tie the vein above and below the clot, divide the vessel in two places, and remove the vein and the clot within it. Thrombosis of a varicose vein is not so apt to lead to emboli as thrombosis in a non-varicose vein, but it may do so, and the condition has some elements of danger.

If edema is marked, and increases in spite of properly applied bandages, etc., it probably signifies clot-formation, and the patient should remain in bed until this question is determined. Hemorrhage from a ruptured varicose vein of an extremity is usually readily arrested by compression and elevation.

The radical treatment of varix of the leg often does good, often relieves some annoying condition, but rarely absolutely cures (W. H. Bennett). There are several methods of operation: ligation with excision of part of the vein, exposure and ligation of the vein below the saphenous opening, or circular incision around the leg. (See Operations Upon Vessels.)

Nevus.—(See Tumors.)

Arteritis, or inflammation of an artery, is *acute* or *chronic*.

Acute Arteritis.—Slight inflammation is by no means unusual, but severe arteritis is decidedly rare. It may follow direct injury or arise secondarily to a perivascular inflammation. An artery is very resistant to the spread of inflammation, but we sometimes encounter suppurative arteritis in a suppurating area. Arteritis may arise in the course of an infective malady, being produced by bacteria, but it is also found in intoxications, and is then due purely to toxins. It may occur in the eruptive fevers, in influenza, typhoid fever, acute rheumatism, gout, syphilis, diphtheria, septicemia, and septic intoxication. Ford points out that acute arteritis developing during acute or chronic infections is particularly apt to arise in the lower extremities (Ford, "Thèse de Paris," 1901). Toxins or bacteria usually reach the artery in the main blood-stream, but may be lodged in the vessel wall by the lymph or the flow in the vasa vasorum. The inner coat of a portion of an artery becomes lined with inflammatory exudate and the coats are infiltrated with small cells. Often parietal thrombi form. Sometimes, though rarely, the vessel is com-

[1] W. H. Bennett, "Lancet," Oct. 15, 1898.

pletely blocked by thrombosis. In acute suppurative arteritis pus accumulates in the arterial wall, a clot forms in the lumen, and the coats of the vessel undergo necrosis and give way. Violent hemorrhage may thus arise, but often, in thrombo-arteritis as in thrombophlebitis, rupture does not cause hemorrhage. Acute arteritis, if non-bacterial in origin, is usually recovered from with slight structural change. Infective arteritis is recovered from if the causative germ is not very virulent or if the toxin is not present in excessive quantity. Acute arteritis may terminate in arterial obstruction with or without gangrene, permanent dilatation, arterial rupture, or chronic arteritis.

The *symptoms* may be merged with those of an acute or chronic intoxication or infection, or with those of a local perivascular inflammation. In arteritis arising during infections the symptoms appear abruptly and the onset is marked by great pain. Ford studied 18 cases in influenza. He says it attacks particularly persons over thirty years of age, occurs in one leg or both, arises most commonly during convalescence, but may not begin until the individual is apparently well. There is pain and tenderness over the vessels, low surface temperature, paresthesia, and mottled skin (Ford, "Thèse de Paris," 1901). The artery may be obstructed, and if a large vessel is blocked, the pulse below the clot is lost. The block may be temporary or persistent. Gangrene may follow. Ford points out that if the artery only is blocked, the gangrene is dry; but if the vein also is occluded it may be moist. I have seen 2 cases of dry gangrene following influenza.

Treatment.—Secure rest in bed; elevate the extremity slightly, relax it, smear the skin over the inflamed vessel with ichthyol ointment or mercurial ointment, or follow Ford's advice and use methyl salicylate or an ointment of salicylic acid, turpentine, and belladonna. Wrap the part in cotton and surround it with bottles or bags filled with warm water. If a patient is very restless, a splint must be used. It may be necessary to give morphin for pain, and any infection or toxemia must be combated with appropriate remedies.

If gout, rheumatism, or syphilis is regarded as causative, proper remedies must be given. It is most important to maintain the secretion of the kidneys. If abscesses form in a septic case, they must be opened and drained. If a large artery of one of the lower extremities becomes occluded, raise the foot about 2 inches from the bed, wrap the foot and leg in cotton-wool, apply a flannel bandage from the toes up, and surround the limb with bags of warm —not hot—water. Hot water would take more blood to the region of the block than could be distributed. If gangrene occurs, amputation is necessary.

Chronic Endarteritis (Arteriosclerosis, Atheroma, Arteriocapillary Fibrosis, Cardiovascular Degeneration).—By these terms we mean thickening of the walls of the arteries, limited in area or widespread, due to inflammation or degeneration of the middle coat, the media undergoing hypertrophy and the intima fibrous hyperplasia (Wm. Russell, "Brit. Med. Jour.," June 4, 1904). Atheroma is used to designate the disease when it attacks the large vessels and is characterized by advanced degeneration. Chronic endarteritis is due to increase of blood-pressure. Hypertension precedes sclerosis and causes it. Hypertension is detected and measured by the sphygmomanometer. Increase of blood-pressure means increase of arterial tension, because the lumen of the vessels is lessened and the heart works more strongly to urge the blood along, and finally hypertrophy of the middle coat occurs. The persistence of arterial contraction which causes increase of blood-pressure may be brought about by kidney disease, hard work, violent strains, heart disease, care and anxiety, worry and mental strain, alcoholic or venereal excesses, habitual gluttony, syphilis, gout, rheumatism, lead-poisoning, diabetes, and acute infections like typhoid fever and influenza. It may arise in an old man who has not suffered particularly from any of the above-named causes, or may occur prematurely

from toxemia or heredity. It is a true saying of Cazalis that "A man is as old as his arteries," and a young man debilitated by syphilitic disease or alcohol may have diseased arteries, and hence be really older than a healthy man of sixty. Heredity may be commonly traced in heart disease due to diseased coronary arteries, and cerebral hemorrhage due to disease of the middle cerebral arteries. The aorta, of all vessels, is most prone to suffer. The large vessels are more apt to be diseased than the small, but even the arterioles can be involved. The arteries of the stomach, liver, and mesentery are rarely sclerotic. In arteriosclerosis connective tissue is substituted for the normal elements of the vascular wall, and this tissue undergoes hyperplasia and subsequent contraction and induration. If the mass of proliferating fibroblasts undergoes fatty degeneration, *atheroma* is said to exist, and an atheromatous vessel may be calcified by deposition of lime-salts. When fatty degeneration occurs the endothelium is destroyed, the vessel wall is damaged, and the blood may obtain access to the deeper coats. Atheroma is a frequent cause of thrombosis, aneurysm, senile gangrene, and apoplexy.

A sclerosed artery is rigid, non-contractile, and inelastic, and the parts it supplies are cold, congested and ill nourished, and often edematous. When the caliber of arteries remains narrowed because of persistent contraction or of arteriosclerosis there is marked accentuation of the second aortic sound. The valve or door which opened during systole is slammed shut during diastole by the peripheral resistance. The heart is obliged to overwork and in consequence undergoes hypertrophy. The hypertrophied heart finally dilates. If a hypertrophied heart exists with diseased arteries, apoplexy or aneurysm is apt to occur (Nammack, "Med. Record," Oct. 26, 1901). Syphilitic arteritis is characterized by an enormous growth of granulation tissue from the inner coats of arteries of small size (*obliterative endarteritis*). Calcification of an artery may be secondary to fatty change, or may occur primarily from deposit of lime-salts in the middle coat. *Periarteritis* is inflammation of the sheath and outer coat. An acute arteritis is always local, but a chronic arteritis may be general. If obliterative endarteritis exists in a limb, the veins are almost certain to be involved as well as the arteries. For this condition of veins and arteries, Buerger suggests the term "thrombo-angiitis obliterans" (see page 165).

Treatment.—In treating chronic arteritis, endeavor to antagonize the dangers to which the patient is obviously liable. Forbid alcohol as a beverage, though a little whisky may be taken at meals. Maintain the activity of the skin by daily baths, and of the kidneys by diuretic waters. A daily bowel movement should be secured. The diet is to be plain and is to contain a minimum of nitrogen. If syphilis has existed, occasional courses of iodid of potassium are to be given. If the arterial tension at any time becomes inordinately high, administer nitroglycerin. One danger to which the patient is liable is apoplexy, hence excitement and violent exercise are to be avoided. Another danger is senile gangrene; hence the patient should wear woolen stockings, put a bottle or bag of warm water to his feet at night, and be careful to avoid injuring his toes or feet, especially when cutting his corns. A bag of *very* warm water is dangerous and may actually excite gangrene. When a patient with atheroma has dyspnea and is of a livid color, or when the arterial tension is very high, a moderate blood-letting (16 to 18 oz.) does good, and may prevent or arrest edema of the lungs. Still another danger is aneurysm, which may appear suddenly from rupture or gradually from progressive distention.

It has been suggested that endarteritis threatening gangrene of the foot should be treated by an anastomosis between the common femoral artery and the femoral vein, in order that the blood may be directed from blocked

to open channels, and hence may still nourish the extremity. The operation is only to be advised when pulsation is absent in the tibials, when the femoral high up seems normal, and when the deep veins are patent (see page 183).

Buerger suggests the following test of the patency of the deep veins ("Jour. Am. Med. Assoc.," April 24, 1909): "I allow the limb to hang, watch for the advent of the erythema, and wait until a fair degree of cyanosis has become established. This may take considerable time—five to ten minutes. The veins are then obliterated above the knee by means of a Martin bandage properly applied. The limb is then raised high and the bandage loosened just enough so as to remove pressure from the deep, but not from the superficial, veins. If the cyanosis is slow in disappearing or fails to disappear, it may be concluded that the function of the deep veins is impaired."

An **aneurysm** is a pulsating sac containing blood and communicating with the cavity of an artery, and formed partly or entirely by the arterial walls or is a fusiform dilatation of an artery. Some restrict the term "true aneurysm" to a condition of dilatation involving *all* the coats of the vessel. We shall consider, with Heath, a *true* aneurysm to be one in which the blood is included in one or more of the arterial coats, and a *false* aneurysm to be a condition in which the vessel has been wounded, has ruptured or has atrophied and the aneurysmal wall is formed by a condensation of the perivascular tissues.

Forms of Aneurysm.—The following forms of aneurysm are recognized:

1. *True aneurysm*—one whose sac is formed of one or more arterial coats.

2. *False aneurysm*—one whose sac is formed of condensed perivascular tissues and contains no arterial coat.

3. *Traumatic diffused aneurysm*—a false aneurysm due to a wound or traumatic rupture of a blood-vessel. At first the blood is widely diffused and unlimited by any sac or capsule, later a limitation or encapsulation may occur by the condensation of tissue, any wound being healed. A traumatic diffuse aneurysm may follow a puncture or an incised wound of an artery, the injury causing the aneurysm directly. It may follow an effort or a strain, the injury indirectly causing the aneurysm by acting on a diseased vessel. As Barwell says, the term "traumatic diffused aneurysm" is an extremely bad one, as the term "aneurysm" conveys the idea of some sort of a sac. In this condition there is no true sac and blood is either unlimited or limited only by condensed tissue.

4. *Diffused aneurysm*—a term used to mean a ruptured aneurysm, the blood being diffused in the tissues and either unlimited or limited only by condensed tissues. The term should be limited to conditions in which the effusion of blood is slow and trivial. If the effusion is large and rapid, the term *ruptured aneurysm* is preferable.

5. *Consecutive aneurysm* results from the rapid growth of a sacculated aneurysm. At a certain portion of the sac of a true aneurysm the arterial coats give way completely, and at this point blood is limited only by clot and by condensed perivascular tissue. The blood is not diffused, but is encapsuled, partly by the old sac, partly by condensed tissues, aided it may be by bone and fascia.

6. *Fusiform* or *tubulated aneurysm*—a variety of true aneurysm, the sac being spindle-shaped and formed, as Matas states, "at the expense of the artery," the artery dilates, the continuity of the parent artery is interrupted for a variable length, and is lost in the sac, to be restored once more as a normal vessel at the outlet of the aneurysm ("Transactions of Am. Surg. Assoc.," 1905). Such an aneurysm has, of course, two openings. This form, according to Matas, comprises 66.6 per cent. of all aneurysms.

7. *Sacculated aneurysm*—a common form of aneurysm, in which the dilatation is like a pouch, arising from a part of the arterial circumference

and adjoining the lumen of the vessel by a single aperture. As Matas points out, the parent artery is involved in but a portion of its circumference, the continuity of the vessel is not lost, the arterial caliber is maintained at a nearly normal diameter, and "the sac is simply grafted or attached to the artery by a narrow neck, forming a sort of diverticulum of variable shape and dimensions" ("Proceedings of Am. Surg. Assoc.," 1905). Such a sac has but one orifice. The opening from the artery into the sac is called the *mouth;* around and just above the mouth is the *neck;* the balance of the sac is much larger than the neck and is called the *body*. A sacculated aneurysm may arise from an artery of normal size, from a dilated artery, or from a fusiform aneurysm. A sacculated aneurysm of unknown cause is called a *spontaneous aneurysm;* one which is due to injury is called a *traumatic aneurysm.* The first step in the formation of a sacculated aneurysm is stretching or giving way of an area of the middle coat (media), followed by a gradually advancing stretching and dilatation of corresponding areas of the outer coat (adventitia) and the inner coat (intima).

8. *Dissecting aneurysm* (*Shekelton's aneurysm*)—a pouch-like dilatation of an artery due to the blood-stream, which has gained access to the middle coat through an atheromatous ulcer or a minute rupture of the inner coat. It used to be taught that the blood flows between the media and adventitia; we now know that it flows between the layers of the middle coat. The outer wall of the aneurysm consists of adventitia and a portion of the middle coat. The unnatural channel may or may not join the lumen of the artery at another point by a fresh aperture in the intima. Dissecting aneurysm is practically only met with in the aorta. It is most common in the thoracic aorta. About 80 cases have been reported.[1]

9. *Arteriovenous aneurysm*, which is divided into aneurysmal varix, or Pott's aneurysm, when there is direct communication between a vein and an artery; and varicose aneurysm, when there is communication between an artery and a vein by means of an interposed sac.

10. *Acute aneurysm*—a cavity in the walls of the heart, which cavity communicates with the interior of this organ, and which is due to suppuration in the course of acute endocarditis or myocarditis.

11. *Aneurysm by Anastomosis.*—(See Angiomata.)

12. *Aneurysm of bone*—an inaccurate clinical term used to designate a pulsatile tumor of bone.

13. *Circumscribed aneurysm*—when the blood is circumscribed by distinct walls.

14. *Cirsoid aneurysm*—a mass of dilated and elongated arteries shaped like varicose veins and pulsating with each heart-beat.

15. *Cylindrical aneurysm*—a dilatation which maintains the same dimensions for a considerable space.

16. *Embolic* or *capillary aneurysm*—dilatation of terminal arteries due to emboli.

17. *Spontaneous aneurysm*—non-traumatic in origin.

18. *Miliary aneurysm*—a minute dilatation of an arteriole.

19. *Secondary aneurysm*—one which, after apparent cure, again pulsates, the blood entering by means of the anastomotic circulation.

20. *Verminous aneurysm*—one containing a parasite. This form of aneurysm is met with in the mesenteric artery of the horse.

The sac of a sacculated aneurysm is at first composed of at least two of the arterial coats, reinforced by the sheath and perivascular tissues. After a time the blood-pressure distends the sac, and the inner and middle coats either stretch with interstitial growth or—what is more common—are worn away

[1] Coleman, in "Dublin Jour. Med. Sciences," Aug., 1898.

and lost. When all the coats are lost and the blood is sustained only by the sheath and surrounding tissue, a true aneurysm becomes a false or consecutive aneurysm, the limiting tissues and sheath being condensed, thickened, and glued together. This limiting process is deficient in the brain, hence cerebral aneurysms break soon after their formation. When all the arterial coats are lost, the blood-pressure, acting on the tissues, finds some spots less resistant than others, the blood follows the lines of least resistance, the aneurysm grows with great rapidity, and soon ruptures externally or into a cavity.

An aneurysm may rupture into a cavity (pleural, pericardial, or peritoneal), into the perivascular tissues, or through the skin. Rupture into the tissues may produce pressure-gangrene. When rupture occurs through the skin the hemorrhage is not often instantly fatal, but during several days recurs again and again in larger and larger amounts. The pressure of an aneurysm causes atrophy of tissues, hard and soft, bones and cartilages being as easily destroyed as muscles and fat. Sometimes the perivascular tissues inflame and suppurate, and the sac is opened rapidly by sloughing. An aneurysm usually progresses toward rupture, the slowest in this progression being the fusiform dilatation, which may exist for many years, but which finally is converted into the sacculated variety.

In some rare instances there takes place spontaneous cure, which may result from laminated fibrin being deposited upon the walls of the sac as the blood circulates through it. The laminated fibrin is known as an "active clot," and eventually fills the sac. The weaker and slower the blood-stream, the greater is the tendency to the formation of an active clot, hence any agent impeding, but not abolishing, the circulation aids in the deposition. The weakening and slowing of circulation may be brought about by great activity of the collateral circulation diverting most of the blood from the area of disease. Sometimes a clot breaks off from the sac wall and plugs the artery beyond the aneurysm, and the anastomotic vessels, enlarging, divert the blood-stream. A large aneurysm, falling over by its own weight upon the vessel above the mouth of the sac, may, in very unusual cases, diminish the blood-stream. The development of another aneurysm upon the same vessel nearer to the heart weakens the circulation in and may cure the older one. Inflammation occasionally forms a clot. The tissues about an aneurysm tend to contract when arterial force is lessened, hence tissue-pressure may more than counteract blood-pressure when the circulation is feeble. Clotting of the blood contained within a sac, circulation through the aneurysm having ceased, causes a "passive clot." A passive clot, which occasionally induces cure, may arise from a twist of the neck of the sac preventing the passage of blood, from the lodgment of a clot in the mouth of the sac, and from inflammation. Spontaneous cure is, unfortunately, very rare.

Causes of Aneurysm.—Gradual distention of arterial coats which are in a condition of arterial sclerosis, or of coats whose resisting power is lowered because of atheroma, may cause aneurysm. Hence, the causes of sclerosis and atheroma are also causes of aneurysm. The principal cause of aneurysm is increased blood-pressure. This increase may be brought about by severe labor; by sudden strains, as in lifting; by violent efforts, as in rowing in a boat-race; by chronic interstitial nephritis; by hypertrophy of the heart; by alcoholic excess, and by syphilis. Arterial disease is commonest in the larger vessels, and in the aged, but it may occur in youth. When an aneurysm follows a strain, it may be due to laceration of the media and loss of resistance at a narrow point. The intima may lacerate, permitting the blood to come in contact with the media or causing blood to diffuse between the coats (dissecting aneurysm). When an embolus lodges in an artery the vessels may

become aneurysmal on the proximal side of the clot. The embolus, if infective, causes softening, and if calcareous causes laceration (Osler). Colonies of micrococci may cause aneurysm.[1] The parasite *Strongylus armatus* causes aneurysm of the mesenteric arteries in horses. Suppuration around a vessel weakens its coats and tends to aneurysm by inducing acute arteritis and softening. Sometimes an individual develops multiple aneurysms the origins of which are absolutely unknown. A bruise of a vessel may be followed by aneurysm. A cut or puncture of a healthy artery may lead, after the surface wound heals, to the development of an aneurysm. Such an aneurysm does not differ in symptoms or treatment from the other form.

The constituent parts of an aneurysm are: (1) the wall of the sac; (2) the cavity; (3) the mouth, and (4) the contents.

Symptoms of Aneurysm.—The formation of an aneurysm, when sudden, is occasionally, though rarely, appreciated by the patient, and is described by him as a feeling of something having given way. In most instances the feeling of beating and the discovery of the lump are the first intimations that anything is wrong. An oval or globular, soft, elastic, and pulsatile protrusion develops in the line of an artery. It is usually quite evident to the touch that the sac contains fluid, but sometimes in old aneurysms the sac feels firm or even hard, because of the deposit of fibrin upon its inner surface. In a partially consolidated aneurysm pulsation may be slight or even inappreciable. The protrusion instantly ceases to pulsate and almost disappears on making firm pressure on the artery above. On relaxing the pressure the pulsatile enlargement at once reappears. Direct pressure upon the tumor may cause it to almost disappear. Pressure upon the artery below causes the tumor to enlarge. The pulsation is expansile—that is, the sac expands in all directions during every cardiac contraction—and if an index-finger be laid on each side of the tumor so that the points nearly touch, each pulsation not only lifts the fingers, but it also separates them. It is important to remember that a *large* intrathoracic aneurysm which is in contact with the chest may not exhibit expansile pulsation, but simply transmit pulsation from the blood-stream (Sidney Lange, in "N. Y. Med. Jour.," Nov. 21, 1908). On placing a stethoscope over the aneurysm or over the vessel below the aneurysm there is imparted to the ear a distinct bruit, which travels in the direction of the blood-stream, is systolic in time, and is usually blowing in character. In some cases bruit is absent (when a sacculated aneurysm has a very small mouth, when the circulation is tranquil, or when the sac is full of blood and clot). When bruit is absent, it may sometimes be developed by muscular exercise or raising the affected limb (Halloway). In rare cases there may be a double bruit. Occasionally, in fusiform aortic aneurysm linked with aortic regurgitation, a diastolic bruit exists. A bruit is arrested by pressing upon the artery between the aneurysm and the heart. A patient who has an aneurysm of an extremity complains of a sensation of beating, of weakness or stiffness of the limb, frequently of pain in a nerve, a feeling of fatigue in the muscles, and edema and dilated veins are apt to develop because of pressure upon large veins and loss of *vis a tergo* in the circulation. The skin over an aneurysm may be normal, may be discolored, may ulcerate, or even slough. The pulse below an aneurysm is weaker than the pulse of a corresponding part of the opposite limb. This is well shown by sphygmographic tracings (Fig. 189). The tracings taken below an aneurysm are rounded without a sudden rise or an abrupt fall. In internal aneurysms pressure symptoms are marked. Thoracic aneurysm causes intercostal pain; iliac aneurysm causes pain in the thigh. Abdominal aneurysm is very rare. It is most common near the diaphragm. It is more apt to be sacculated than fusiform. As a rule, it distends forward; if it distends back-

[1] See Osler on "Malignant Endocarditis."

ward it may destroy the vertebræ and press upon the cord. Pain practically always occurs, usually in the back, sometimes in the abdomen. Expansile pulsation and bruit make the diagnosis clear. The x-rays may be valuable in establishing the diagnosis. Aneurysm of the thoracic aorta pressing upon the pneumogastric nerve causes spasmodic dyspnea, and upon the recurrent

Fig. 189.—Radial pulse-tracings in aneurysm of right brachial artery: 1, Left radial pulse; 2, right radial pulse (after Mahomed).

laryngeal causes hoarseness, which may be associated with loss of voice, cough, and laryngeal spasm, and is due to unilateral abductor paralysis. Pressure upon a bronchus or the trachea causes dyspnea from obstruction, dysphagia, and cough from laryngeal spasm. Pressure upon the cervical sympathetic

Fig. 190.—X-ray of aneurysm of thoracic aorta.

first causes dilatation and later contraction of the pupil of the same side. A thoracic aneurysm may erode the ribs, sternum, or vertebræ. The x-rays are of great value in diagnosticating thoracic aneurysm (Fig. 190). An aneurysm in the neck may interfere with the cerebral circulation and produce vertigo and even attacks of unconsciousness. The evidences of rupture of an aneurysm of

an extremity into the tissues are loss of distinctness of outline and increase in area of the swelling, weakening or disappearance of both bruit and pulsation, absence of pulse below the aneurysm, severe pain, edema and coldness of the surface, shock, and possibly syncope. External hemorrhage may arise; the tissues may become extensively infiltrated with blood; sloughing or gangrene may ensue. Death is frequent, and only in very rare cases does spontaneous cure take place. Rupture of a large aneurysm into a cavity causes intense pallor, advancing weakness, syncope, and death.

Diagnosis.—A cyst or abscess over a vessel may show transmitted pulsation which is not expansile, and the swelling does not disappear when pressure is made upon the vessel above it. The pulsation ceases when the growth is lifted off the vessel, or when the position is changed so as to permit it to fall away from the vessel. There is no true bruit, and the history is widely different. A growth under a vessel may lift the vessel and simulate an aneurysm, but the pulsation is not noted in the entire growth, the growth does not disappear on proximal pressure, and there is only a false, and never a true, bruit. The larger the growth under a vessel the less is the pulsation, because of pressure narrowing the caliber of the vessel. A sarcoma, especially a soft sarcoma attached to the bone, and also a nevoid mass, pulsate and often have a bruit; the tumor never disappears from proximal pressure, though it may slowly diminish in size, to gradually enlarge again when pressure is withdrawn. These growths do not feel fluid, and are rarely circumscribed. An aneurysm may cease to pulsate from consolidation leading to cure or from rupture. Rupture of a large aneurysm into a cavity induces deadly pallor, syncope, and rapid death. Rupture of an aneurysm of an extremity into the tissues is made manifest by a sensation of something breaking, by pain, by sudden increase in size, by diminution or absence of bruit and pulsation, by absence of pulse below the aneurysm, by swelling and coldness of the limb, and by shock. The x-rays are valuable in diagnosticating thoracic aneurysm and abdominal aneurysm.

Treatment.—(For the history of the evolution of the treatment of aneurysm, see "Studies in Aneurysm," by James G. Mumford, "Cleveland Med. Jour.," Feb., 1908.) In inoperable aneurysms, *general*, *medical*, and *dietetic* treatment must be tried. A chief element in treatment is rest in bed to diminish the rapidity and force of the circulation and favor fibrinous deposit. Valsalva long ago suggested rest, occasional bleeding, and a diet just above the point of starvation. Tuffnell's plan is to reduce the heart-beats by rest and mental quiet, and to rigidly restrict the diet so as to diminish the total amount of blood and render it more fibrinous. Liquids are restricted in amount, and the patient lives through each twenty-four hours upon 4 oz. of bread, a very little butter, 8 oz. of milk, and 3 oz. of meat. This plan is pursued for several months if possible, or it is employed for several weeks, intermitted for a short period, the rigid diet again returned to, and so on, over and over again. There can be no doubt that Tuffnell's treatment sometimes cures aneurysm by decidedly lowering the blood-pressure. Many who suffer from aneurysm may be permitted to go about, taking their time about everything and avoiding work, worry, and excitement. The diet should be low and non-stimulating, and the bowels must be maintained in a loose condition.

Even in an operable case diet and rest are of importance. Often a patient is kept in bed for a number of days before operation, the daily diet consisting of 10 or 12 oz. of solid food with a pint of milk. If the circulation is very active, use aconite and allay pain by morphin.

Iodid of potassium in doses of 20 gr. undoubtedly does good in aneurysm and not only in syphilitic cases. It seems to lower the blood-pressure. Balfour taught that it thickened the walls of the sac. Osler says it relieves the

pain. Iron, acetate of lead, and ergotin are prescribed by some. Digitalis is contra-indicated, as it raises the blood-pressure. S. Solis-Cohen has used with some success the hydrated chlorid of calcium. Morphin and bromid of potassium are occasionally useful to tranquilize the circulation, allay pain, or secure sleep. Aconite and veratrum viride have long been employed.

Lancereaux and others claim that hypodermatic injections of gelatin at some indifferent point may cure aortic and subclavian aneurysm. In 1896 Dastres and Floresco proved that gelatin injected into the blood increases coagulability. Later, Lancereaux and Paulesco showed that injections into the subcutaneous tissue act similarly. Carnot pointed out that gelatin applied to a wound may arrest bleeding. How gelatin acts is uncertain, but that it does increase blood coagulability seems proved. The value of injections of gelatin for aneurysm is in dispute. Lancereaux warmly advocates its use for sacculated aneurysm, and says that after the first dose the aneurysm is seen to shrink and the pulsation is observed to lessen. He injects it slowly and with aseptic care into the subcutaneous tissue of the thigh, using normal salt solution containing from 5 to 10 per cent. gelatin. He never injects less than 5 gm. He gives an injection every tenth to fifteenth day and administers from ten to twenty injections. But the treatment is not free from danger; several deaths have taken place, and several persons have died from tetanus. Care must be taken not to inject gelatin into a vessel, and it must never be thrown about the aneurysmal sac. It irritates the kidneys and its use is contra-indicated in renal disease. The injections cause much pain, and it is very doubtful if they do any real good in aneurysm. If used it should be given at the temperature of the body, and not over 3 gm. should be administered at one dose. A 10 per cent. solution is the proper strength and from 10 to 20 c.c. the correct dose. Gelatin can be given by the mouth. When thus given it is not so powerful, but its coagulating property is not destroyed by digestion. Gelatin in normal salt solution is known as Carnot's solution. *Carnot's solution* is best prepared by Sailer's formula, as follows (Joseph Sailer, in "Therapeutic Gazette," August, 1901): Take 5 gm. of common salt, 1 liter of distilled water, and 100 gm. of gelatin. Bring the water to a temperature of 80° C. and slowly stir in the gelatin until it is all in solution. Remove the solution from the stove, cool it to 40° C., add to it the white of one egg, and stir for several minutes, and then put the flask on the stove and boil the fluid. The white of egg coagulates and clears the solution. Filter through gauze and then through paper. Place the fluid in test-tubes, each of which will contain 10 c.c., and insert a cotton plug in the mouth of each tube. Sterilize by putting the tubes in a steam sterilizer for fifteen minutes on three successive days. When wishing to use a tube, place it in a cup of hot water until the gelatin liquefies, pour the gelatin into a sterile glass, and draw it up into a sterile syringe. When kept several weeks the gelatin dries out.

Other expedients sometimes used in the treatment of aneurysm are: the kneading of the sac to release a clot, in the hope that it will plug the mouth of the sac or the artery beyond it—this is dangerous; electricity; electrolysis; the injection of an astringent liquid; the insertion of a fine aspirating needle and the pushing through it into the sac of a large quantity of silver wire, in the hope that it will aid in whipping out fibrin. Some physicians have inserted needles and others horsehair.

Treatment by Pressure.—Instrumental pressure is made by applying two Signorini tourniquets or some specially devised apparatus to limit the flow of blood through an aneurysm without entirely stopping it, the aneurysmal sac being felt to still slightly pulsate. In some situations Lister's abdominal tourniquet is applied; in other regions we may use Tuffnell's compress, which

is like a spring truss and is strapped in place. A heavy body suspended over the artery and resting part of its weight upon the vessel has occasionally brought about cure. Compressing instruments can be worn for from twelve to sixteen hours at a time; usually they are removed to permit sleep and are reapplied the next day, and so on for several days. Before applying the compress be sure the sac is full of blood, and render this certain by applying for a few minutes distal compression. This method may cure, but it is very painful. It cannot be used successfully in treating aneurysm of the axillary, subclavian, or carotid artery. It aids in the formation of an active clot.

Digital pressure, made with the thumb aided by a weight, and maintained for many hours by a relay of assistants, has cured many cases. This method may be used alone or may be used as an accessory to instrumental pressure. Its chief field is in the treatment of aneurysm for which other methods are inapplicable (orbit and some aneurysms at the root of neck). It entirely cuts off the blood and promotes the formation of a passive clot. If cure does not take place in three days, abandon pressure. It must often be abandoned far earlier because of pain.

Direct pressure upon the sac has been used in aneurysm of the popliteal artery, the pressure being obtained by flexing the leg; and in aneurysm of the brachial artery pressure has been applied at the bend of the elbow by flexing the elbow. The pressure of a hollow rubber ball has been used in aneurysm of the subclavian.

Rapid pressure completely arrests the passage of blood through the sac for a limited time, and is applied while the patient is under the influence of an anesthetic. Take, for example, a case of popliteal aneurysm: the patient is placed under the influence of ether; two Esmarch bandages are used, one being applied to the limb from the toes up to the lower limit of the aneurysm, and the other from the groin down to the upper limit of the sac, and the Esmarch band is fastened above the upper bandage. This prodecure stagnates the blood both in the veins and in the arteries, and the sac remains full of blood. Pressure is thus maintained for three or four hours, and on removing the Esmarch apparatus a tourniquet is put on the artery above the aneurysm and partly tightened in order to limit the amount of blood passing through and thus prevent the washing away of clot. This method of rapid pressure sometimes cures by forming a passive clot, but it sometimes results in gangrene. It was devised by John Reid.

Operative Treatment: By the Ligature and by Sutures.—Ligation of the main artery was the operation employed by most surgeons until the Matas operation was introduced. The methods of ligation are: (1) the method of Antyllus; (2) extirpation of the sac; (3) the method of Anel; (4) the method of Hunter; (5) the method of Wardrop, and (6) the method of Brasdor.

Aneurysmotomy, the *method of Antyllus* (Fig. 191), a Roman successor to Galen, who lived in the third century, A. D., is usually described as a method involving a direct attack upon the sac itself. The artery is ligated immediately above and below the sac, the sac is opened and its contents turned out, or the sac is extirpated. As a matter of fact, Antyllus advocated applying a ligature on each side of the sac and opening the sac in order to evacuate its contents, but he distinctly opposed extirpation because of its danger. All we know of Antyllus is found in the writings of Oribasius, who lived in the fourth century. Syme maintained many years ago that incision of the sac is the proper operation for aneurysm of the gluteal, iliac, carotid, and axillary arteries, but Syme's method is productive of fearful hemorrhage, and the plan of Antyllus is vastly better. Syme opened the sac, inserted his finger, and plugged the artery toward the heart until a ligature was applied and tied. He then packed the sac with lint.

Aneurysmectomy (*extirpation of the sac*), if practised, should be carried out after applying a ligature on each side after the method of Antyllus. It was originally practised by Philagrius and was reintroduced by Purmann in 1699 (Moynihan, in "Annals of Surgery," July, 1898).

Extirpation finds warm advocates in Delbet, Littlewood, and Moynihan. Moynihan claims that, as compared with distal ligature, there is a greater chance of recovery, no chance of recurrence, less risk of gangrene, and complete recovery from troubles due to nerve interference (Ibid.). Extirpation is regarded by some surgeons as the best operation for traumatic aneurysm, but if the vessel is seriously diseased near the sac some other method should certainly be employed. In aneurysm of the common carotid after extirpation (as after ligation) there is grave risk of cerebral embolism, and it might be wise to attempt a re-establishment of the circulation by circular suture of the two ends, or, as Lexer did in the axillary artery, autoplasty with a piece of the internal saphenous vein. In the extremities there is less danger of gangrene after Matas's operation than after extirpation. Monod and Vanverts ("Rev de. Chir.," 1910, xli and xlii) collected 205 cases of excision. Of these, 90 per cent. were cured. Relapse occurred in 1½ per cent. Direct operative mortality was 3 per cent. Gangrene occurred in 4 per cent. Extirpation shows a higher percentage of cures, a lower rate of mortality, fewer cases of gangrene, and fewer relapses than any operation except that of Matas. Monod and Vanverts collected 138 cases of ligation by different methods. The mortality was 7 per cent. There were 12 per cent. of relapses and 6½ per cent. of gangrene. The cures numbered 74 per cent.

Fig. 191.—Old operation of Antyllus for aneurysm ("Am. Text-Book of Surgery").

Fig. 192.—Anel's operation for aneurysm ("Am. Text-Book of Surgery").

The Method of Anel.—Anel, of Turin, devised and performed this operation in 1710. In Anel's method the artery is ligated above the sac, and so close to it that there are no anastomotic branches between the sac and the ligature (Fig. 192). It is used only for traumatic aneurysms, and is never employed when the vessel is diseased beyond the aneurysm. Either extirpation or Matas's operation is preferable to Anel's operation.

The Method of Hunter.—This operation, which is the modern method of ligation, was devised by the illustrious John Hunter, and was first employed by him in January, 1786. He is said by Sir Everard Home to have recognized the fact that the vessel adjacent to an aneurysm was apt to be diseased, and he discovered the anastomotic circulation. Putting together these two facts, he devised the operation which goes by his name. It consists in applying a ligature between the heart and the aneurysm, but so far above the sac that collateral branches are given off between it and the point of ligation (Fig. 193). This operation, which is done upon a healthy portion of the artery, does not permanently cut off all blood, but so diminishes the force and frequency of the circulation that an active clot forms within the sac. Thus are lessened the dangers of secondary hemorrhage and gangrene. According to Stimson ("New York Med. Jour.," July, 1884), Hunter really builded better than he knew, for he sought only to tie the artery without opening the sac and at a healthy point, but said not a word about the necessity of having branches between the sac and the ligature or about the desirability of diminishing the flow of blood instead of cutting it off completely (Moynihan, in "Annals

of Surgery," July, 1898). Hunter tied the artery in the region now known as Hunter's canal. Scarpa introduced the custom, which we still follow, of tying it in Scarpa's triangle. The Hunterian method was for many years regarded by most surgeons as the proper operation for aneurysm in the majority of cases. In some cases pulsation does not return in the aneurysm after tightening the ligature; in most cases, however, it reappears for a time after about thirty-six hours, but is weak from the start, constantly diminishes, and finally disappears permanently. Previous prolonged compression by enlarging the collateral branches permits strong pulsation to recur soon after ligation, and thus militates against cure; hence, it is a bad plan to use pressure in cases admitting of ligation and in which the success of pressure is very doubtful. Occasionally after Hunter's operation the sac suppurates, producing symptoms like those of abscess. Suppuration may occur between the first and the thirty-second week after ligation.[1] When pus forms, open freely, as we would open an abscess, and if no blood flows, treat as an abscess, but have a tourniquet loosely applied for several days ready to screw up at the first sign of danger. If hemorrhage occurs, tie the vessel above and below the aneurysm, open the sac, and pack with iodoform gauze. If bleeding recurs, there is no use reapplying the ligature and there is little use tying higher up.

Fig. 193.—Hunter's method of ligating for aneurysm: *a*, The aneurysm; *b*, point of ligation; *c*, the branches between the aneurysm and the ligature. The arrow shows the direction of the blood-current.

If dealing with the upper extremity, try the application of a ligature higher up; if dealing with the lower extremity, amputate at once.

Distal Ligation.—When an aneurysm is so near the trunk that Hunter's operation is impracticable, or when the artery on the cardiac side of the tumor is greatly diseased, distal ligation may be employed. Distal ligation forms a barrier to the onflow of blood, collateral branches above the aneurysm enlarge, the blood-current is gradually diverted, and a clot may form within the aneurysm. Distal ligation is used in some aneurysms of the aorta, iliac, innominate, carotid, and subclavian. It occasionally causes rupture of the sac of the aneurysm. I have obtained two notably successful results in aneurysms of the innominate artery by ligation of the common carotid and subclavian of the right side. In each of these cases I tied both vessels at one séance, tying the carotid first. In 1 case I tied the third part of the subclavian and in the other the first part. The first patient returned to his work as a blacksmith and died over a year and a half later from rupture of a secondary aneurysm of the carotid at the point where the ligature had been applied. The second case is living and apparently well over five years after the operation (the author, in "Surg., Gyn., and Obst.," June, 1910).

The *operation of Brasdor* consists in tying the main trunk some little distance below the aneurysm (Fig. 194). It completely arrests circulation in the sac. The operation was introduced in 1760 by the French surgeon Brasdor.

[1] See the case described by Sir Astley Cooper.

The *operation of Wardrop* consists in tying one of the branches of the artery beyond the aneurysm. Wardrop originally advocated ligation at a point where there is no intervening branch between the sac and the ligature. Later, he advocated ligation at a point where there is an intervening branch. Since then it is the custom to consider Wardrop's operation to be the ligation of one branch beyond the aneurysm, as shown in Fig. 195. The circulation is but partially arrested by Wardrop's operation. The operation was introduced in 1825. An *x*-ray picture should be taken in every case of aortic aneurysm. Such a picture may aid us in coming to a conclusion as to which vessel or vessels to tie.

Matas's Operation (*Aneurysmorrhaphy*).—This procedure is the greatest advance in the surgery of the arterial system since the observations of John Hunter. It was first practised by Matas in 1889 on a negro suffering from traumatic aneurysm of the brachial artery in the middle of the arm. The operation was a complete success. In 1900 he began again to use this method, and in 1902 described it to the profession ("Trans. of Am. Surg. Assoc.," 1902; "Annals of Surg.," Feb., 1903; "Trans. of Am. Surg. Assoc.," 1905).

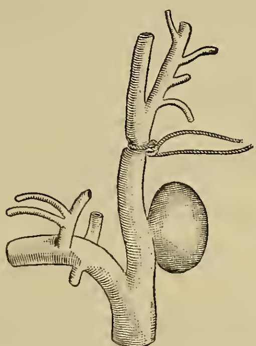

Fig. 194.—Brasdor's operation (Holmes).

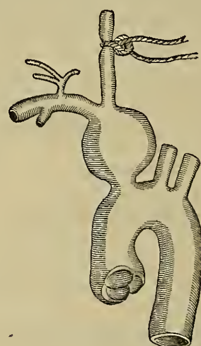

Fig. 195.—Wardrop's operation (Holmes).

One procedure, applicable to ordinary fusiform aneurysms, is called *obliterative endo-aneurysmorrhaphy without arterioplasty* (Fig. 196). "No attempt is made to reconstruct the parent artery (arterioplasty), and the arterial orifices are simply obliterated by suture." By sutures applied within the incised sac the sac is cut off from the circulation without disturbing adjacent collaterals and without interfering with the nutrition of the sac walls. After this operation there is very seldom secondary hemorrhage, gangrene, or relapse.

A modification of the above operation applied to sacculated aneurysms in which there is one orifice of communication with the artery is called *endo-aneurysmorrhaphy with partial arterioplasty* (Fig. 196). The sac is opened, clots are washed away, the opening of the aneurysm into the artery is closed by a continuous suture passing through all the coats of the sac at the edge of the opening into the artery. Blood is thus excluded from the sac, the lumen of the artery is not, however, obliterated, and the blood-supply of parts beyond is not interfered with. After closing the cut in the arterial wall the sac is obliterated by rows of sutures inserted in its walls. Matas reports 4 cases operated upon successfully by this plan. In a fusiform aneurysm with a firm and resisting sac wall, and in which there are two openings near together on the floor of the sac, *endo-aneurysmorrhaphy* with complete *arterioplasty* may be performed (Fig. 196). This operation restores arterial continuity, a new channel being made out of the sac walls "by simply holding these over a rubber guide (tube or catheter) and suturing them firmly together so as to restore

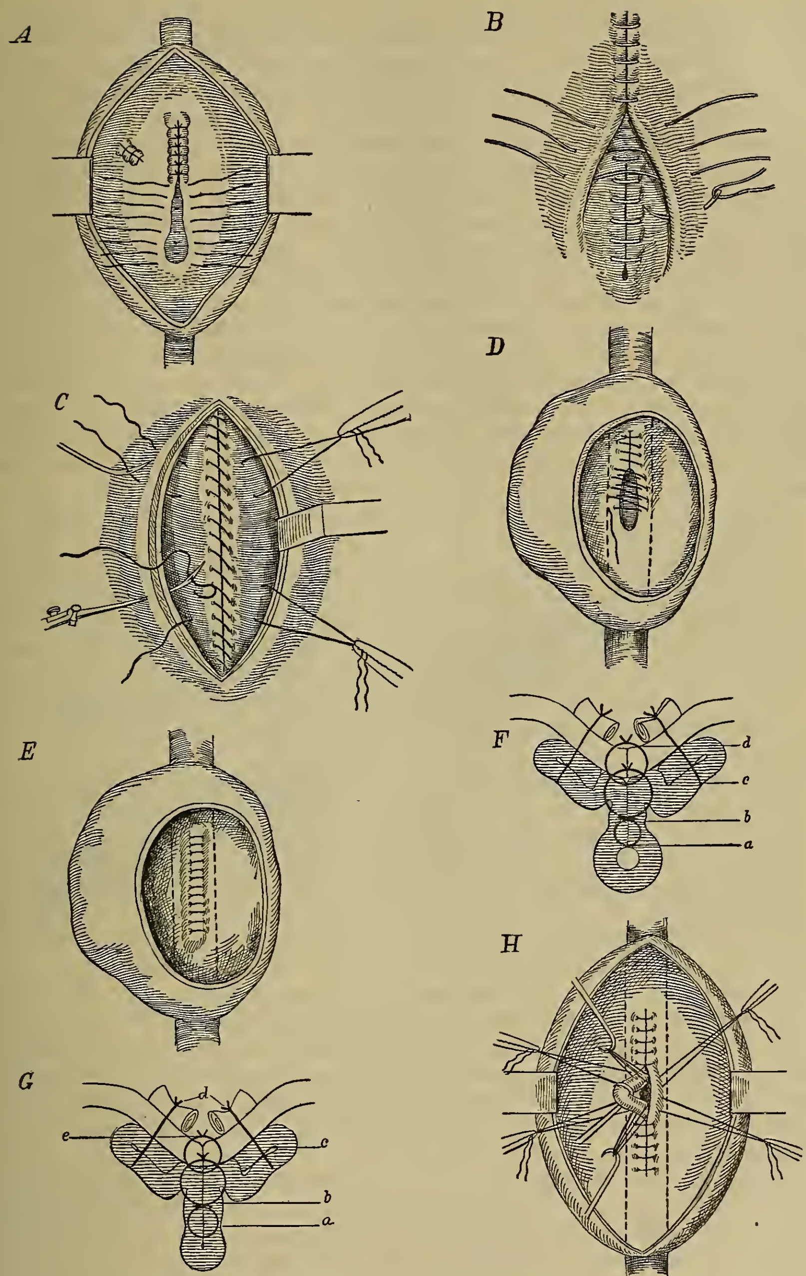

Fig. 196.—The radical cure of aneurysm based upon arteriorrhaphy (Matas): *A*, First tier of sutures in a fusiform aneurysm; *B*, second tier of sutures, some of which are tied; *C*, sutures to approximate the walls of the aneurysm; *D*, suturing the opening in a sacculated aneurysm—the main artery is not obliterated; *E*, opening completely closed; *F*, diagram of cross-section of parts after complete obliteration of sac, but with restoration of blood-channel; *G*, diagram of cross-section of parts after complete obliteration of sac and blood-vessel; *H*, operation for fusiform aneurysm when we wish to restore the blood-channel—sutures applied over a rubber tube, most of the sutures tied, tube withdrawn, and remaining sutures tied.

the continuity of the artery lost in the sac." The catheter is withdrawn before the final sutures are tied. This operation has been performed successfully by Morris and also by Craig. Some surgeons are fearful that such an operation will be followed by relapse, and one of the reported cases did relapse. Matas says that preservation of the arterial lumen is "only indicated positively in the sacciform aneurysms with a single opening where the parent artery already exists as a formed vessel, and in which the closure of the fistulous opening can be accomplished with the greatest facility and simplicity" (address delivered at the Medical Assoc. of Alabama, April 22, 1906). It is not probable that the artery remains patent long, because the seat of aneurysm is a diseased vessel and vascular disease will probably cause clotting, but even a temporary restoration of circulation if followed by *gradual* abolition prevents gangrene. The Matas operation differs notably from the Antyllus operation in the fact that it saves certain collaterals which the Antyllus method destroys, and the retention of these collaterals may prevent gangrene in the limb. It differs from it further in the fact that it occludes certain small vessels which after the Antyllus method continue to convey blood into the sac. It is superior to extirpation because it does not destroy the vascular walls of the sac, the blood-vessels of which, if unblocked, aid in preventing gangrene of the limb.

Matas points out that suture of an aneurysm is indicated only when certain essentials exist.

1. The situation of the aneurysm must admit of the control of the circulation temporarily on the proximal side of the sac. In most aneurysms of the extremities this is done by the elastic band of Esmarch. In the neck and abdomen both the cardiac and peripheral sides of the main vessels must be secured by traction loops and compression.

2. The sac must be freely opened in a longitudinal direction. Its wall must not be dissected and must be separated as little as possible from surrounding tissue.

3. Every orifice opening into the sac must be thoroughly exposed so that they can be closed by sutures. The suture material is chromic gut, the number being 1, 2, or 3, according to the size of the aneurysm.

Fig. 196, *A* to *H*, shows Matas's various operations. For a full description of them see the previously quoted articles of the author. I believe that the Matas operation is a very notable advance in surgery, that it is safer than older methods, and much less apt to be followed by gangrene. The idea seems to be general that Matas always seeks to restore arterial lumen. This is not the case. He only seeks to do this in exceptional cases. The essence of his method is to cure the aneurysm by sutures within the sac and by obliteration of the sac. I have performed the Matas operation (obliterative endo-aneurysmorrhaphy) successfully on a case of ruptured fusiform popliteal aneurysm and on a case of ruptured sacculated popliteal aneurysm. In the latter case there was profuse hemorrhage during the operation from vessels opening into the sac.

Matas, in "Annals of Surgery," July, 1910, collected 149 cases with 133 cures. In Monod and Vanvert's 103 cases there were 89 cures. Relapse occurred in 1.5 per cent. Gangrene occurred in from 3 to 5 per cent. of the cases. Direct operative mortality was 3 per cent. ("Rev. de Chir.," 1910, xli and xlii).

Less than 2 per cent. of cases relapse. The direct mortality is 3 per cent. Gangrene occurs in 3 per cent. of cases. Secondary hemorrhage is very rare.

The operation has been performed upon the abdominal aorta, the external iliac, and the subclavian, as well as upon smaller vessels. Munro, Martin and Parham, Lilienthal, Pringle, and Lozano performed endo-aneurysmorrhaphy for subclavian aneurysm (Eliot, in "Annals of Surgery," July, 1912).

Halsted's Method by Partial, Progressive, and, Finally, Complete Occlusion by Metal Band.—This method is applied only to the aorta and other very large arteries. A number of surgeons have sought a method to gradually and safely occlude the abdominal aorta in order that they may attempt to cure aneurysm of the aorta or of the iliac arteries. The usual thought was to leave a metal instrument fixed to the aorta, the handle projecting from the abdominal wound, and a metal clamp or a snare of silk or catgut being around the vessel, so that by means of a screw arrangement pressure could be gradually increased.

Halsted showed that by this plan sepsis almost certainly occurs along the track of the instrument. (See W. S. Halsted, in "Johns Hopkins Bulletin," 1905, xvi, 346; "Jour. Am. Med. Assoc.," 1906, xlvii; "Jour. Experimental Medicine," 1909, vol. xi, No. 2.) Halsted sought for a method "permitting, in each entre-act, complete closure of the wound." He uses a band of aluminum curled in cylinder form about the vessel. This material admits of easy readjustment at a future operation, and it is tightened by the fingers.

Halsted's band, when used to partially occlude, seldom causes macroscopic alteration in the wall of the vessel; when used to completely occlude, the vessel may undergo atrophy. Ideal closure is when the lumen was nearly but not

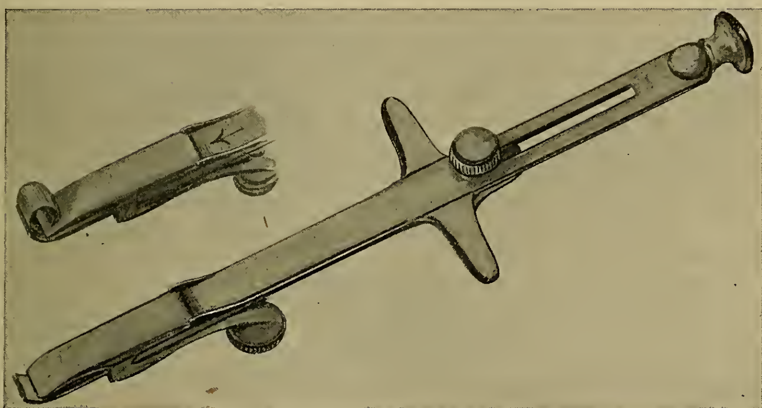

Fig. 197.—Halsted's improved band roller: The instrument shown in full length is unloaded; in the abbreviated cut the band is about to be expelled from the roller (Halsted).

quite occluded, spontaneous obliteration having arisen, the arterial wall embraced by the band having undergone conversion into "a solid cylinder of living tissue." Animals tolerate gradual occlusion very well indeed.

Halsted has made numerous experiments on dogs and has used the band with encouraging results on the human being (partial occlusion of the innominate, twice; common carotid, four times). In a case of aneurysm of the abdominal aorta Halsted partially occluded the aorta near the diaphragm. Seventeen days later he placed another band on the aorta below the aneurysm. The patient lived twenty-four days after the second operation. The operation checked growth and arrested pain ("Trans. Am. Surg. Assoc.," 1909–10). In another case of abdominal aneurysm Halsted put a band above the renals. Seventeen days later Finney inserted wire into the aneurysm. The patient lived forty-five days after the first operation (Ibid.).

In preparing for application it is rolled by means of the instrument shown in Fig. 197. It is well to fasten the band with a silver ligature after application. The ligature prevents unrolling (Ibid.).

Treatment After Operation for Aneurysm.—After operating for aneurysm of an extremity by the ligature or by sutures, elevate the limb slightly, keep

it warm by wrapping in cotton and surrounding with bags of warm water, and subdue arterial excitement. When gangrene of a limb follows ligation, await a line of demarcation, and when it forms, amputate. Rupture of the sac after ligation may produce gangrene or be associated with suppuration, the first condition demanding amputation; the second, incision for drainage.

Injection of coagulating agents into the sac (ergot, perchlorid of iron, etc.) is very dangerous and is to be utterly condemned. It may lead to suppuration, gangrene, rupture, or embolism.

Manipulation to break up the clot was suggested by Sir Wm. Fergusson and has been practised by some. The object aimed at is to have a fragment of clot block up the vessel upon the peripheral side of the artery and act like a distal ligature. The method is dangerous, especially in carotid aneurysm, and should never be employed.

Amputation, instead of distal ligation, is performed in some perilous cases of subclavian aneurysm.

Electrolysis.—An attempt may be made to at once coagulate the blood in the sac, or from time to time an endeavor may be made to produce fibrinous deposits, but the first method is the better. It is, however, seldom possible to at once occlude a sac, and pulsation, which is for a time abolished, usually recurs as the gas present is absorbed. Use the constant current. Take from three to six cells which stand in point of size between those used for the cautery and those used for ordinary medical purposes. A platinum needle is attached to the positive pole and a steel needle to the negative pole, each needle being insulated by vulcanite at the spot where the tissues would touch it. The asepticized needles are plunged into the sac where it is thick, and they are kept near together. The current is passed for a variable period (from half an hour to an hour and a half). This operation is not dangerous. Pressure stops the bleeding. Electrolysis often ameliorates and sometimes greatly improves aortic aneurysms.

Acupuncture consists of the partial introduction of a number of ordinary sewing needles into an aneurysmal sac and leaving them in it for five or six days or more. Professor Macewen introduces a needle, and with it irritates the interior of the sac of an aneurysm, hoping thus to cause deposition of leukocytes, thickening of the sac, and clot formation.

Introduction of Wire.—This operation is performed by inserting into the sac a hypodermatic or small aspirating needle, and pushing in through the needle or cannula a considerable quantity of aseptic gold or silver wire, which is allowed to remain permanently. Wiring is used for aneurysms otherwise inoperable. Electrolysis should be combined with the introduction of wire. Wiring was first proposed by Moore, of London, in 1864. The details were improved by Corradi in 1879. Loreta and Barwell both inserted wire into an aneurysm before Corradi, but Corradi inserted wire and also used electricity. The first American wiring operation was performed by Ransohoff in 1886. Corradi's operation can be used when distal ligation cannot be carried out, and can be used even when the vessel is extremely atheromatous. It finds its chief use in aneurysms of the thoracic aorta and innominate. In some cases of abdominal aneurysm the belly has been opened and the operation carried out. It is used for sacculated, never for fusiform, aneurysms. The operation has not many elements of danger. Sepsis would inevitably cause death. If the wire is carried on into the aorta and heart death will follow. A cause of death is embolism. In one of Finney's cases gangrene of the arm resulted from embolism. Too strong a current may cause sloughing of the aneurysmal wall. The wall of the aneurysm may rupture because of deviation of the strong blood-current in another direction. Some cases have been notably improved. The operation is performed with aseptic care. If the thoracic aorta is to be oper-

ated upon, an anesthetic is not required. If the abdominal aorta is to be wired, the patient must be anesthetized, because the abdomen needs to be opened. The wire used must have been previously drawn, so that it will easily pass through a hypodermatic needle and will coil up spirally within the sac. The best wire is of silver or gold. A special reel is used to keep the wire from getting kinked. It is a great mistake to introduce a large quantity. Stewart decided that a globular sac 3 inches in diameter requires from 3 to 5 feet, and a sac 5 inches in diameter requires from 8 to 10 feet. A hypodermatic needle, insulated up to $\frac{1}{4}$ inch of the point, is carried into the interior of the aneurysm through a fairly thick portion of the sac. The shoulder of the needle is not insulated and must not be permitted to touch the skin, because if it did so it would cause a burn by electrolysis. The required amount of wire is introduced. The wire is attached to the positive pole of the battery. The negative pole is fastened to a large flat piece of clay or a pad of moistened absorbent cotton, and the negative electrode is placed upon the back or abdomen. The current is turned on gradually until the necessary strength is obtained (40 to 80 ma.). When ready to terminate the operation the current is lowered gradually to zero, the needle is withdrawn, the wire is cut off close to the skin, the end is pushed under the skin, the puncture is covered with iodoform collodion, and pressure is applied to keep blood from gathering in the tissue. Such a hematoma might cause the formation of a slough. The entire operation requires from three-quarters of an hour to one and a half hours. A clot forms with considerable rapidity and expansile pulsation may lessen or cease. It requires from a number of days to several weeks for the clot to become hard. The operation can be repeated if necessary. Injections of gelatin after wiring may be beneficial. Rest is imperative for months after wiring.

Notable improvement is common, but genuine cure is not obtained. As Hare says, "adjacent tissues of the vessel sooner or later give way, because the effort is like an effort to mend a rotten hose; though mended at one spot it breaks at another." One of Jones's cases remained well for six years and then pain recurred. The operation causes prompt and marked diminution of pain, an amelioration usually spoken of by the patient before he leaves the operating table. In 2 of my cases pain, which had been severe, disappeared completely during the operation. "Dyspnea is also benefited and just as rapidly" (H. A. Hare, in "Therapeutic Gazette," April, 1908). Finney ("Annals of Surgery," May, 1912) reported 23 cases (mostly thoracic, some abdominal). Of these cases only 2 were known to be living at the time of the report.

Treatment of Aneurysm Following Wound of a Healthy Artery.—The prognosis in such a case is usually extremely good. The treatment is as for the other forms. Extirpation is particularly adapted to such direct traumatic aneurysms in the neck and Matas's operation to those in the extremities.

Diffuse Traumatic Aneurysm.—When an artery ruptures or an aneurysm ruptures and a large mass of blood is extravasated into the tissues, no complete sac exists, and the condition is usually called diffuse traumatic aneurysm. In diffuse traumatic aneurysm a large oblong, fluctuating swelling is found. If the rent is large there may be bruit and pulsation. There is no pulsation in the artery below the aneurysm, and the limb is cold and swollen. The skin is at first of a natural color, but later becomes thin and purple.

Treatment.—If an aneurysm ruptures, cut down upon the aneurysm, incise the sac longitudinally, and perform Matas's operation. Some surgeons cut down to the aneurysm, tie on each side of the tear, open the sac, and pack it (the operation of Antyllus), but Matas's operation is the preferable procedure. If an artery is ruptured, empty the limb of blood, apply an Esmarch band above, and expose the seat of rupture by incision. If possible, suture the opening; if this is not possible, tie the vessel on each side of the rupture and

excise the intervening portion. If the main vein is also ruptured, suture the vessels if possible. If suture is impossible, apply ligatures. The attempt will probably not succeed in saving the extremity, and in most cases amputation will be required.

Arteriovenous aneurysm was first described by Wm. Hunter in 1757. By this term we mean an unnatural passageway between a vein and an artery, through which passage blood circulates. There are two forms: (*a*) *aneurysmal varix*, or *Pott's aneurysm*, a vein and an artery directly communicating (Fig.

Fig. 198.—Dilatation of veins in arteriovenous aneurysm of the femoral vessels.

199); and (*b*) *varicose aneurysm*, a vein and an artery communicating through an intervening sac. These conditions arise usually from punctured wounds, the instrument passing through one vessel and into the other, blood flowing into the vein, the subsequent inflammation gluing the two vessels together, and the aperture failing to close (aneurysmal varix, Fig. 199). After the infliction of the wound the two vessels may separate; the blood continuing to flow from artery into vein, and the blood-pressure, by consolidating tissue, forming

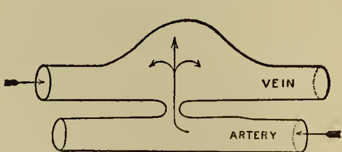

Fig. 199.—Plan of aneurysmal varix.

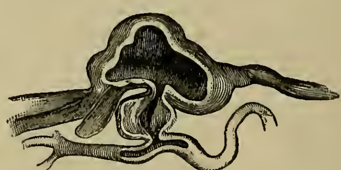

Fig. 200.—Varicose aneurysm (Spence).

a sac of junction (varicose aneurysm, Fig. 200). Wounds produced by a small bullet may result in arteriovenous aneurysm (Matas, in "Transactions of Amer. Surg. Assoc.," vol. xix). Aneurysmal varix is a less grave disorder than varicose aneurysm. Arteriovenous aneurysm used to be most frequent at the bend of the elbow, the vessels being injured during venesection. The condition may occur in the neck, the axilla, the extremities, or the groin. I assisted Professor Keen in an operation upon an aneurysmal varix of the common carotid and internal jugular vein, and assisted Professor Hearn in operating on a varicose aneurysm involving the external iliac vessels. Sir Frederick Treves operated on a case involving the internal maxillary vessels. Very

rarely an arteriovenous aneurysm forms spontaneously. Spontaneous arteriovenous aneurysm is most frequent between the aorta and vena cava. There is no tendency to spontaneous cure in arteriovenous aneurysm. Edema is the rule, muscular atrophy is common, and ulceration or even gangrene of a limb may occur. Matas has collected 17 cases of arteriovenous aneurysm of the subclavian vessels ("Transactions of Amer. Surg. Assoc.," vol. xix). In this list is the celebrated case of his own, a traumatic (gunshot) arteriovenous aneurysm, in which cure followed operation; in the operation it was necessary to obliterate the artery by ligatures, but the venous orifice was closed by sutures without obliterating the lumen of the vein. In the analysis of Matas's paper 15 cases are used, 2 having been noted too late for incorporation; 9 of the cases resulted from "stab or penetrating cut wounds," 6 from bullets—in 5 of the cases the brachial plexus was injured. In 8 out of the 11 unoperated cases the time after the injury when symptoms of arteriovenous aneurysm was noted is stated; in 1 signs were definite within four hours, in 3 they were noted on the second day, in 3 on the third day, in 1 on the sixth day, in 1 on the eighth day, in 1 on the ninth day, and in 1 a few days later. In 3 of the 15 cases secondary hemorrhage followed the injury. Eleven of the 15 cases were treated expectantly; 1 died from secondary hemorrhage and sepsis three weeks after the injury and 10 "survived the immediate effects of the injury, their wounds healing after the cessation of the primary hemorrhage."

In 4 of the 15 cases operation was performed. In 3 the operation was done soon after the injury because of violent secondary hemorrhage. In 1 (Matas's own case) operation was done deliberately to prevent complications. Three of these cases recovered (including Matas's); 1 died of renewed secondary hemorrhage on the twenty-fourth day after operation. Matas points out the fact that in stab-wounds of the subclavian vessels the largest proportion of cases die of primary hemorrhage before assistance is obtained, but in a considerable number of cases temporary hemostasis occurs, which is followed by secondary hemorrhages or arteriovenous aneurysm.

Symptoms of Aneurysmal Varix.—The arterial blood is cast forcibly into the vein, and as a consequence the vein becomes enlarged, tortuous, and thickened. The scar of a wound is almost invariably apparent. At the seat of vascular trouble the most marked dilatation exists and it is of bluish color. The swelling pulsates markedly, imparts a sensation to the finger like that felt when the hand is laid upon the back of a purring cat. This thrill or vibration is very characteristic. A sound of a hissing or buzzing nature can be easily heard. The swelling at once disappears on pressure being made upon it or on the artery between it and the heart. It is diminished in size by raising the limb, is increased in size by a dependent position of the limb and by compressing the vein between the heart and the tumor. The adjacent veins are dilated and often the dilatation is manifested over a wide area above and below (Fig. 198), and the thrill and bruit are transmitted a considerable distance. If an extremity is involved it is usually edematous. The parts, as a rule, are painful. The condition progresses, but very slowly, and sometimes years may elapse without any notable aggravation.

Symptoms of Varicose Aneurysm.—In this condition we find many of the symptoms of aneurysmal varix, but in varicose aneurysm pressure over the artery of supply between the heart and the lesion does not cause the entire disappearance of the swelling; the veins collapse, it is true, but a distinct sac remains, which may be emptied by direct pressure.

Treatment.—The prognosis after operation is better than in ordinary aneurysm, but nevertheless it is wisest to refrain from operating on aneurysmal varix so long as the condition is not progressing obviously, is borne without inconvenience, and is not leading to complications. Varicose aneu-

rysm should be operated upon. If we refrain from operating upon aneurysmal varix the patient should wear a support; but if the part becomes painful or if there seems to be danger of rupture of the vein, operation should be performed. Until recently, when operation was indicated, surgeons advised that each vessel should be tied above and below the opening and a portion of each vessel should be excised, the excised area including the opening. In varicose aneurysm it was the custom to tie each vessel above and below the sac, and excise the sac with a portion of vessel. At the present time surgeons prefer the Matas operation for both varicose aneurysm and aneurysmal varix. In some cases of varicose aneurysm, however, the sac is extirpated and the openings in the vessels closed by suture, and in some cases of aneurysmal varix the adherent vessels are separated and the opening in each is sutured. In a case of aneurysmal varix of the popliteal due to a gunshot-wound, I opened the vein and closed the fistula in the arterial wall. In accomplishing this I gathered so much of the vein wall in the sutures as to render it impossible to suture the vein and retain its lumen. I cut the vein across, a little above and a little below the sutured fistula, used the trapdoor-like piece of vein to reinforce the arterial suture line, and did end-to-end anastomosis of the vein ends. The result was a complete success ("Annals of Surgery," April, 1912).

I attempted a similar operation on a varicose aneurysm of the brachial in the middle of the arm. I found that the superior profunda also ran into the sac, and that a saccular aneurysm had formed on the brachial a little below the varicose aneurysm. I was obliged to ligate the profunda and tie the artery and vein above and below before extirpating the aneurysm. I feared gangrene, but, fortunately, the patient escaped it.

Cirsoid aneurysm, or **aneurysm by anastomosis,** consists in great dilatation with pouching and lengthening of one or several arteries. The disease progresses and after a time involves the veins and capillaries. The walls of the arteries become thin and the vessels tend to rupture. Cirsoid aneurysm is most commonly met with upon the forehead and scalp of young people, where it sometimes takes origin from a nevus. It is sometimes seen upon the back or upper extremity. The cause is unknown. Usually there is no assignable cause, but occasionally the condition follows an injury. Pregnancy causes a cirsoid aneurysm to grow rapidly, and so usually does the onset of puberty. Occasionally some of the enlarged vessels fuse and form a great cavity. If rupture occurs, desperate hemorrhage inevitably ensues.

Symptoms.—There is a pulsating mass, irregular in outline, composed of dilated, elongated, and tortuous vessels that empty into one another. The mass is soft, can be much reduced by direct pressure, and is diminished by compression of the main artery of supply. A thrill and a bruit exist.

Treatment.—In treating a cirsoid aneurysm the ligation of the larger arteries of supply is a wretched failure. Subcutaneous ligation at many points of the diseased area has effected cure in some cases, but it has failed in more. Direct pressure is also entirely useless. Ligation in mass has been successful. Destruction by caustic has its advocates. Electropuncture with circular compression of the arteries of supply has once or twice effected a cure. Injection of astringents has been recommended. Verneuil ligated the afferent arteries, incised the tissues around the tumor, and sank a constricting ligature into the cut. The proper method of treatment is excision after exposure and ligation of every accessible tributary of supply. In a very extensive mass extirpation is impossible; hence one of the other methods suggested must be employed. A very considerable mass can be excised, and the resulting wound should be covered with Thiersch skin-grafts.

Wounds of arteries are divided into contused and incised, lacerated, punctured and gunshot-wounds, and vascular ruptures.

Contused and Incised Wounds.—A contusion may destroy vitality and be followed by sloughing and hemorrhage. A contusion may rupture a blood-vessel, and is especially apt to do so if the vessel is diseased. Blood is at once effused at the seat of rupture. If an artery is ruptured, there may or may not be a bruit and pulsation over the seat of rupture, pulse is absent below, and the leg below the injury swells and becomes cold. If a large vein ruptures, a blood tumor forms, which does not pulsate and has no bruit, and the limb below becomes intensely edematous. Gangrene is apt to follow the rupture of a main blood-vessel of an extremity. A contusion may rupture the internal and middle coats of an artery, the external coat remaining intact. When this happens the internal coat curls up and the middle coat contracts and retracts, the blood-stream is arrested, and a large clot forms within the artery. If the clot blocks up many collaterals, gangrene may follow, and, as has been pointed out, the gangrene will not be preceded by swelling at the seat of injury, which always occurs if a vessel is ruptured. A contused wound may do little damage, may produce gangrene from thrombosis, or may cause secondary hemorrhage. In an incised wound of an artery there is profuse hemorrhage. The artery after a time is apt to contract and retract, bleeding being thus arrested. A transverse wound causes profuse bleeding, but there is a better chance for natural arrest than in an oblique or in a longitudinal wound. The clot which forms within a cut artery is known as the

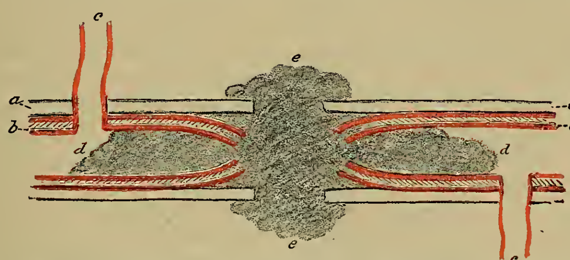

Fig. 201.—Clots formed after division of an artery: 1, 2, 3, Outer, middle, and inner coats; *c*, *c*, branches; *d*, *d*, internal clot; *e*, *e*, external clot.

"internal clot." It used to be taught that the internal clot always reaches as high as the first collateral branch, and subsequently is replaced by fibrous tissue, which permanently obliterates the vessel, and converts it into a shrunken fibrous cord. As a matter of fact, when the parts are aseptic after a ligation the clot is rarely bulky and is often very scanty, repair being quickly effected by proliferation of endothelial cells. Between the vessel and its sheath, over the end of the vessel, and in the surrounding perivascular tissues is the "external clot" (Fig. 201).

A **lacerated wound** of an artery causes little primary hemorrhage. The internal coat curls up, the circular muscular fibers of the media contract upon it, the longitudinal fibers retract and draw the vessel within the sheath, and the external coat becomes a cap over the orifice of the vessel. All of these conditions favor clotting. The vessel wall is so damaged that secondary hemorrhage is usual.

Punctured Wounds.—In punctured wounds primary hemorrhage is slight unless a large vessel is punctured. Secondary hemorrhage is not common. Traumatic aneurysm and arteriovenous aneurysm are not unusual results.

Gunshot-wounds of arteries by pistol balls and the balls of large-caliber rifles are apt to be contusions which may eventuate in sloughing and secondary hemorrhage or thrombosis and gangrene. A shell-fragment makes a lacerated wound. A military rifle-bullet usually makes a clean-cut division of

an artery, but may contuse it. Secondary hemorrhage after gunshot-wounds is most likely to occur during the third week after the injury. Partial rupture of an artery may cause sloughing and secondary hemorrhage, thrombosis and gangrene, or aneurysm. A complete rupture constitutes a lacerated wound, and is a condition accompanied by diffuse hemorrhage into the tissues.

Wounds of veins are classified as are wounds of arteries. The symptom of any vascular wound is hemorrhage.

Hemorrhage, or Loss of Blood

Hemorrhage may arise from wounds of arteries, veins, or capillaries, or from wounds of the three combined. In arterial hemorrhage the blood is scarlet and appears in jets from the proximal end of the vessel, which jets are synchronous with the pulse-beats; the stream, however, never intermits. The stream from the distal end is darker and is not pulsatile. Venous hemorrhage is denoted by the dark hue of the blood and by the continuous stream. In capillary hemorrhage red blood wells up like water from a squeezed sponge, and the color is between the bright red of arterial blood and the dark color of venous blood.

In *subcutaneous hemorrhage* from rupture of a large blood-vessel there are great swelling, cutaneous discoloration, and systemic signs of hemorrhage. If a main artery ruptures in an extremity, there is no pulse below the rupture, and the limb becomes cold and swollen. At the seat of rupture a large fluctuating swelling forms, and sometimes there are bruit and pulsation. If a vein ruptures in an extremity, a large, soft, non-pulsatile swelling arises, there is no bruit, and intense edema occurs below the seat of rupture. Profuse hemorrhage induces constitutional symptoms, and death may occur in a few seconds. Loss of half of the blood (from 4 to 6 pounds) will usually cause death, though women can stand the loss of a greater relative proportion of blood than men. Young children, old people, individuals exhausted by disease, drunkards, sufferers from Bright's disease, diabetes, and sepsis stand loss of blood very badly. An individual with *obstructive jaundice* is apt to suffer from persistent oozing of blood after operation, an oozing which is particularly persistent and dangerous in obstruction of the bile-ducts due to malignant disease. It not unusually causes death. After profuse bleeding has gone on for a time, syncope usually occurs. Syncope is Nature's effort to arrest hemorrhage, for during this state the feeble circulation and the increased coagulability of blood give time for the formation of an external clot. When reaction occurs the clot may hold and be reinforced by an internal clot, or it may be washed away with a renewal of bleeding and syncope. These episodes may be repeated until death supervenes. Nausea exists and there may be regurgitation from the stomach. Vertigo is present. The room may seem to be turning around. There is dimness of vision or everything looks black; black specks float before the eyes (muscæ volitantes), or the patient sees flashes of light or colors. There is a roaring sound in the ears (tinnitus aurium). The patient yawns, is restless, tosses to and fro, casts off the bedclothes, and great thirst is complained of. The mind may be clear, but delirium is not unusual, and convulsions often occur. After a very severe hemorrhage an individual is intensely pale and his skin has a greenish tinge; his lips are blanched, the tongue is cold and white; the brow is covered with cold moisture, the breath is cold; the eyes are fixed in a glassy stare and the pupils are widely dilated, and react slowly to light; the respirations are shallow and sighing; the skin is covered with a cold sweat; the hands are clammy and look like wax; the legs and arms are extremely cold, and the body temperature is below normal. The pulse is very frequent, soft, small, compressible, flut-

tering, or often cannot be detected; the heart is very weak and fluttering, and the arterial tension is almost abolished. There is muscular tremor; the patient tosses about, and asks often and in a feeble voice for water. The suffering from thirst is terrible and no amount of water gives relief. There is often dreadful dyspnea; at each inspiration the nostrils open widely and the accessory muscles of respiration are all in action. A man who is bleeding to death grasps at his chest, makes efforts to rise, and then falls back in a dead faint. Usually reaction occurs after a faint, though the patient is obviously weaker than before; again a faint may happen, and so there is fainting spell after fainting spell until death ensues. Convulsions frequently precede death. In hemorrhage the hemoglobin is greatly diminished in amount. In an *intra-abdominal hemorrhage* the above symptoms are noted, and, except in splenic hemorrhage, blood gathers in both loins, and dulness on percussion exists which gradually rises and shifts as the patient's position is shifted. The blood also gathers in the rectovesical pouch in the male, and in the recto-uterine pouch in the female, and may be detected by digital examination. If the spleen is wounded the blood usually clots quickly, and if it does, an area of dulness, which does not shift and which progressively increases, is noted in the splenic region.

Treatment.—When serious hemorrhage exists the surgeon should, when possible, arrest bleeding temporarily, and should then bring about reaction and arrest bleeding permanently. Temporary arrest is not possible in an intra-abdominal hemorrhage. In any case of severe hemorrhage lower the head, and have compression made upon the femorals and subclavians, so as to divert more blood to the brain, or bandage the extremities (autotransfusion). Apply artificial heat. The value of adrenalin in restoring or maintaining arterial tension has been demonstrated by Crile. We should give the patient by hypodermoclysis 1 pint of hot normal salt solution containing 1 dr. of the 1:1000 solution of adrenalin chlorid. The fluid is allowed to run in the subcutaneous tissue beneath the breast. The infusion of 1 pint or more of hot salt solution into a vein is a very valuable remedy; it gives the heart something to contract upon and thus maintains cardiac action. If the depression is very severe, inject ether hypodermatically, then brandy, and then atropin. Strychnin may be given hypodermatically in doses of $\frac{1}{20}$ gr., but atropin is of more service. Digitalin is advised by some, but it is not sufficiently rapid in action. Give enemata of hot coffee and brandy. Apply mustard over the heart and spine. Lay a hot-water bag over the heart.

In hemorrhage from a vessel of an extremity temporarily arrest bleeding while bringing about reaction. Do so by digital pressure in the wound, or, if the bleeding is arterial, by the application of an Esmarch band. In some cases forced flexion is used. As soon as reaction is established, permanently arrest bleeding by the ligature. In intra-abdominal or concealed hemorrhage it is not possible to temporarily arrest it and wait for reaction, but the abdomen must be opened and the work proceeded with in spite of the patient's condition. Every moment we wait he is growing worse.

A severe hemorrhage is apt to be followed by fever, due to the absorption of fibrin ferment from extravasated blood and its action upon a profoundly debilitated system. After a severe hemorrhage leukocytes are increased, not only relatively, but absolutely. Red corpuscles are diminished both relatively and absolutely. Hemoglobin diminishes; many of the corpuscles become irregular and microcytes are noticed.

In treating a patient who has thoroughly reacted after a severe hemorrhage, apply cold to the head. Fluids and ice are grateful. Frequently sponge the skin with alcohol and water. Milk-punch, koumiss, and beef-peptonoids are given at frequent intervals.

Hemostatic agents comprise: (1) the ligature and suture; (2) torsion; (3) acupressure; (4) elevation; (5) compression; (6) styptics; (7) the actual cautery; (8) forced flexion of a limb.

Fig. 202.—Halsted's straight artery forceps.

The *ligature* was known to the ancients, but was rediscovered by Ambroise Paré. The ligature may be made of silk, floss-silk, or catgut. Whatever

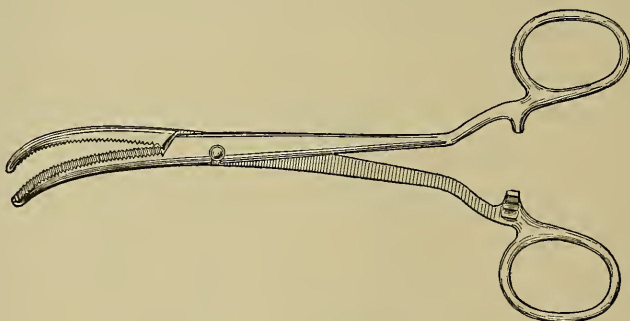

Fig. 203.—Curved hemostatic forceps.

material is used must, of course, be rendered aseptic. A ligature should be about 10 inches long. The vessel to be tied must be drawn out with for-

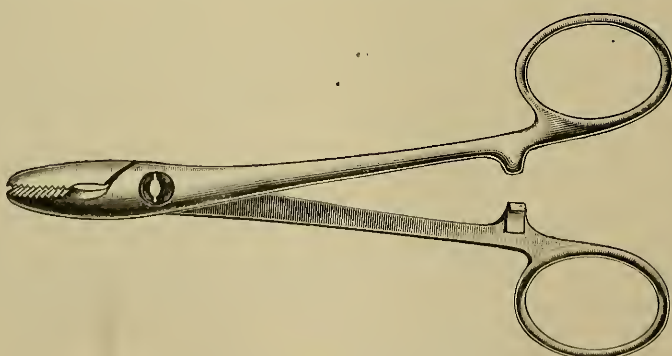

Fig. 204.—Straight hemostatic forceps.

ceps and separated for a short distance from its sheath, but must not be separated to any considerable extent; to do so may lead to necrosis of the

vessel and secondary hemorrhage. The hemostatic forceps (Figs. 202, 203, 204) is in most cases a better instrument than the tenaculum (Fig. 205). The tenaculum makes a hole in the vessel, and sometimes a slit-like tear. A portion of this opening may remain back of the tied ligature, the vessel may retract a little, or the ligature may slip slightly, and bleeding may occur. When the artery lies in dense tissues or is retracted deeply in muscle or fascia,

Fig. 205.—Tenaculum.

the tenaculum, when carefully used, is the better instrument. The ligature is tied in a reef-knot (Fig. 206), not in a granny-knot (Fig. 207) and not in a surgeon's knot (Fig. 208). It is often the purpose of the surgeon to divide the internal and middle coats of the vessel, and if such is his desire the first knot is firmly tied. The second knot must not be tied too tightly or it will cut the ligature. The ligature must not be jerked as it is being tied. If a third knot

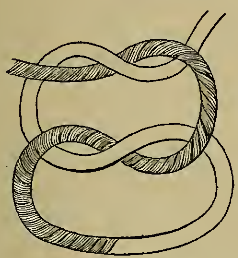

Fig. 206.—Method of tying square or reef-knot.

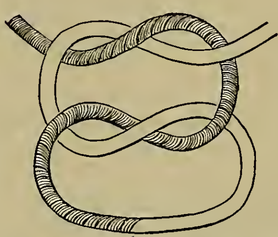

Fig. 207.—Method of tying granny-knot.

overlies the first two, the ligature can be cut off close to the knot, otherwise it is cut off so that short ends are left. Both ends of a divided vessel should be ligated. If a vessel is atheromatous, it is not desirable to divide the internal and middle coats. In this case a ligature should be applied firmly rather than tightly, and another ligature should be put on above it, or ligation can be effected by the stay knot. If an artery is incompletely divided, a ligature should be applied on each side of the wound and the vessel divided between the ligatures.

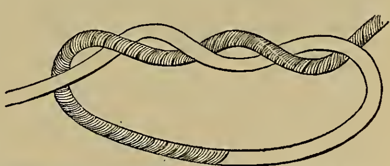

Fig. 208.—Method of tying surgeon's knot.

When the parts about an artery are so thickened that the vessel cannot be drawn out, arm a curved Hagedorn needle (Fig. 209) with catgut and pass the latter around the vessel in such a manner that the catgut will include the vessel with some of the surrounding tissue. Then tie the ligature (Fig. 211). This method is known as the application of a *suture-ligature*, and is pursued in necrosis, atheroma, scar-tissue, sloughing, etc. Never include a nerve of any size in the ligature. If this mode of ligation fails, we may try acupressure.

Doyen, when about to tie a thick pedicle, crushes it by means of a very powerful instrument and then ties a ligature about the crushed and attenuated area. The vessels are closed by laceration wide of the ligature and the ligature does not tend to slip. Some trust such a stump without a ligature, but most surgeons prefer to ligate. This instrument is known as the vasotribe or angiotribe and is used particularly in hysterectomy. Figure 212 shows a vasotribe.

Veins are ligated as are arteries. If a large vein is torn, we wish, if possible, to control hemorrhage without obliterating the lumen of the vein by ligation.

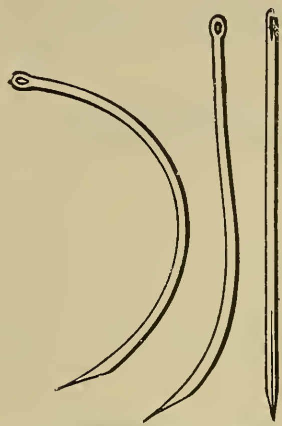

Fig. 209.—Hagedorn's needles.

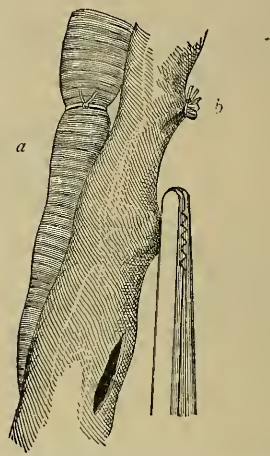

Fig. 210.—Method of controlling hemorrhage by ligature (after Esmarch): *a*, Artery ligated; *b*, lateral ligature of vein.

If the wound is not greater in length than the measure of the diameter of the lumen, a lateral ligature may be used. It is practically always used in small transverse wounds. In order to apply a lateral ligature the two lips of the vein wound are seized by forceps and drawn out into a tit (Figs. 210 and 227). A ligature is placed around the base of the cone and tied. The pull in the cone is relaxed while the first knot is being tied in order that the ligature may constrict tightly. In a large vessel the thread should be passed by a needle through the outer coats of the vein before it is used to encircle the cone. This plan prevents slipping. In some cases when a lateral ligature or suture cannot be applied, forcipressure will succeed. One or more clamp forceps are applied and are left in place for several days.

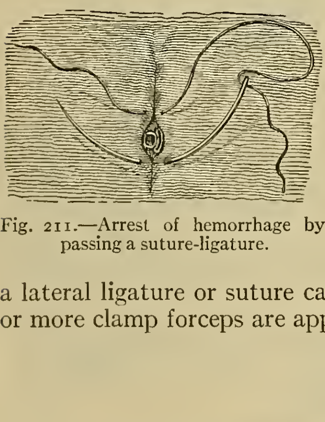

Fig. 211.—Arrest of hemorrhage by passing a suture-ligature.

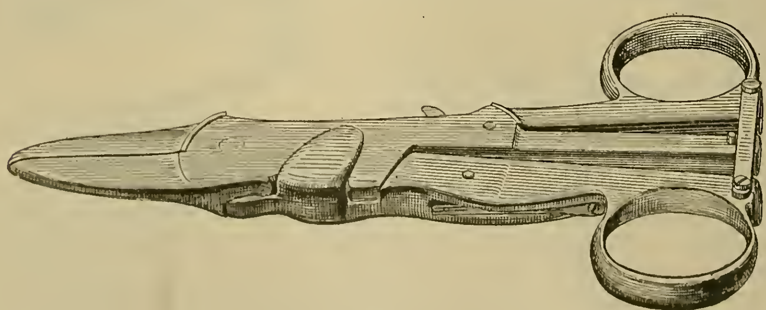

Fig. 212.—Vasotribe of Doyen.

Phleborrhaphy is suture of a vein, with preservation of the lumen of the vessel. It is used when complete ligation is undesirable (as in a large vein), and when lateral ligation without obliteration of lumen is impossible. It is

commonly employed for longitudinal wounds and for wounds in any direction when the length of the wound is greater than the diameter of the vessel. Fine catgut or silk may be used. An intestinal needle threaded with silk is entirely satisfactory. The thread is passed through the external coat and part of the middle coat on each side of the wound. Interrupted sutures are employed and thus the two lips of the wound are approximated. A vein completely divided across can be united by end-to-end suturing. Figure 213 shows the operation of phleborrhaphy.

By suturing I successfully closed a tear in the innominate vein inflicted during the removal of a retrosternal goiter, and also a considerable longitudinal tear in the internal jugular vein inflicted during the removal of lymph-nodes.

Murphy and Damar Harrison each succeeded in suturing a wound of the inferior vena cava. Bier successfully applied sutures in 2 cases of wound of the inferior vena cava.

Israel points out how difficult it is to suture in the depths of a cavity full of blood. This complication always exists in wounds of the inferior cava, and in them it may be necessary to use forcipressure. He did this in 2 cases.

In a case of Körte's the cava was wounded during nephrectomy. Forcipressure and lateral sutures were found impracticable. The cava was tied. Thrombophlebitis arose in both legs, but the patient eventually recovered ("Zentralbl. für Chir.," August 8, 1911).

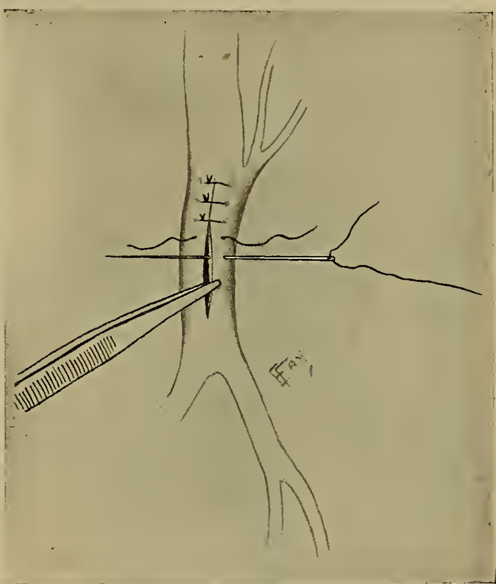

Fig. 213.—Phleborrhaphy: Forceps are seen everting lip of wound for passage of needle and interrupted sutures (Bickham).

Arteriorrhaphy.—The studies of Carrel, Murphy, Matas, Abbe, and others have shown that wounded arteries can be repaired by suturing; that a portion of an artery can be removed and repair be obtained by end-to-end suturing, implantation, or lateral anastomosis; that an artery can be obliterated by suturing the intima from within; that an artery can be anastomosed into a vein, and that after resection of a portion of an artery vascular integrity may be restored by suturing into the gap a portion of a vein or artery recently resected.

We now suture certain wounds in large vessels which until very recently would have caused us to completely ligate the artery. In extirpating malignant tumors it is sometimes necessary to remove large arteries or veins. This may cause grave danger of gangrene, and we now may attempt to prevent gangrene by the restoration of vascular continuity.

The wonderful experiments of Carrel on the transplantation of organs and the brilliant studies and operations of Matas and Murphy have been the great influences that have brought vessel suture into the field of practical surgery.

There is yet much to learn. What we do know is really little, but we are probably at the threshold of great events.

We know that we can close by suture a lateral wound or a transverse wound

of less than half the circumference of the vessel; that we can perform end-to-end suturing; that we can insert a piece of resected vein to re-establish vascular continuity; and that after such an operation the blood-current will be re-established. We do not know how long the circulation will continue after re-establishment. A sutured artery will certainly carry blood for a time, but in most cases, at least, only for a time, the ultimate fate of the vessel being obliteration by endothelial proliferation. If the vessel operated upon is diseased, obliteration by clot is practically certain to ensue. But even temporary re-establishment of circulation is of the greatest value. Even though the lumen is finally closed, the closure is gradual. While the vessel is closing the collaterals are dilating. By the time one source of supply for the tissues is cut off, another has come into being. Thus gangrene is prevented. There appears to be a certain amount of danger of the development of aneurysm at the seat of suturing. In a longitudinal wound of an artery or in a transverse wound of not over half the circumference of the vessel, the wound may be closed by interrupted sutures, passing the threads through the two outer coats and bringing the wound edges together without inversion. Floss silk is used, and it should be as large as the eye of a curved conjunctival needle will carry in order to lessen the danger of leaking of blood through the stitch holes. The sheath is sutured over the stitch line ("Bickham's Operative Surgery").

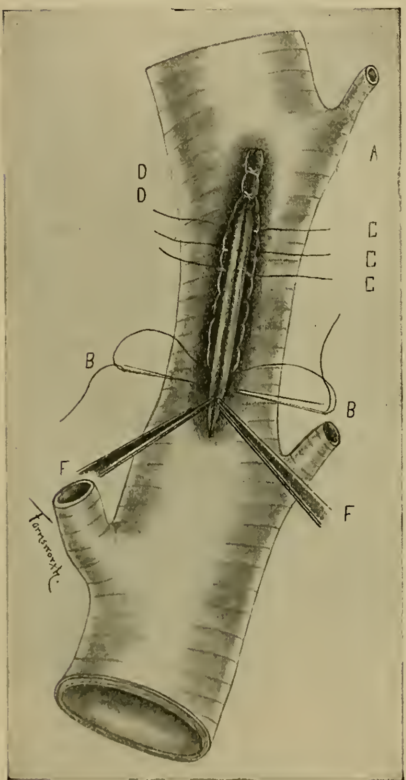

Fig. 214.—Repair of longitudinal wound of artery by combination cobbler's stitch through all coats, and interrupted sutures through outer coats, as suggested by the author: A, Beginning of cobbler's stitch through all coats; B, B, needles in act of passing through same opening in opposite directions, in characteristic cobbler fashion; C, C, C, three interrupted sutures through outer coats, ready to be tied; D, D, two interrupted sutures tied, passing through outer coats (Bickham).

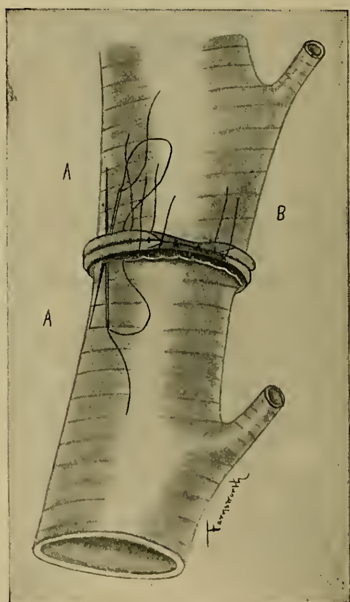

Fig. 215.—Repair of complete transverse division of artery by combination cobbler's stitch through all coats, followed by interrupted sutures through outer coats, as suggested by the author: A, A, Needles passing in opposite directions through all coats, in act of placing cobbler's stitch; B, superficial tier of interrupted stitches through outer coats, showing three untied and two tied (Bickham).

A better plan in such wounds is that of Bickham, viz., a cobbler's stitch through all the coats to bring the intima of each lip together and interrupted sutures through the outer coats (Fig. 215). An oblique wound may be repaired

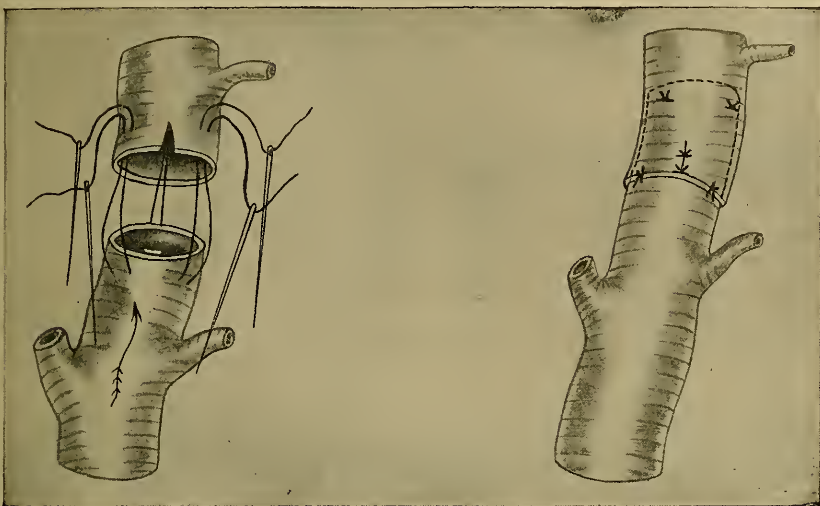

Fig. 216.—Artenorrhaphy in complete circular division of an artery (Murphy's method): A, Intussusception, with sutures passing through outer and middle coats; B, intussuscipiens (split to aid invagination), with sutures passing through all coats; C, showing all sutures tied (Bickham).

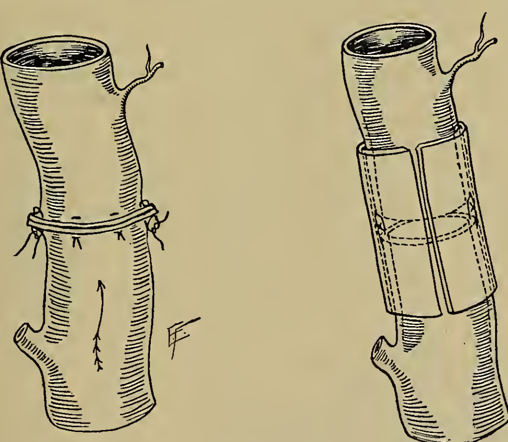
in the same manner. If a vessel is divided transversely through more than half of its circumference Murphy believes that the division should be made complete as a preliminary to suturing.



A B

Fig. 217.—Circular arteriorrhaphy in complete division of an artery: A, Method of Salomoni and Tomaselli—interrupted sutures through all coats; B, method of Gluck—interrupted sutures through outer coats, protected by cylinder of decalcified bone, ivory, or rubber (Bickham).

Complete circular division may be treated by Murphy's plan, viz., invagination of one end of the cut vessel into the other end split to receive it (Figs. 215 and 216), by Bickham's plan of a cobbler's stitch followed by interrupted sutures, or by one of the plans shown in Fig. 217.

The author successfully sutured a small wound in the axillary artery. Stewart removed a clot from the femoral and sutured the vessel. Murphy removed a clot from the external iliac artery and sutured the vessel. Braun ("Zentralblatt für Chirurgie," August 29, 1908) resected a portion of the aorta along with a tumor and performed circular suture. Depage successfully sutured the common carotid artery. Pringle sutured a wound of the external iliac artery. The wound was $\frac{1}{4}$ inch in length. Dejemil Pasha sutured a lacerated wound of the axillary artery. Torance sutured a wounded brachial artery. Martin sutured a lacerated wound of the femoral artery ("Annals of Surgery," Oct., 1905). Henderson sutured a transverse wound extending half across the femoral artery ("American Medicine," Jan. 14, 1905). A. E. Halstead cut two-thirds through the circumference of the axillary artery and sutured the wound directly instead of making the wound first of all a complete division, as advised by Murphy. Two months later the radial pulse was present.

Faykiss made an end-to-end suture of a divided carotid artery ("Centralb. für Chirurgie," 1908, xxxv).

Lexer ("Archiv. für klinische Chirurgie," 1907, No. 2) resected the sac of a traumatic arteriovenous aneurysm of the popliteal vessels, removing at the same time 5 cm. of artery and as much vein.

He performed end-to-end anastomosis of each vessel over a thin magnesium tube (*Payr's tube*). The pulse was restored. Nine months after operation the pulse was present below the seat of operation, but was weaker than it had been some months before. In this paper Lexer speaks of a case of diffuse aneurysm of the axillary artery. The surgeon resected the sac and a portion of the artery. The gap of over 3 inches was filled by a piece of internal saphenous vein sutured in place (*autoplasty*). The circulation was re-established in the limb, but the patient died of complications. Postmortem demonstrated that the transplanted vein was patent and the sutures firm. There was a clot above the piece of vein due to the action of the clamp upon a sclerotic artery. Gangrene began on the fourth day after operation.

Manteuffel successfully sutured a wound of the femoral artery. This was the first case to be recorded (Bloodgood, in "Progressive Medicine," Dec. 1, 1908), although Hallowell, in 1759, successfully closed a wound in the brachial artery by means of a harelip pin and a ligature (Mumford). Bloodgood in the same article notes that Körte, in 1904, performed lateral suture of the popliteal artery and vein, and that Garré closed a wound in the popliteal artery by suture, and in the vein of the same patient by lateral ligature.

Murphy was the first surgeon to succeed in resecting a portion of a large artery (the femoral) and doing end-to-end suturing ("Med. Record," Jan. 16, 1897).

Lund ("Annals of Surgery," March, 1909) sutured a double stab-wound of the femoral artery and vein, and six months later there was a pulse in the dorsalis pedis. Routier tore the aorta in removing a hypernephroma of the kidney. He sutured the wound with catgut. The patient died on the fourteenth day, but not from hemorrhage ("Gaz. des Hôpitaux," 1911). Mantelli closed a gap in the femoral artery by a segment of a vein (autoplastic graft). Buchanan performed circular resection and suture of the axillary artery, the vessel having been lacerated by the bone fragments after fracture-dislocation of the anatomical neck of the humerus. Buchanan has collected 29 instances of end-to-end suture of divided arteries ("Surgery, Gynecology, and Obstetrics," Dec., 1912).

Among other surgeons reporting successful cases of arterial suture are Heidenhain, Orlow, Pean, Baum, Sherman, Krause, Payr, Kummell, Seggel, Lindner, and Brougham.

Torsion was practised by the ancients, but was reintroduced in modern times, particularly by Amussat, Velpeau, Syme, and Bryant, of London.

By means of torsion the internal and middle coats are ruptured and the external coat is twisted. The middle coat retracts and contracts, and the inner coat inverts into the lumen of the artery. It is a safe procedure, and is practised upon vessels as large as the femoral by many surgeons of high standing. Before the days of asepsis torsion possessed the signal merit of not introducing possible infection in ligatures. At the present time it offers no particular advantage. It is no quicker than the ligature, and damages the vessel so much that necrosis may occur. It cannot be used if the vessels are diseased. In what is known as free torsion the vessel is grasped, drawn out, and twisted until the free end of the vessel is twisted off. Limited torsion is more often used. The vessel is drawn out of its sheath by a pair of forceps held horizontally, and is grasped a little distance above its extremity by another pair of forceps held vertically (Fig. 218). The first instrument is used to twist the artery six to eight times.

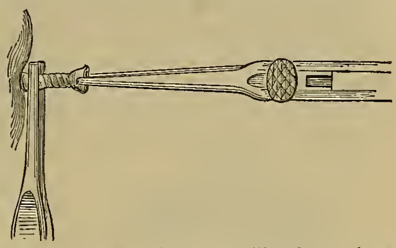


Fig. 218.—Method of controlling hemorrhage by torsion.

Acupressure is pressure applied by means of a long pin. The method of hemostasis by acupressure was devised by Sir James Y. Simpson. A pin is simply passed under a vessel (transfixion), leaving a little tissue on each side between the pin and vessel. A pin can be passed under a vessel, and a wire be thrown over the pin and twisted (circumclusion). The pin can be inserted upon one side, passed through $\frac{1}{2}$ inch of tissues up to the vessel, be given a quarter twist, and be driven into the tissues across the artery (torsoclusion). Some tissue may be picked up on the pin, folded over the vessel, and pinned to the other side (retroclusion). Acupressure is occasionally used to arrest hemorrhage if vessels are inflamed or atheromatous, in sloughing wounds, in scar-tissue, and when a ligature will not hold firmly.

Elevation is used as a temporary expedient or in association with some other method. It is of use in a wound of a bursa, in bleeding from a ruptured varicose vein, and its use is frequently associated with compression.

Compression is either direct or indirect—that is, in the wound or upon its artery of supply. In the removal of the upper jaw arrest bleeding by plugging. In injury of a cerebral sinus plug with gauze. Compression and hot water (115°–120° F.) will stop capillary bleeding. A graduated compress was formerly recommended in hemorrhage from the palmar arch (Fig. 220). A compress will arrest bleeding from superficial veins. The knotted bandage of the scalp will arrest bleeding from the temporal artery. Long-continued pressure causes pain and inflammation.

Fig. 219.—Tamponade of intercostal artery (after Von Langenbeck).

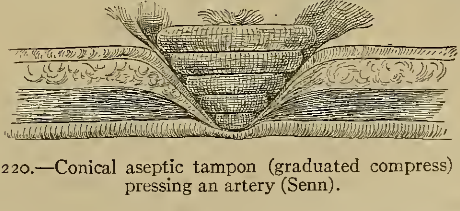

Fig. 220.—Conical aseptic tampon (graduated compress) compressing an artery (Senn).

Indirect compression is used to prevent hemorrhage or to temporarily

arrest it. It may be effected by encircling a limb above a bleeding point with an Esmarch band or by applying a tourniquet or an improvised tourniquet (Fig. 221). It may also be effected by a clamp. Crile has devised a clamp to effect temporary closure of the carotid artery. In operations about the head one or both carotids may be closed for a considerable time and bleeding may thus be largely prevented. In 10 cases Crile temporarily closed both carotids. A hypodermatic injection of atropin is given to prevent inhibition, the vessels are exposed, and the clamps are applied with just sufficient firmness to approximate the vessel walls. No clot will form if the walls are not compressed. The patient is in the Trendelenburg position. If it is found that respiratory difficulty occurs, one clamp must be loosened. After the completion of the operation the patient must be brought to the horizontal before the clamps are removed (Crile, in "Annals of Surgery," April, 1902).

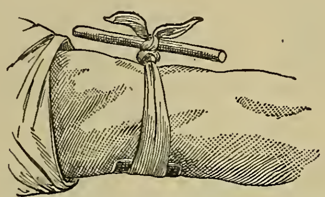

Fig. 221.—Impromptu tourniquet for compressing an artery with a handkerchief and a stick.

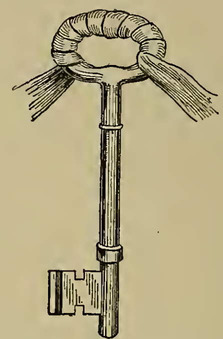

Fig. 222.—Handle of door-key, padded.

Digital compression is a form of indirect compression. It can be maintained for only a few minutes by one person, but a relay of assistants can carry it out for a considerable time. In compressing the subclavian artery wrap a key as shown in Fig. 222, and compress the artery against the outer surface of the first rib. The shoulder must be depressed and pressure applied in the angle between the posterior border of the sternocleidomastoid and the upper border of the clavicle. The direction of the pressure should be downward, backward, and inward.

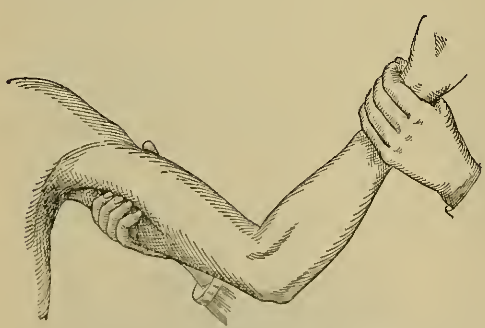

Fig. 223.—Digital compression of the brachial artery.

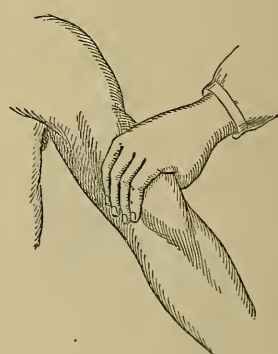

Fig. 224.—Digital compression of the brachial artery.

The brachial artery can be compressed against the humerus. In the upper part of the course of the artery the pressure should be from within outward (Fig. 223), in the lower part from before backward (Fig. 224). The abdomi-

nal aorta can be compressed by Macewen's method (*q. v.*). The common iliac can be compressed through the rectum by means of a round piece of wood known as Davy's lever. The femoral artery can be compressed just below Poupart's ligament against the psoas muscle and head of the femur (Fig. 225). The pressure should be directly backward. In the middle third of the thigh digital compression is unsatisfactory, and a tourniquet should always be used or an Esmarch band be employed.

Forced flexion is a variety of indirect compression introduced by Adelmann. It will arrest bleeding below the point compressed, but soon becomes intensely painful. Forced flexion can be maintained by bandages. Brachial hyperflexion is maintained by tying the forearm to the arm. It is often associated with the use of a pad in front of the elbow. Genuflexion is maintained by tying the foot to the thigh. It is increased in efficiency by placing a pad in the popliteal space.

Fig. 225.—Digital compression of the femoral artery.

Styptics.—Chemicals are now rarely used to arrest hemorrhage. In epistaxis we may pack with plugs of gauze saturated with a 10 per cent. solution of antipyrin. In bleeding from a tooth-socket freeze with chlorid of ethyl spray, and then pack with gauze soaked with 10 per cent. solution of antipyrin or pack with dry sponge or styptic cotton (absorbent cotton soaked in Monsel's solution and dried). A bit of cork may be forced into the socket. In bleeding from an incised urinary meatus pack with styptic cotton and compress the lips of the meatus. Cold water, chlorid of ethyl spray, and ice act as styptics by producing reflex vascular contraction. Hot water produces contraction and coagulates the albumin. The temperature should be from 115° to 120° F. A mixture of equal parts of alcohol and water stops capillary oozing.

The Use of Gelatin in Controlling Hemorrhage.—It seems very positively proved that gelatin increases the coagulability of the blood if given hypodermatically. It has been shown by Horatio C. Wood, Jr. ("American Medicine," May 3, 1902), that, even when administered by the stomach, digestion does not destroy its coagulating effect upon the blood. Carnot, of Paris, used it locally and with success to control epistaxis in a sufferer from hemophilia He then employed it to arrest bleeding from hemorrhoids, tumors, and incised wounds; and demonstrated in animals that it will arrest oozing from the cut surface of the liver. Carnot used a 5 or 10 per cent. solution. It has been employed with success to control hemorrhage in many situations, is of value when applied locally, and possibly of use when injected subcutaneously.

Intravenous injections are extremely dangerous, and are apt to be followed by embolism. Subcutaneous injections are decidedly painful and are not altogether safe, producing albuminuria and occasional embolism. Another danger that may follow the subcutaneous administration of gelatin is the development of tetanus, and several cases have been reported. The existence of disease of the kidneys contra-indicates the hypodermatic use of gelatin.

It has been successfully used as an enema in intestinal hemorrhage, and as an injection in hemorrhage from the bladder. I have used it with success in arresting bleeding from the cut surface of the human liver; to check bleed-

ing from an incised wound in a victim of leukemia; to arrest postoperative oozing in sufferers from cholemia; and in several cases of severe epistaxis.

When employed locally in solution, it should be of a strength of from 2 to 10 per cent. in normal salt solution. For hypodermatic use some employ a 5 per cent., some a 2 per cent., and some a 1 per cent. solution. In using a 1 or 2 per cent. solution a very large amount of fluid must be injected. This causes pain; and Sailer maintains that the pain is slight or absent if the solution is not turbid and if but 10 c.c. of a 10 per cent. solution are injected. The injection may be repeated until from 1 to 3 gm. of gelatin have been administered. It should be injected on the outer side of the thigh, under the breast, or between the shoulder-blades. If the drug is given by mouth, 100 c.c. of a 10 per cent. solution is the dose, and this may be repeated every two or three hours.

On account of the possible danger of the development of lockjaw after infection great care in sterilizing must always be exercised. The method of preparation suggested by Joseph Sailer will be found of the greatest value. (For the formula for this see page 422.)

In view of the fact that gelatin is such an excellent culture material, whenever it is used in the rectum, nose, pharynx, vagina, or bladder it should be mixed with some antiseptic agent.

The exact mode in which gelatin acts in producing coagulation is not certain. Floresco maintains that it acts like an acid. Laborde states that undissolved particles of gelatin serve as centers for coagulation. Other experimenters insist that gelatin destroys the leukocytes, and thus liberates fibrin ferment.

Suprarenal extract is a valuable agent to control capillary oozing. It constricts capillaries, and if applied to a mucous membrane will rapidly blanch it. It is extensively used to check bleeding during operations on the nose, throat, larynx, and ear, and to arrest epistaxis and bleeding from the uterus. The solution to employ is adrenalin chlorid of a strength of from 1: 10,000 to 1: 1000. A piece of cotton soaked in this solution is pressed lightly upon the part or it is sprayed upon the part by an atomizer.

Chlorid of calcium, given internally, is said to favor coagulation of the blood and is used to check oozing or to prevent hemorrhage. It is used particularly in jaundice cases when operation must be performed. If given several times a day for two or three days it increases the coagulability of the blood; but if given for more than four days, actually diminishes it. The initial dose is from 15 to 30 gr., then 5 gr. every hour are given until five or six doses have been taken. It is apt to provoke gastric irritability, and it is often given by the rectum. I have never been convinced of the value of the drug.

Blood-serum.—In hemophiliacs and in the postoperative oozing of jaundiced patients blood-serum is of great value. The wound may be tamponed with fresh animal blood or blood-serum. A suitable material for local use can be made by grinding up the fresh liver of an animal, soaking it in water, filtering the mixture through gauze, soaking gauze in the filtrate, and tamponing the wound with the wet gauze. This fluid contains the thrombokinase necessary in coagulation (Kottmann and Lidsky, in "Deutsch. medizin. Wochen," 1910, vol. i). Human serum is even more efficient locally. In ordinary cases of hemorrhage serum may be given subcutaneously in very severe hemorrhage intravenously. In jaundice cases a serum injection should precede operation. As a prophylactic or for therapeutic effect human serum, horse serum, rabbit serum, antistreptococcus serum, or diphtheria antitoxic serum may be used. The dose is 10 to 40 c.c. subcutaneously.

The *actual cautery* is a very ancient hemostatic. It is still used occasionally after excising the upper jaw, in bleeding after the removal of some malignant growths, in continued hemorrhage from the prostatic plexus of veins after lateral lithotomy, and to stop oozing after the excision of venereal warts. We are often driven to its use in "bleeders," that is, those persons who have a hemorrhagic diathesis, and who may die from having a tooth pulled or from receiving a scratch. It will arrest hemorrhage, but the necrosed tissue separates, and when it separates secondary hemorrhage is apt to set in. The iron for hemostatic purposes must be at a cherry heat. The old-fashioned iron, which was heated in a charcoal furnace, is rarely used. It is large, clumsy, and cools quickly if the bleeding is profuse. In an emergency we may heat a poker or a coil of telegraph wire. The best instrument is the Paquelin cautery. The Paquelin cautery consists of an alcohol lamp, a metal chamber containing benzene, a tube of entrance for air containing two bulbs, an exit tube, and a wooden-handled cautery instrument, the tip of which is hollow and composed of platinum (Fig. 226). The tip can be kept hot even when bleeding is profuse. If the iron is very hot, it will not stop bleeding completely. In order to use the Paquelin cautery, light the lamp, heat the cautery-tip in the flame until it becomes red, remove it from the flame, and squeeze the bulb repeatedly until the tip becomes bright red. Each time the bulb which is not covered with netting is squeezed air is driven through the metal chamber into the tube and cautery, and this air carries with it the vapor of benzene, which passes to the hot tip and takes fire. The degree of heat maintained depends upon the rapidity with which the bulb is squeezed.

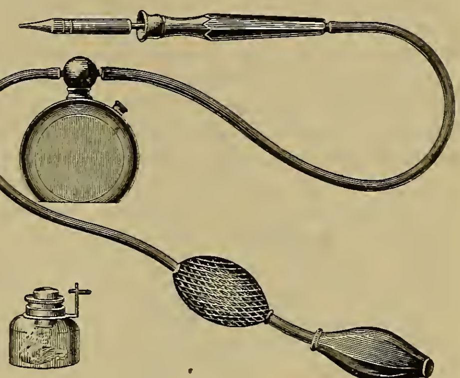

Fig. 226.—Paquelin cautery.

Skene has devised a method known as electrohemostasis. He grasps the vessel or tissue with specially constructed forceps, an electric current generates heat, the tissue is cooked, and the walls of the vessel united. For the small instrument Skene uses a current of 2 ma. and for the larger instrument a current of 8 ma.[1]

Downes has devised an instrument to apply electrothermic hemostasis in abdominal and pelvic operations. He asserts that by this method an intra-abdominal operation can be rendered bloodless; that the lymph-ducts are sealed and the stump rendered sterile; that adhesions are less apt to form; and that there is less postoperative pain than if the ligature were used ("Boston Med. and Surg. Jour.," July 10, 1902).

Rules for Arresting Primary Hemorrhage.—1. In arterial hemorrhage tie the artery in the wound, enlarging the wound if necessary (*Guthrie's rule*). In tying the main artery of the limb in continuity for bleeding from a point below we fail to cut off the bleeding from the distal extremity, and hemorrhage is bound to recur. If the surgeon does not look into the wound, he cannot know what is cut: it may be only a branch and not a main trunk. The same rule obtains in secondary hemorrhage.[2]

2. We can safely ligate veins as we would arteries.

[1] "New York Medical Journal," Feb. 18, 1898.
[2] For observations on suture of vessels, see page 444.

3. In a wound of the superficial palmar arch tie both ends of the divided vessel.

4. In a wound of the deep palmar arch enlarge the wound, if necessary, in the direction of the flexor tendons, at the same time maintaining pressure upon the brachial artery. Catch the ends of the arch by hemostatic forceps and tie both ends. If the artery can be caught by, but cannot be tied over the point of the forceps, leave the instrument in place for four days. If the artery cannot be caught by forceps, use a tenaculum. The ends of the divided vessel can be caught and must be caught even if large incisions are needed to effect it. An incision which will probably always expose the vessel is as follows: Make a cut on a line with the injury from the web of the fingers to above the carpus, separating the metacarpal and carpal bones, until the artery is reached. (This is really Mynter's incision for excision of the wrist.) In former days, if the surgeon found trouble in grasping the ends of the vessel, he applied a graduated compress (see Fig. 220). This is applied as follows: Insert a small piece of gauze in the depths of the wound, put over this a larger piece, and keep on adding bit after bit, each successive piece larger than its predecessor, until there exists a conical pad, the apex of which is at the point of hemorrhage and the base of which is external to the surface of the palm. Bandage each finger and the thumb, put a piece of metal over the pad, wrap the hand in gauze, bandage each finger, the thumb, palm, and wrist, place the arm upon a straight splint, apply firmly an ascending spiral reverse bandage of the arm, starting as a figure-of-8 of the wrist, and hang the hand in a sling. Instead of applying a splint, we may place a pad in front of the elbow and flex the forearm on the arm. The palmar pad is left in place for six or seven days unless bleeding continues or recurs. The graduated compress is unreliable, hence it is a dangerous method of treatment. It is an evasion. It should be employed at the present time only as a temporary expedient until ligatures can be applied. The old rule of surgery was as follows: If bleeding is maintained or begins again after application of a graduated compress, ligate the radial and ulnar arteries. If this maneuver fails, we know that the interosseous artery is furnishing the blood and that the brachial must be tied at the bend of the elbow. If this fails, amputate the hand. At the present day it is hard to conceive of such radical procedures being necessary for hemorrhage from a palmar vessel.

5. In primary hemorrhage, if the bleeding ceases, do not disturb the parts to look for the vessel. If the vessel is clearly seen in the wound, tie it; otherwise do not, as the bleeding may not recur. This rule does not hold good when a large artery is probably cut, when the subject will require transportation (as on the battlefield), when a man has delirium tremens or mania, or when he is a heavy drinker. In these cases always look for the artery and tie it.

6. When a person is bleeding to death from a wound of an extremity, arrest hemorrhage temporarily by digital pressure in the wound and apply above the wound a tourniquet or Esmarch bandage. Bring about reaction and then ligate, but do not operate during collapse if the bleeding can be controlled by pressure.

7. If a transverse cut incompletely divides an artery, it may be found possible and may be considered desirable to suture the cut. Longitudinal cuts can certainly be sutured (see page 441). If suturing is impossible, or if the surgeon prefers not to attempt it, apply a ligature on each side of the vessel wound and then sever the artery so as to permit of complete retraction.

8. If a branch comes off just below the ligature, tie the branch as well as the main trunk.

9. If a branch of an artery is divided very close to a main trunk, the rule

used to be, tie the branch and also the main trunk. It was thought that if the branch alone were tied the internal clot, being very short, would be washed away by the blood-current of the larger vessel. We now know that the clot is not required in repair, and under aseptic conditions it is trivial in size and rarely reaches the first collateral branch. Repair is effected by endothelial proliferation.

10. If a large vein is slightly torn, put a lateral ligature upon its wall (Fig. 227). Gather the rent and the tissue around it in a forceps and tie the pursed-up mass of vein wall. It is a wise plan to pass the ligature through the two outer coats by means of a needle and tie the knot subsequently. This expedient prevents slipping. If a longitudinal wound exists in a large vein, take an intestinal needle and fine silk and sew it up (see page 440). Transverse wounds can also be sutured.

11. When a branch of a large vein is torn close to the main trunk, tie the branch and not the main trunk. Apply practically a lateral ligature.

12. If, after tying the cardial extremity of a cut artery, the distal extremity cannot be found, even after enlarging the wound and making a careful search, firmly pack the wound.

13. In bleeding from diploë or cancellous bone, use Horsley's antiseptic wax, or break in bony septa with a chisel, or plug with threads of gauze or scrapings of catgut. If the bleeding is very free, wax will not stick and mash-

Fig. 227.—Application of lateral ligature to a vein.

ing the bone edges usually fails. The expedient suggested by Vaughan should then be employed, viz., a piece of muscle or other tissue is cut off, and, by means of the fingers or a knife handle, forcibly rubbed against the bleeding bone surface. Minute fragments of the soft tissue plug the open vessels and arrest the bleeding (George Tully Vaughan, in "Jour. Am. Med. Assoc.," Nov. 9, 1907).

14. In bleeding from a vessel in a bony canal, plug the canal with an antiseptic stick and break the wood, or fill up the orifice of the canal with antiseptic wax or a separated bit of tissue. If this fails, ligate the artery of supply.

15. In bleeding from the internal mammary artery the old rule was to pass a large curved needle holding a piece of silk into the chest, under the vessel and out again, and tie the thread tightly; but it is better to make an incision and ligate the artery.

16. In bleeding from an intercostal artery make pressure upward and outward by a tampon (see Fig. 219), or throw a ligature by means of a curved needle entirely over a rib, tying it externally; or, what is better, resect a rib and tie the artery.

17. In collapse due to puncture of a deep vessel, the bleeding having ceased, do not hurry reaction by stimulants. Give the clot a chance to hold. Wrap the sufferer in hot blankets. If the condition is dangerous, however, stimulate to save life.

18. In punctured wounds, as a rule, try pressure before using ligation.

19. After a severe hemorrhage *always* put the patient to bed and elevate the damaged part (if it be an extremity or the head).

20. A clot which holds for twelve hours after a primary hemorrhage will probably hold permanently; but even after twelve hours be watchful and insist on rest.

21. If recurrence of a hemorrhage from a limb is feared, mark with anilin or iodin the spot on the main artery where compression is to be applied, apply a tourniquet loosely, and order the nurse to screw it up and to send for the physician at the first sign of renewed bleeding. This must be done in many gunshot-wounds.

22. When the femoral vein is divided high up, the advice commonly given is to ligate the vein and also the femoral artery. Braune taught that because of the venous valves there is no collateral circulation, and to tie the vein alone renders gangrene inevitable. Niebergall shows that the valves may be overcome by moderate arterial pressure, and thus collateral circulation be established. Hence, when the femoral vein is divided tie the vein, but leave the artery untied, so as to furnish the necessary pressure.[1]

23. In extradural hemorrhage, trephine. The side to be trephined is determined by the symptoms, and not by the situation of the injury. The opening is made on a level with the upper orbital border and $1\frac{1}{4}$ inches behind the external angular process. This opening exposes the middle meningeal and its anterior branch. If this does not expose a clot, trephine over the posterior branch, on the same level and just below the parietal eminence. When the clot is found, enlarge the opening with the rongeur, scoop out the clot, and arrest the bleeding by passing ligatures on each side of the injury in the vessel through the dura, under the artery and out again, and then tying them. If the artery lies in a bony canal, plug the canal with Horsley's wax. In some cases packing must be used to arrest bleeding. In subdural hemorrhage open the dura and endeavor to ligate. If this procedure is impossible, pack with iodoform gauze.

24. In hemorrhage from a cerebral sinus catch the edges of the opening with forceps, if possible, and apply a lateral ligature, or leave the forceps in place for forty-eight hours, or compress firmly with iodoform gauze.

25. In extramedullary spinal hemorrhage rapidly advancing and threatening life perform laminectomy and arrest the hemorrhage.

26. In bleeding from a tooth-socket use chlorid of ethyl spray or ice. If this treatment fails, plug with gauze infiltrated with tannin or soaked in antipyrin solution of a strength of 10 per cent., or in Carnot's solution of gelatin. Close the jaws upon the plug, and hold them with Barton's bandage. If this expedient fails, soak the plug in Monsel's solution, or plug with a bit of cork or dry sponge, and if this is futile, use the cautery. Pressure on the carotid and ice over the jaw and neck are indicated. It may be necessary to tie the external carotid artery.

27. In intra-abdominal hemorrhage open the belly. In intra-abdominal hemorrhage it is necessary to operate during shock. If the blood accumulates so rapidly as to prevent the location of the bleeding point, compress the aorta or pack the abdominal cavity with large sponges. In seeking for the bleeding point remove the sponges one by one, or have the pressure momentarily relaxed from time to time. In parenchymatous hemorrhage from the liver, suture the torn edge or use the cautery. In some cases the liver is sutured to the abdominal wall and the wound is packed. Severe wounds of the spleen demand splenectomy. Wounds of the kidney may be sutured, but may require partial or complete nephrectomy. Wounded mesenteric vessels are ligated *en masse* with silk (Senn). If a portion of intestine is found to be deprived

[1] Niebergall, "Deut. Zeit. f. Chir.," vol. xxxvii, Nos. 3 and 4.

of blood it must be resected. Wounds of the stomach and intestines causing hemorrhage require stitching of their edges. When there are a great many points of bleeding, take a number of gauze sponges, tie a piece of tape firmly to each one, pack many places in the belly with the sponges, bring the tapes out of the wound, and remove the sponges from below upward one at a time, securing the bleeding points as they come into view.

28. In abdominal section for disease of the female pelvic organs bleeding is limited by the clamp or by pressure-forceps. Ligation *en masse* is often practised. A large mass can be transfixed and tied in sections. Bleeding edges are stitched. Areas of oozing are treated by temporary pressure and hot water or, if this fails, by the cautery. Packing can be used as a tamponade, which is a gauze pouch, pieces of gauze being packed into this pouch after its insertion into the belly (see Fig. 42).

29. A ruptured varicose vein requires a compress, a bandage from the periphery up, and elevation.

30. Most cases of capillary bleeding can be controlled by compression with gauze pads soaked in water at a temperature of 115° to 120° F. This contracts the vessels and seals them with coagulated albumin. Keetly in 1878 impressed the profession with the value of hot water as a styptic. Centuries ago surgeons used hot oil for the same purpose. Capillary bleeding can often be controlled by the application of gauze soaked in Carnot's solution of gelatin. A solution of suprarenal extract may control capillary oozing. If other means fail to control capillary hemorrhage, the cautery must be used. Understand that the term "capillary bleeding" does not so much mean bleeding from genuine capillaries as it does bleeding from arterioles and venules.

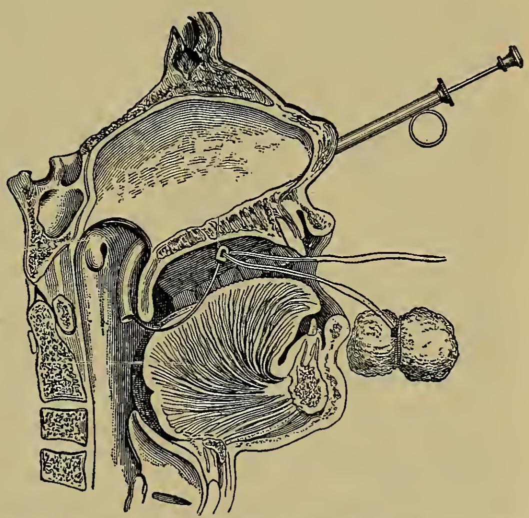

Fig. 228.—Plugging the nares for epistaxis by the aid of Bellocq's cannula (Guérin).

31. Pressure above a wound may arrest arterial hemorrhage, but aggravate venous bleeding. Pressure below a wound may arrest venous hemorrhage, but increase arterial bleeding.

32. A moderate epistaxis, or bleeding from the nose, may be arrested by an injection of peroxid of hydrogen, an injection of a solution of antipyrin, or an injection of Carnot's solution of gelatin. Favorite domestic expedients are keeping the arms raised above the head and applying ice to the back of the neck. In severe epistaxis examine the nose by means of a head-mirror and a speculum. If a little point of ulceration is found, touch it by a cautery. If the bleeding is a general ooze, if it is high up, or if the cautery does not arrest it, pack the nares. It may be necessary to pack one nostril or both. Pass a Bellocq cannula (Fig. 228) along the floor of one nostril into the pharynx, project the stem into the mouth, tie a plug of lint or gauze wet with Carnot's solution of gelatin to the stem, and withdraw it. Hold the double string which emerges from the nostril in the hand and

pack gauze wet with gelatin solution from before backward. Tie the strings together over the plug; if both nostrils are plugged, the strings from one nostril are fastened to the strings from the other. Do not use subsulphate of iron, as it forms a disgusting, clotty, adherent mass. If Bellocq's cannula is not obtainable, push a soft catheter into the pharynx, catch it by a finger, pull it forward, and tie the plug to it. Remove the plug in two or three days. Do not leave it longer. It blocks up decomposing fluids and may lead to blood-poisoning. Pick out the front plug first, hold the string of the second plug in the hand, push the plug back into the pharynx, catch it by forceps, and withdraw plug and string through the mouth.

33. In gunshot-wounds the primary hemorrhage is slight unless a large vessel is cut. The bleeding may be visible or may be internal (concealed), the blood running into a natural cavity or among the muscles. Capillary oozing is arrested by very hot water and compression. Venous bleeding is usually arrested by compression. If a large vessel is the source of bleeding, enlarge the wound and tie the vessel. If the artery cannot be found in the wound, tie the main trunk.

34. In prolonged bleeding from a leech-bite try compression over a plug saturated with alum or with tannin. If this fails, pass under the wound a harelip pin and encircle it with a piece of silk. If this fails, use the actual cautery or excise the bite and suture the incision.

35. In severe bleeding from the ear elevate the head, put an ice-bag over the mastoid, give opium and acetate of lead, and, if blood runs into the mouth, plug the Eustachian tube with a piece of catheter.

36. Umbilical hemorrhage in infants requires pressure over a plug containing tannin, alum, or gelatin solution. If compression fails, pass harelip pins under the navel and apply a twisted suture. If this fails, use the actual cautery.

37. Rectal bleeding requires elevation of the buttocks, insertion of pieces of ice, ice to the anus and perineum, astringent injections (alum), injections of gelatin, injections of adrenalin, and the internal use of opium and acetate of lead. If these means fail, plug the bowel over a catheter, or insert and inflate a Peterson bag or a colpeurynter, or tampon and use a T-bandage. If the bleeding persists or if a considerable vessel is bleeding, stretch the sphincter, catch the bowel and draw it down, seize the vessel, and tie it if possible; if not, leave the forceps in place. Failing in this, the actual cautery must be used.

38. Subcutaneous hemorrhage, if severe and persistent, demands that an incision be made and ligatures be applied.

39. Bleeding from a cut urethral meatus requires the insertion of styptic cotton and the application of pressure. Moderate bleeding from the deeper urethra can usually be arrested by a very warm bougie, by very warm injections, or by tying a condom over a catheter, and, after inserting it, inflating the condom by blowing through the catheter and plugging the orifice of the instrument, thus using pressure. Sitting with the perineum on a thickly folded towel is useful. Ice to the perineum does good. The patient can lie down, have a folded towel applied to the perineum, and a crutch-handle pushed upon the towel, the lower end of the crutch being jammed against the foot of the bed. If a solid bougie has been first introduced, firm pressure can be made by this method. If these means are futile, perform external urethrotomy and reach the bleeding point.

40. Hemorrhage from the prostate requires hot injections, the introduction of a large bougie first dipped in very warm water, and the retention of a catheter for two days. Perineal section may be required, or suprapubic cystotomy with packing which does not occlude the ureteral orifices.

41. Vesical hemorrhage usually ceases spontaneously, in which case the urine must be drawn off and the viscus be washed out frequently with a solution of boric acid, to prevent septic cystitis. If blood-clots prevent the flow of urine, break them up with a catheter or a lithotrite and inject vinegar and water, a 2 per cent. solution of carbolic acid, or a solution of bicarbonate of sodium. Perfect quiet is to be maintained, cold acid drinks are given, ice-bags are put to the perineum and hypogastric region, and opium with acetate of lead, or gallic acid is to be given by the mouth. If the hemorrhage is severe or persistent, perform suprapubic cystotomy, wash out the bladder, and, if necessary, plug the bladder with gauze, leaving the ureters uncovered.

42. In hemorrhage after lateral lithotomy, ligate if possible. If the vessel can be caught but cannot be ligated, leave the forceps in place. If it is not possible to catch the vessel with forceps, use a tenaculum. If the tenaculum fails, pass a threaded curved needle through the tissues around the vessel and tie the ligature (suture ligature). Plugs of ice and injections of hot water may be tried. These means failing, pressure is indicated. Take a cannula, fasten to it a chemise (Fig. 229), empty clots from the bladder, insert the instrument into the viscus, and pack gauze between the sides of the cannula and the chemise. The chemise is bulged out and pressure is made. Tie the cannula by means of tapes to a T-bandage. Pressure is thus combined with vesical drainage. Buckstone Brown makes pressure by inflating a rubber bag with air. The hot iron may occasionally be demanded.

Fig. 229.—Cannula à chemise.

43. Renal bleeding requires ice to the loin, tannic acid and opium, gallic acid or sulphuric acid internally, and perfect quiet. The use of a cystoscope will show from which ureter blood is emerging. If the bleeding threatens life and the diseased organ is identified, make a lumbar incision and suture or perform nephrectomy.

44. Vaginal hemorrhage requires the ligature or the tampon.

45. Severe uterine hemorrhage (unconnected with pregnancy) requires the tampon. Persistent hemorrhage due to morbid growths may require removal of the tubes and appendages, ligation of the uterine and ovarian arteries, or hysterectomy.

46. Hematemesis, or bleeding from the stomach, is treated by the swallowing of ice, giving tannic acid (dose, 20 or 30 gr.), or Monsel's solution (3 drops). Gelatin by the mouth is recommended. Never give tannic acid and Monsel's solution at the same time, as they mix and form ink. Opium is usually ordered. Acetate of lead and opium and gallic acid are favorite remedies, and ergot is used by many. Give no food by the stomach. If life is threatened by bleeding from an ulcer, open the belly and excise the ulcer and suture the wound. If severe hemorrhage follows injury, perform an exploratory laparotomy. Always remember that furious and even fatal gastro-intestinal hemorrhage may be due to cirrhosis of the liver, and a slight injury may be the exciting cause of such a hemorrhage. In this condition, of course, operation is useless.

47. In bleeding from the small bowel give acetate of lead and opium, sulphuric acid, or Monsel's salt in pill form (3 gr.), allow no food for a time, and insist on liquid diet for a considerable period. If hemorrhage threatens life, do a celiotomy and find the cause. If ulcer exists, excise it and suture, or

suture a perforation without previously excising. If violent hemorrhage follows injury, explore to discover the vessel.

48. In bleeding from the large bowel, use styptic injections (10 gr. of alum or 5 gr. of bluestone to 1 oz. of water). If bleeding is low down, use small amounts of the solution; if high up, large amounts. Do not use absorbable poisons. In dangerous cases perform an exploratory operation to find the vessel. (For rectal bleeding, see page 454.)

49. Hemoptysis, or bleeding from the lung, is treated by morphin hypodermatically, by perfect rest, by dry cups or ice over the affected spot if it can be located, and by the administration of gallic acid, which drug aids coagulation.[1] Nitrite of amyl by inhalation has given good results.

50. In hemorrhage from wound of the lung do not open the chest unless life is threatened. If life is endangered, resect a rib, allow the lung to collapse, and see if this arrests bleeding. If bleeding still continues, remove several ribs, find the bleeding-point, ligate or employ forcipressure. A small cavity may be packed with gauze. If a large surface is bleeding, fill the pleural sac with gauze and pack more gauze against the oozing surface.[2]

Reactionary or Recurrent Hemorrhage (called also *Consecutive, Intermediate,* or *Intercurrent*).—This form of hemorrhage comes on during reaction from an accident or an operation, that is, during the first forty-eight hours, but in most cases within twelve hours. It is usually bleeding from a vessel or vessels which did not bleed during the shock which accompanied operation, and which vessels were overlooked and not tied. It may be due to faultily applied ligatures. It is favored by vascular excitement or hypertrophied heart. The bleeding is rarely sudden and severe, but is usually a gradual drop or trickle. The Esmarch apparatus is not unusually the cause. The constricting band paralyzes the smaller arteries, which do not bleed during shock and do not contract as shock departs; hence bleeding comes on with reaction. To lessen the danger of the Esmarch apparatus use a broad constricting band rather than a rubber tube. After an amputation, when the larger vessels have been tied, gauze pads wet with hot water (115° to 120° F.) should be placed between the flaps. This not only arrests capillary oozing, but stimulates vessels and shows points of bleeding which were not previously visible, and these points are ligated. During reaction after an amputation, if slight hemorrhage occurs, elevate the stump and compress the flaps. If the hemorrhage persists or at any time becomes severe, make pressure on the main artery of the limb, open the flaps, turn out the clots, find the bleeding point, ligate, asepticize, drain, close, and dress. In any severe reactionary hemorrhage open the wound at once and ligate.

Secondary hemorrhage may occur at any time in the period between forty-eight hours after the accident or operation and the complete cicatrization of the wound. Secondary hemorrhage may be due to atheroma, to slipping of a ligature, to inclusion of nerve, fascia, or muscle in the ligature, to sloughing, to erysipelas, to septicemia, to pyemia, to gangrene, and to overaction of the heart. The great majority of cases of secondary hemorrhage are due to infection, and the application of modern surgical principles has rendered secondary bleeding a rare calamity. If during an operation the vessels are found atheromatous, a thread should be passed, by means of a curved needle, around the vessel, including a cushion of tissue in the loop of the ligature (this prevents cutting through, see Fig. 211). Acupressure may

[1] The use of ergot is a general but questionable practice. Bartholow and others hold that this drug does harm; it contracts all the arterioles, and hence more blood flows from an area where there is damage. Purgatives do good in bleeding from the lung by taking blood to the abdomen and lowering blood-pressure.

[2] See author's case, "Annals of Surgery," Jan., 1898.

be used in such a case. If the surgeon decides to employ the ligature, he must not tie tightly, but must endeavor to approximate the coats rather than to cut them. Two ligatures can be applied or the stay-knot may be used. One great trouble with atheromatous arteries is that their coats cannot contract; another trouble is that the ligature is apt to cut entirely through them. If after an operation the pulse is found to be forcible, rapid, and jerking, give aconite, opium, and low diet. The bleeding may come on suddenly and furiously, but is usually preceded by a bloody stain in wound-fluids which had become free from blood.

Treatment of Secondary Hemorrhage.—Suppose a case of leg amputation in which, several days after the operation, a little oozing is detected: the treatment is to elevate the stump, apply two compresses over the flaps, and carry a firm bandage up the leg. If the bleeding is profuse or becomes so, make pressure on the main artery, open and tear the flaps apart with the fingers, find the bleeding vessel and tie it, turn out the clots, asepticize, drain, close, and dress. If the bleeding begins at a period when the stump is nearly healed, cut down on the main artery just above the stump and ligate. In secondary hemorrhage from a blood-vessel in nodular tissue apply a suture-ligature or tie higher up, or, if this fails, amputate. When secondary hemorrhage arises in a sloughing wound apply a tourniquet or an Esmarch bandage, tear the wound open to the bottom with a grooved director, look for the orifice of the vessel, dissect the artery up until a healthy point is reached, cut it across, and tie both ends. If this fails, apply a suture-ligature or use acupressure. In secondary hemorrhage from atheromatous vessels use the suture-ligature, double ligature with a stay-knot, or employ acupressure.

Secondary hemorrhage may occur after ligation in continuity, the blood usually coming from the distal side. If the dressings are slightly stained with blood, put on a graduated compress. If the bleeding continues or is severe, make pressure on the main artery of the limb, open the wound and ligate, wrap the part in cotton, elevate, and surround with hot bottles. If this religation is done on the femoral and fails, do not ligate higher up, as gangrene will certainly occur, but amputate at once above the point of hemorrhage. If dealing with the brachial artery, do not amputate, but ligate higher up and make compression in the wound. In a secondary hemorrhage from the innominate, tie the innominate again and also tie the vertebral.

Hemorrhage After an Abdominal Operation.—Hemorrhage may occur after an abdominal operation. It may come on gradually with reaction. If it does so, it causes thirst, restlessness, an increasing pulse-rate, pallor, increasing rate of respiration, and coldness of extremities. The temperature is normal or subnormal. If the hemorrhage is small in amount the condition may be recovered from. If it continues it produces the grave symptoms set forth on page 436. A rapid secondary or reactionary hemorrhage produces those grave symptoms almost suddenly. If a severe hemorrhage is occurring in the abdomen nothing but an operation can save life (see page 452).

Hemophilia, Hemorrhagic Disease, or Hemorrhagic Diathesis.—The term "hemophilia" expresses the existence in an individual of a tendency to profuse or even uncontrollable hemorrhage spontaneously or as a result of some very trivial injury.

Hemorrhage may take place from mucous or serous membranes or from wounds of the cutaneous surface, into tissue, into organs, into a joint, under the scalp, or into the external genitals. In a hemophiliac, if a cut is made, the hemorrhage from the larger vessels is easily arrested, but capillary oozing continues.

The condition is far more common in males than in females, and if it exists in a female, which it rarely does, it is not usually provocative of dangerous hemorrhage. The disease is nearly always transmitted by heredity. It

is usually transmitted to a son by a mother who is free from the disease, but whose father had it, and the son bleeds dangerously from slight causes. Some reported cases were transmitted in the male line (Goodall, in "Scottish Med. and Surg. Jour.," Feb., 1905). There is, however, an acquired form of hemophilia. The existence of the tendency is rarely suspected until the first dentition, and possibly not till puberty; "70 per cent. of cases appear before the fifth year."[1] The discovery of the existence of such a condition may not be made until a tooth is pulled, and extraction is followed by persistent bleeding. It is alleged that the tendency may disappear in middle life. The victims of this hemorrhagic tendency are called "bleeders."

The cause of hemophilia is unknown. It has been assumed that there is a condition of the blood which prevents coagulation. The blood-changes are not characteristic. The blood is similar to that found in secondary anemia, the red corpuscles are diminished, but the hemoglobin is diminished more distinctly, hence there is a low color index. The white corpuscles are not increased as in scurvy and purpura, and often there is a positive leukopenia. Blood coagulation is slow and often imperfect. In some cases coagulation occurs in nine minutes, but in one of Wright's cases it required over an hour. It is important to remember as against failure of coagulating elements as the cause that Agnew had a case in which hemophilia was limited to the head and neck, and that there have been cases in which bleeding occurred into one joint or from one kidney. Some maintain that there is structural defect in the capillaries. In a case of hemophilia in the Jefferson Medical College Hospital, in which it was absolutely necessary to amputate a finger because of a crush, a careful study of the vessels of the finger by Dr. Coplin failed to show any disease of the blood-vessels. Wright believes with Morawitz that the serum of circulating blood contains fibrinogen and a ferment called thrombogen. The leukocytes and other cells of the body produce thrombokinase. Thrombokinase is only set free when leukocytes or body-cells break down. Thrombokinase in the presence of calcium converts thrombogen into thrombin, and thrombin converts fibrinogen into fibrin (Wood, in "Australian Med. Jour.," 1910, vol. xv). Sahli believes that hemophilia depends on defects in certain cells which entail a deficiency of thrombokinase, and hence impairment of coagulating power in the blood ("Deutsch. Archiv. für klinische Medizin," 1910, vol. xcix). A surgeon must be on the lookout for hemophilia, and should inquire for it before deciding to do an operation. If it exists, only an operation of imperative necessity should be undertaken. It is now well recognized that joint lesions may occur in hemophilia (*hemophilic arthritis*). The condition is most common in children. As a rule, more than one joint is involved, but only a few joints suffer. In Rugh's case only one knee-joint suffered ("Annals of Surg.," May, 1907). If more than one joint is attacked, the involvement may or may not be symmetrical.

The acute form resembles acute rheumatism and lasts about ten days. In the subacute form the temperature is lower, the symptoms less intense, and the duration shorter. In both forms joint function is restored (Frolich, "Centralb. für Chir.," 1905, vol. xxxii). The chronic form resembles tuberculous arthritis or osteomyelitis. In this form there is a tendency to loss of function, but there is no reaction to tuberculin.

A child who is a "bleeder" must be unceasingly watched and guarded. A tendency to profuse oozing exists in leukemia because of the condition of the blood, but this is not hemophilia. A tendency to oozing also exists during jaundice.

Treatment.—The oozing is difficult and often impossible to control, although most of these cases, in the long run, recover. In the acquired form

[1] R. C. Cabot, in "International Text-Book of Surgery."

the prognosis is better than in the congenital (Weil, "Centralb. für Chir.," 1907, vol. xxxiv). Internal administration of such drugs as ergot, gallic acid, and acetate of lead is useless. It is claimed that chlorid of calcium internally is of service. Lactate of calcium, 15 to 20 gr., is sometimes given three times a day by the mouth. It may also be given by the rectum. Milk may be given by rectum, in order to obtain the combination of salts of milk unchanged by gastric juice (Solt, Ibid.). The local use of astringents is of no avail. Prolonged elevation may in rare cases succeed. In the case in the Jefferson Medical College Hospital the bleeding was arrested, after numerous expedients failed, by compression and hot water. Nurses sat by the bed for several days, constantly compressed the wound with gauze pads soaked in hot water, and changed the pads as soon as they cooled. The local use of Carnot's solution of gelatin has apparently saved several cases from death. A valuable plan is to tampon the wound with gauze containing fresh animal or human blood or blood-serum.

Serum in doses of from 5 to 10 c.c. may be given hypodermatically or, if bleeding is very severe, intravenously. We may use human serum, horse serum, rabbit serum, diphtheria serum, or antistreptococcus serum (see page 448). After each injection of serum there is leukocytosis, and leukocytosis means increase of cells containing fibrin ferment or thrombokinase. (See Tremburg, in "Medizinische Klinik," Berlin, Nov. 7, 1910.) A rapid method of obtaining thrombokinase is to take the liver from a rabbit or other animal, chop it, grind it, soak in water, and filter through cloth. Gauze soaked in this fluid is used to tampon a wound (Koltmann, Ibid., June 2, 1910).

Witte applies locally an extract of lymphoid organs (spleen, lymph-glands, or thymus) and injects hypodermatically a 5 per cent. solution of sterile peptone in .5 salt solution. The dose is 3 c.c. every other day until three or four doses have been taken. Then the injections are intermitted for three or four weeks (Nolf and Herry, "Reme de Medécine," Feb., 1910, and "Gaz. des Hôpitaux," 1911). Thyroid extract should be tried, as in some cases it seems to have been of value. The dose is 5 gr. after each meal. Eugene Fuller's case of hemophilia ("Med. News," Feb. 28, 1903) was apparently cured by the administration of 5 gr. of thyroid extract three times a day. In a case of hemophilia in the Jefferson Hospital thyroid extract apparently arrested the bleeding. In Rugh's case, after excision of a knee-joint, bleeding was profuse and continued, but ceased in eight days. The patient was given 5 gr. of thyroid extract three times a day. The cases are particularly interesting in connection with W. J. Taylor's observation that thyroid extract increases the rapidity of blood coagulation in jaundice cases and lessens the tendency to postoperative oozing in such cases.

Operations On the Vascular System

Paracentesis auriculi, or tapping the heart-cavity, has been suggested for the relief of an overdistended heart from pulmonary congestion. The right auricle can be tapped. Push the aspirator needle directly backward at the right edge of the sternum, in the third interspace. This operation is not recommended, as it is highly dangerous and is of questionable value.

Paracentesis pericardii, or tapping the pericardial sac, is done only when life is endangered by effusion. Introduce the needle 2 inches to the left of the left edge of the sternum, in the fifth interspace, and push it directly backward (thus avoiding the internal mammary artery). The operation of tapping is extremely dangerous. The heart is lifted up and pushed forward by an effusion and the needle is apt to enter it. The puncture of a ventricle may do no harm, although it is very apt to, but the puncture of an

auricle is almost certain to be followed by fatal hemorrhage. It is wiser and safer to expose the pericardium and incise it, as is done for pericardial suppuration.

Operation for Pericardial Effusion or Suppuration.—The operation of tapping should be abandoned in favor of a safer but more radical procedure. There is no spot where we can introduce the needle with perfect safety, and the heart or pleura may be wounded; further, as Brentano shows,[1] tapping will not completely empty the sac. In a purulent case tapping gives practically no chance of cure. No general anesthetic should be used. A portion of the fourth rib or the cartilage on the fourth rib on the left side should be excised, the pericardium exposed and punctured in order to determine the nature of the fluid present. If the fluid is serous, it can be drained away through a small incision and the pericardium may be sutured. If the fluid be purulent, the pericardium should be stitched to the chest wall and opened. Clots should be removed by hot salt solution irrigation and a drainage-tube should be introduced.

Operation for Wound of the Heart.—In many cases it is obviously impossible to administer an anesthetic, but when possible it should be given because the movements of the patient while under the knife make operation difficult and increase bleeding. Ether may be used or we may take Hill's advice and give chloroform. Hill would give an anesthetic unless the patient is unconscious and the corneal reflex is abolished. Personally, I would be disposed to use chloroform unless the patient's general condition forbade it (see page 405). The pericardium can be exposed freely and Rotter's incision gives excellent access, although it always opens the pleura. This exposure is described by Hill in the "Medical Record," November 29, 1902, and was employed in his successful case. Begin an incision over the third rib ⅝ inch from the left edge of the sternum and carry it outward along the rib for 4 inches. Begin an incision over a corresponding point of the sixth rib and carry it out for a like distance. Join the outer extremities of these cuts. Cut through the ribs and pleura by bone forceps and scissors. Raise the flap upon its hinges of cartilages, and have an assistant grasp the lung to prevent collapse. The pericardium thus exposed is opened widely if necessary. Hill advises us to steady the heart by pressing the hand under it and lifting it. Parrozzani did this by inserting a finger in the wound. Other surgeons have used traction sutures of silk. For wound closure interrupted sutures are preferred to the continuous suture. Either silk or catgut can be used. They should be inserted by a round-edged needle. "As few as possible should be passed commensurate with safety against leakage, as they cause a degeneration of the muscular fiber." It does no harm apparently if they enter a heart chamber, but it is wiser not to have them do so. If the heart fails, use heart massage (L. L. Hill, Ibid.). The pericardial and pleural sacs are cleansed by salt solution. The question of drainage is still *sub judice*. The pleural sac is treated according to indications in each case.

George Tully Vaughan, in reporting his second case of heart suture and a table of 150 operations ("Jour. Am. Med. Assoc.," Feb. 6, 1909), mentions five methods for exposing the heart, and states that no single method has yet been agreed on as the best. The kind of operation is often determined by the external wound, and, begun as an exploration, the subsequent steps depend on the necessities which arise during its progress. The five methods mentioned by Vaughan are: (*a*) Through an intercostal space, with or without the division of one or two cartilages; (*b*) resection of one or more cartilages, with or without a portion of rib; (*c*) flap method across the sternum, dividing the sternum and cartilages (this avoids opening the pleura); (*d*) flap of cartilages and

[1] "Deut. Med. Woch.," Feb. 11, 1890.

ribs with an external hinge; (*e*) flap of cartilages and ribs with an internal hinge.

Vaughan's table shows that in 46 patients the pericardium was drained, with 25 recoveries and 21 deaths; in 44 the pericardium was not drained, with 25 recoveries and 19 deaths; in 42 both the pericardium and pleura were drained, with 21 recoveries and 21 deaths; in 19 both pericardium and pleura were closed without drainage, with 12 recoveries and 7 deaths; in 72 the pleura was drained, with 30 recoveries and 42 deaths; in 21 the pleura was not drained, with 13 recoveries and 8 deaths. These figures would indicate that drainage should not be the rule. It should be used though if bleeding continues or if we greatly fear infection. Of course, drainage causes irritation, prevents the lung expanding, and makes secondary infection more probable (Vaughan, in "Jour. Am. Med. Assoc.," Feb. 6, 1909).

In Vaughan's table of 150 cases we find that 98 died and 52 recovered, a mortality of 65 per cent.; 32 patients died in less than twenty hours after the operation for the injury and 15 died on the table or just after the operation. In all but 1 of these cases death was due to hemorrhage. In 1 it was due to pneumothorax on opening the pleura. The remaining 66 deaths occurred in from twenty-four hours to five months after the operation: 6 died of pleurisy, 5 of pericarditis, 21 of combined pleurisy and pericarditis, 3 of pneumonia, 3 of peritonitis, 2 of pericarditis and nephritis, 1 of pleurisy and cerebral abscess, 1 of pleurisy and wound of the tricuspid valve, 1 of pleurisy and double pneumonia, 1 of gangrene of the lung, 1 of two wounds, one of which was not sutured, 3 of bleeding into the pleura, 2 of bleeding into the pericardium, 1 of clot in the tricuspid opening, and 15 of unassigned causes.

Cardiolysis.—As a result of pericarditis the heart may adhere to the pericardium and the pericardium to the chest wall. This condition is dangerous, and, if unrelieved, will eventually prove fatal.

Delorme has suggested that the pericardial sac be opened and the adhesions be broken down with the finger, a very dangerous procedure, which is almost certain to inflict serious injury upon the heart.

Brauer's method, which he suggested in 1902, consists in removing the several ribs and portion of the sternum to which the pericardium adheres. The periosteum is to be removed with the bone to prevent the formation of new bone. This is the preferable operation. The safest plan is to remove the anterior, but not the posterior, periosteum. The danger of fresh ossification is slight and we avoid injuring the left pleura (Poynton and Trotter, quoted by Simon, in "Brit. Med. Jour.," Dec. 14, 1912).

Decompression for Heart Hypertrophy.—In a case of cardiac hypertrophy in which the heart knocked violently against the ribs, Morrison performed thoracotomy. He removed several inches of the fifth rib and an equal length of the sixth rib. The patient was much improved, the capacity of the chest was increased, and the painful attacks were practically cured ("Lancet," July 4, 1908).

Operation for Varix of Leg.—Many cases do not require operation. In some, operation is positively harmful. In some selected cases operation is very useful to remove certain complications (ulcer, eczema, etc.), and to relieve the patient from annoyance, but the operation rarely absolutely cures the condition. As Blake points out, a cure cannot be claimed until at least one year has passed after operation without reappearance of the varix ("Boston Med. and Surg. Jour.," Sept. 25, 1902). The indications and contra-indications are discussed on page 412. Never operate if phlebitis exists except to treat thrombosis. After any operation for varicose veins of the leg follow Bennett's advice and keep the patient in bed for three weeks and do not let him resume active work for three weeks more ("Lancet," Nov. 22, 1902).

Trendelenburg's Operation.—I have employed this with much satisfaction in cases of varix of the leg following involvement of the saphenous in the thigh. Trendelenburg believes that in varix the valves in the saphenous become incompetent because of high central pressure. The veins of the leg distend, as they are unable to support such a long column of blood, and finally the blood begins to flow in the wrong direction in the saphenous, a "vicious circle" being established. We determine whether a case is a suitable one for Trendelenburg's operation as follows: While the patient is lying down raise the extremity as though we intended to empty it of blood previous to amputation. After three minutes compress the saphenous vein about the lower third of the thigh by means of a moist gauze bandage, which must not be so tight as to shut off the deeper vessels. Lower the leg and have the patient stand up. If blood flows into the saphenous from above and distends the portion of the vein above the compress, the valves are incompetent and Trendelenburg's operation may be performed. The operation is performed as follows: Make an incision about 4 inches in length over the internal saphenous vein at the junction of the lower and middle thirds of the thigh. Expose the vein, ligate each visible branch, ligate the saphenous at the lower end of the wound and also at the upper end, and remove the portion of vein included between the ligatures. By this operation the central pressure is intercepted and the dilated veins in consequence shrink. Some surgeons have advised the removal of the entire length of the long saphenous vein. If Trendelenburg's operation fails and a relapse occurs, extirpate the varicose veins of the leg.

Madelung cuts down over the varices and ligates at various points. *Schede* makes a circular cut (a circumcision) completely around the leg at the junction of the upper and middle thirds, the incision reaching to the deep fascia. All bleeding points are ligated and the edges of the incision are stitched together. This operation is so often followed by persistent hard edema that it is now seldom performed. A recent operation is to place the internal saphenous beneath the deep fascia. *Delbet* implants the saphenous into the femoral 10 cm. below its normal point of junction. The valvular arrangement of the femoral restores normal tension in the saphenous. *Fergusson* ties the saphenous vein near the femoral and removes a section from it. This makes the varices clearly evident. A semilunar incision is made to surround the varices, which incision reaches to the deep fascia. The flap is raised and dissected up, the vessels are tied, and the flap is sutured in place. *Phelps* advises multiple ligation. Sir Wm. H. Bennett thinks that in ordinary cases the best operation consists in removing a portion of the long saphenous in the thigh and also in removing 3 inches of the vein from below the knee. If there are cystic dilatations above the knee he removes the saphenous from the thigh. Some local varices he dissects out ("Lancet," Nov. 22, 1902). As a matter of fact, excision of a short piece of vein seems to do as much good as excision of a long piece. Excision of a piece at several points is valuable. The object of excision is to reduce pressure on the vein walls by breaking up the column of blood (Barker, in "Practitioner," Oct., 1910). Any of the suggested operations may be followed by relapse.

Phlebotomy, or Venesection.—**Operation.**—The patient sits on a chair "with the arm abducted, extended, and inclined outward" (Barker). The parts are ascepticized and a tape is tied around the arm just above the elbow. The patient grasps a stick firmly and works his fingers in order to cause the veins to distend. The surgeon stands to the right of the arm, holds the elbow with his left hand, and puts his thumb upon the vein below the intended point of puncture. Either the median cephalic or the median basilic may be opened (Figs. 230, 231). The median basilic is the more distinct, and is the vein usually

selected. In opening it do not cut too deep, as nothing but the bicipital fascia separates it from the brachial artery. The median cephalic may be selected (we thus avoid endangering the brachial artery); under this vein lies the external cutaneous nerve (Fig. 231). Steady the vein with the thumb and open it by transfixion, making an oblique cut which divides two-thirds of it. Remove the thumb and allow bleeding to go on, instructing the patient to work his fingers. When faintness begins, remove the fillet, put an antiseptic pad over the puncture, apply a spiral reversed bandage of the hand and arm and a figure-of-8 bandage of the elbow, and place the arm in a sling for several days.

Transfusion of Blood.—This operation has been a recognized procedure since 1824, though it has been known since 1492, when transfusion was employed in the case of Pope Innocent VIII. Its chief use was in severe hemorrhage, especially postpartum, in which it served to replace the blood lost and supplied something for the heart to contract upon until new blood formed. Senn insisted that the operation had proved an absolute failure, that it did not prevent death from hemorrhage, and that the transferred blood-elements did not retain vitality. Von Bergmann maintained that after severe hemorrhage we do not need to inject nutritive elements, but do need to restore the greatly diminished intracardiac and intravascular pressure. At the present day a saline fluid is usually infused in preference to transfusing blood. In fact, the operation of transfusion had become all but extinct until Crile revived it. The old operation, as it used to be performed, exposed the patient to the danger of embolism and infection. It had come to be believed that transfusion had no single element of value beyond that secured by the use of salt solution, except in cases overcome by illuminating gas, in which a more prolonged good effect was known to be produced than by salt solution.

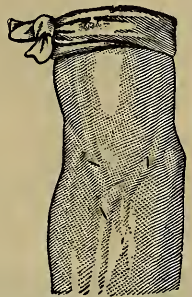

Fig. 230.—Incisions for venesection (Bernard and Huette).

Fig. 231.—Superficial veins in front of elbow (Bernard and Huette).

Arteriovenous Anastomosis for Transfusion of Blood (Crile's Operation).—This is a method of the very greatest value in the treatment of the condition resulting from violent or prolonged hemorrhage. It is incomparably the best treatment for severe hemorrhage. It can be employed during the performance of an exhausting operation and its use will bring not a few cases to operation which, without its aid, would be esteemed inoperable. It should be used for severe typhoid hemorrhage and in jaundiced cases requiring operation, but showing very slow coagulation. It seems devoid of value in blood diseases. There are certain dangers in it unless there is time to examine the blood of both donor and recipient. It is known that admixture of certain bloods results in thrombosis. If the corpuscles of the donor are not agglutinated by the serum of the recipient, and vice versâ, the operation is safe.

In Crile's operation the vascular system of the donor is united to the vascular system of the recipient. He places intima in contact with intima. This is accomplished by means of a modification of Payre's magnesium tube or by Crile's tube, which is of German silver. The vein of the recipient is drawn through the tube, is everted, and is tied into the second groove on the tube.

The end of the tube with the everted vessel over it is passed into the vessel of the donor and fixed temporarily by a ligature. The left arm of each subject is usually employed and the radial artery of the donor is anastomosed to a superficial vein of the recipient. Each patient should be on a table the

head of which can be raised or lowered at will. The region over the radial artery of the donor is exposed under local anesthesia. Every small branch over the artery is carefully tied in order to prevent obstruction by blood. The artery is bared for a distance of about 3 cm., tied distally, lightly clamped with a screw clamp proximally, and divided. The vein of the recipient is bared, clamped, and divided, the tube (dipped in sterile olive oil) is inserted into the vein, the cuff of everted vessel is formed over the end, and the artery is pulled over the tube and the cuff of vein, and held by a ligature tied into the first groove (Bevan, in "General Surgery," by Lexer-Bevan).

The flow is at first slow, but after eight or ten minutes becomes more rapid, especially if warm salt solution is run into the wounds. The amount used depends on the strength of the donor and the needs of the recipient.

I have used Brewer's tube in this operation with much satisfaction. It makes the procedure vastly easier of execution. Fig. 232 shows Brewer's tubes.

I am indebted to Dr. George Emerson Brewer for describing in a note to me the technic of his operation. The description follows:

"After thorough sterilization, the tubes are prepared by dipping them in melted paraffin, shaking them out, and allowing them to cool, or immersing

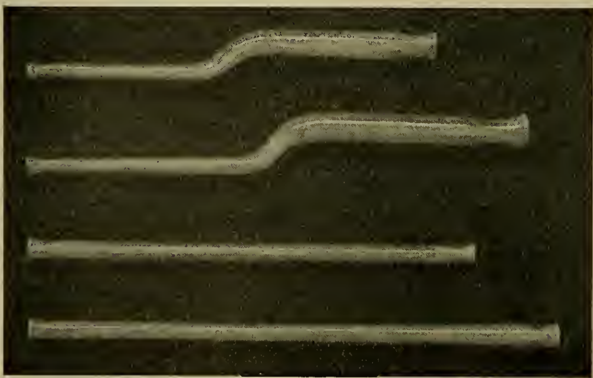

Fig. 232.—Brewer's tubes for direct transfusion.

them in a solution of paraffin in benzine. The radial artery of the donor is exposed in the usual manner, and also the median basilic or some other available vein of the donee. The proximal end of the artery is next drawn over one extremity of the glass tube and secured by a silk ligature. This is facilitated by expanding the lumen of the artery by means of three mosquito forceps or artery clamps. When all is ready to insert the free extremity of the tube into the vein of the donee, the arterial clamp is temporarily released and a few jets of blood allowed to pass through the tube, which is then quickly placed within the lumen of the vein and secured by another silk ligature. If the vein of the donee is large, the distal end of the glass tube may be inserted through a longitudinal slit in the vein, after the manner usually adopted when introducing the cannula for salt infusion. When sufficient blood has been transfused the tube is removed, the vessels ligated, and the cutaneous wounds closed. In certain rare instances where it is advisable to transfuse from an adult into an infant, the popliteal vein of the infant may be employed, as the subcutaneous veins are generally too small to admit of the introduction of the tube. In these cases a tube of diminishing caliber should be used, the larger end for the donor's artery, the smaller for the donee's vein."

Fauntleroy's Vein-to-vein Anastomosis.—This is a much simpler operation

than arteriovenous anastomosis. I have used it with great satisfaction. A glass tube is fixed in a vein of the donor and a vein of the recipient. I use the tubes devised by Dr. A. M. Fauntleroy of the United States Navy ("Med. Rec.," Sept. 3, 1910). The tube is $\frac{1}{8}$ inch in diameter and each end is flanged to prevent slipping. The veins in front of the elbow are used. The tube chosen may be full curved or S shaped (Fig. 233). The full curved tube is called the "hand-to-shoulder tube," because when it is used the hand of the donor is toward the shoulder of the recipient and the hand of the recipient is toward the shoulder of the donor. The S-shaped tube is called the "shoulder-to-shoulder tube." It is used when donor and recipient are placed side by side in the same direction, with the shoulders together (Fauntleroy, Ibid.).

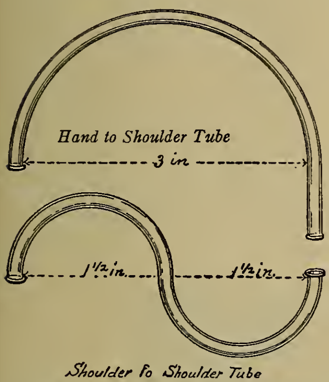

Fig. 233.—Tubes for transfusion, one-half natural size (A. M. Fauntleroy, in "Medical Record").

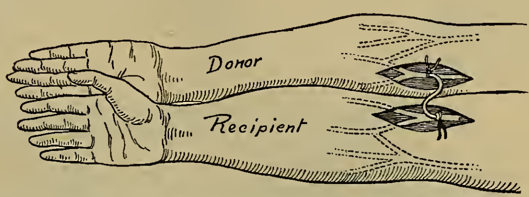

Fig. 234.—Vein-to-vein transfusion with the shoulder-to-shoulder tube (A. M. Fauntleroy, in "Medical Record").

The tubes are prepared with paraffin. A rubber band is placed around the arm of the recipient in order to make the veins prominent. The median basilic or median cephalic vein is exposed and freed for at least $1\frac{1}{2}$ inches. A ligature is passed under the vein at the lower angle of the wound, another under the vein at the upper angle of the wound. The lower ligature is tied and the rubber band removed.

The tourniquet is now applied to the donor and the vein exposed as just described. The ligatures are placed, but only the upper one is tied. The vein below the ligature is gently grasped with rubber-protected forceps and is cut completely across. The intima is grasped with fine forceps and one end of the tube is inserted $\frac{1}{4}$ inch into the vein, and the lower ligature is tied in order to fix the tube in the donor's vein.

The elbows are now brought together, a nick is made in the vein of the recipient, the rubber-protected forceps are released from the vein of the donor, and, while blood flows, the tube is inserted in the vein of the recipient, and is held by the tying of the upper ligature. During the operation the rubber band is kept on the arm of the donor, sufficiently tight "to secure well-marked venous hyperemia in the forearm and a consequent increased venous pressure." The tourniquet must not cause stoppage of the radial pulse.

It is well to have a blood-pressure apparatus on the free arm of the donor and one on the free arm of the recipient. The pulse and general condition of donor and recipient are carefully watched.

Angulation of the veins would cause clotting and must not be permitted. We can tell that blood is passing by the improvement in color, in pulse, and in blood-pressure of the recipient and by the fulness of his vein near the tube. Fauntleroy in 1 case kept up the flow for thirty minutes. At the termination of the operation the tubes are removed, the veins tied, the tourniquet taken from the arm of the donor, and the wounds sutured and dressed.

Intravenous infusion of saline fluid is used after severe hemorrhage, in shock, in diabetic coma, in postoperative suppression of urine, and occa-

sionally in sepsis. After a hemorrhage its beneficial effects are often prompt and obvious. The saline fluid increases the arterial tension, gives the heart enough matter to contract upon, and so restores the activity of the circulation, and does not destroy the red corpuscles as plain water would do. We may use a simple apparatus consisting of a rubber tube, a funnel, and an aspirating needle. Some employ an Aveling syringe, and others Collin's apparatus (Fig. 236). The last-named instrument can be used without any danger of air entering with the fluid. Spencer's instrument (Fig. 237) is convenient and useful. Normal salt solution is the fluid usually employed, of a strength of 0.9 per cent. (1 heaping teaspoonful of common salt to 1 quart of warm boiled water). Some surgeons employ an artificial serum which contains 50 gr. of chlorid of sodium, 3 gr. of chlorid of potassium, 25 gr. of sulphate of sodium, 25 gr. of carbonate of sodium, and 2 gr. of phosphate of sodium in 1 quart of boiled water. Szumann's solution consists of 6 parts of common salt, 1 part of sodium carbonate, and 1000 parts of water. The following solution is used by Locke and Hare: Calcium chlorid,

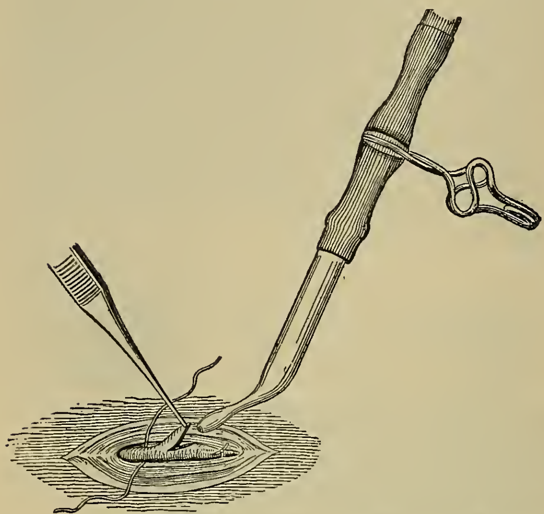

Fig. 235.—Intravenous saline infusion. Manner of incising vein and inserting glass tube (Senn).

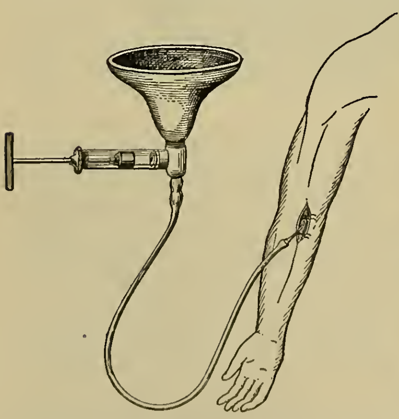

Fig. 236.—Intravenous injection of saline fluid.

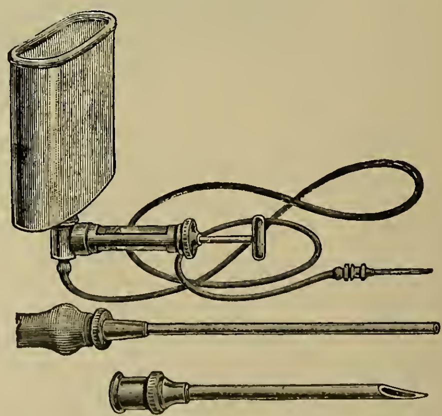

Fig. 237.—Spencer's apparatus for the infusion of saline fluid into a vein. The cannula can be plunged directly into the vessel without preliminary incision.

25 gm.; potassium chlorid, 1 gm.; sodium chlorid, 9 gm.; sterile water sufficient to make 1 liter. One bottle of the commercial fluid when diluted to 1 liter gives a solution of the above composition. The results from artificial serum containing many elements are no better than from normal salt

solution. Adrenalin may be added to the normal salt solution (1 dram of the 1:1000 solution of adrenalin to 1 pint of salt solution). The results of a single dose of adrenalin are very transitory. Whatever fluid is used, it should be at a temperature of 105° F. or over as it enters the vein. The stimulant effect of the heat is of great value. The fluid must not be allowed to cool; and a nurse gives constant attention to the temperature of the fluid in the reservoir. This degree of heat will not damage the corpuscles; in fact, Dawbarn has used saline fluid at a tempertature of 118° F. without doing damage to corpuscles and with great benefit to the patient. From ½ pint to 2 pints or even more are slowly injected, the condition of the patient determining the amount given. In one case of violent hemorrhage the author used over 2 quarts. In order to infuse this fluid tie a fillet well above the elbow, and expose by dissection the median basilic vein, or the basilic vein in the portion of its course where it is superficial to the deep fascia. Tie the vein. Incise it above the ligature, insert a fine cannula toward the heart, and hold the cannula firmly in the lumen by tightening a second ligature (Figs. 235, 236). Remove the fillet. Slowly and gradually introduce the fluid, carefully watching the

Fig. 238.—Injection of saline solution and adrenalin into an artery by the method of Crile.

pulse. Occupy at least ten minutes in introducing 1 pint, except in a very desperate case of hemorrhage, when the rapidity of the flow may be accelerated. When the tension of the pulse returns, withdraw the cannula, tie the second ligature tightly, sew up the wound, and dress it aseptically. In very severe operations an assistant should conduct the infusion while the surgeon is operating. It may be necessary to repeat the injection if the circulation fails again. The infusion of a very large amount of saline fluid may do harm. It may embarrass the heart and cause acute dilatation, may lead to edema of the lungs or brain, and cause marked anemia which lasts for days. The giving of salt solution intravenously should never be regarded as routine treatment, judgment is required in determining that it should be used, when it should be used, and how much is required, and there is a distinct element of danger in the procedure.

Arterial Transfusion and Infusion of Saline Fluid in Arteries.—Hueter preferred the arterial method of transfusion, in order to send the blood more gradually to the heart, and thus prevent sudden disturbance of the circulation. A little air in an artery will do no harm, and the danger of venous embolism is avoided. Saline fluid can be infused into an artery. The radial artery is

exposed and surrounded by three ligatures, and the thread toward the heart is at once tied. The distal ligature is slightly tightened to cut off anastomotic blood-supply. The artery is cut transversely half through; the syringe is inserted, pointed toward the periphery, and fastened by the third ligature; the second ligature is loosened and the material is injected. On finishing, the peripheral thread is tied tightly and that portion of the artery which held the cannula is excised. Dawbarn puts a hypodermatic needle into the radial artery and injects saline fluid.

Crile (Crile and Dolley, in "Jour. of Exper. Med.," Dec., 1906) has shown that when a patient is nearly dead or apparently dead the introduction of saline fluid by a vein may overwhelm the heart. He gives it in these cases by an artery and has succeeded in resuscitating those apparently dead. The tube of the apparatus is quickly inserted into the carotid artery and toward the heart. The reservoir is raised, and as the saline fluid begins to flow the tube is punctured with a hypodermatic needle and adrenalin is added to the saline stream. If the heart starts to beat, blood will appear in the tube and then the administration is discontinued. By this method we may re-establish blood-pressure in the coronary arteries (Fig. 238).

Ligation of Arteries in Continuity

The **instruments** used in this operation are two scalpels (one small, one medium), two dissecting forceps, several hemostatic forceps, blunt hooks or broad metal retractors, an Allis dissector, an aneurysm needle, for superficial arteries the instrument of Saviard (Fig. 239), for deep vessels the needle

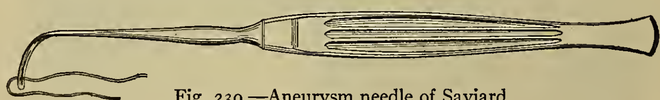

Fig. 239.—Aneurysm needle of Saviard.

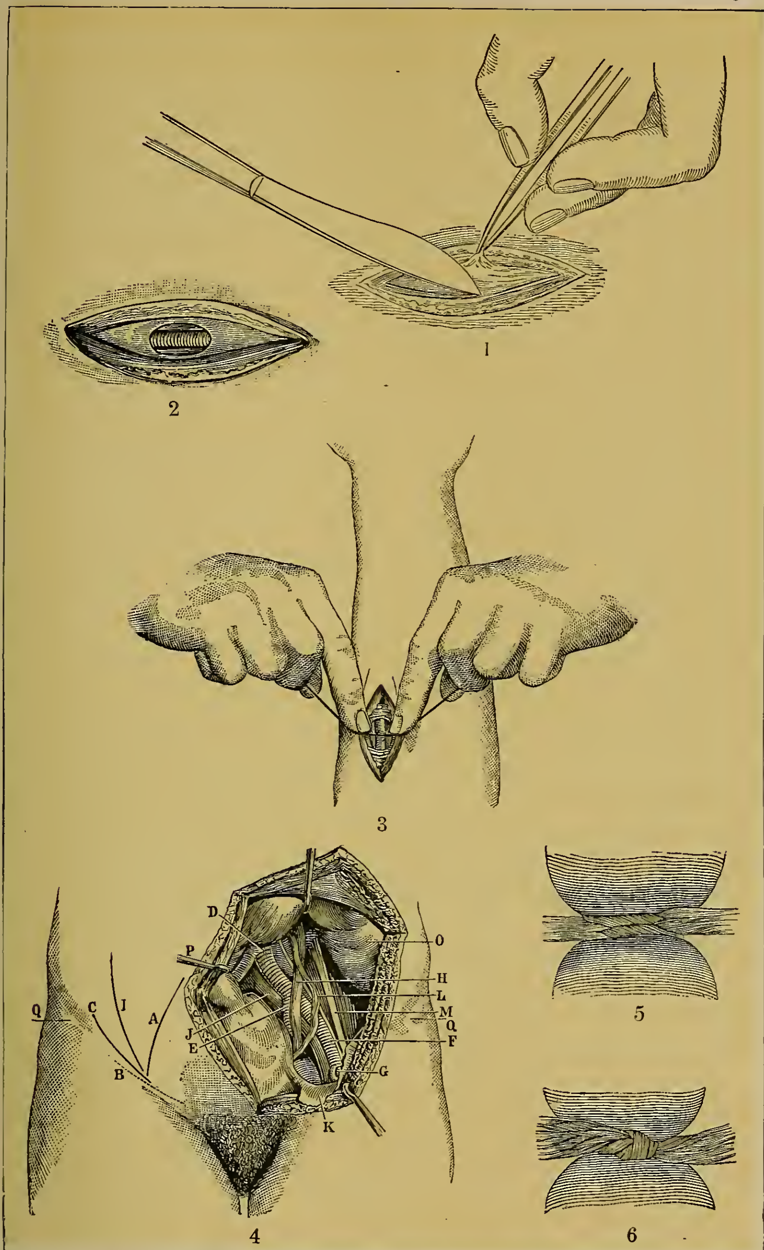
of Dupuytren (Fig. 240), ligatures of catgut, of chromicized gut, or of silk, curved needles and a needle-holder, sutures of silkworm-gut, and the reflector or electric forehead-lamp for deep vessels.

The **position** in which the patient is placed varies according to the vessel to be ligated, though the body is supine except when ligation is to be performed on the gluteal, sciatic, or popliteal artery. The operator, as a rule, stands upon the affected side, cutting from above downward on the right side, and from below upward on the left side.

Operation.—Accurately determine the *line* of the artery, and make an incision at a slight angle to this line, avoiding subcutaneous veins, and holding the scalpel like a fiddle-bow or a dinner-knife while cutting the superficial parts, and like a pen while incising the deeper parts. On reaching the deep fascia make out the required muscular gap by the eye and finger, so moving the extremity as to bring individual muscles into action. Treves ("Operative Surgery") cautions us not to depend upon the yellow line of fat, which often cannot be seen in emaciated people or when an Esmarch bandage is employed; nor upon the white line due to attachment to the fascia of an intermuscular septum. In opening the deep portion of the wound relax the bounding muscles by altering the posture. Open a muscular interspace by a sharp knife, not by a dissector. Make the depths of the wound as long as the superficial incision. Do not tear structures apart with a grooved director; cut them. Arrest hemorrhage as it occurs. Try to find the situation of the artery with the finger. Pulsation is present, but it may be very feeble and hard to detect. The artery feels like a very thin rubber tube; it is compressible, though not so easily as a vein, and when compressed



1. Opening the Sheath for Ligation of an Artery (Guerin). 2. Sheath of Artery Open (Guerin). 3. Tightening the Knot in Ligation (Guerin). 4. Anatomy of the Iliac Arteries, and showing the lines of incision for their ligation: 1, Abernethy's incision (Guerin). 5, 6. Ballance and Edmunds' Stay-knots.

feels like a flat band which is thinner in the center than at the edges. A nerve feels like a hard, round cord. Veins are soft, larger than their related arteries, and so very compressible that they can scarcely be felt when pressed upon, and compression causes distal distention. If the wound can be seen into clearly, it will be noted, as Treves ("Operative Surgery") asserts, that "the nerves stand out as clear, rounded, white cords; that the veins are of a purple color and of somewhat uneven and wavy contour; that the artery is regular in outline and of a pale-pink or pinkish-yellow tint, the large vessels being of lighter color than the small." Each artery of the upper extremity and each artery below the knee is accompanied by two veins, known as "venæ comites." The arteries of the head and neck, except the lingual, have each a single attending vein; the lingual has venæ comites. Most of the smaller arteries of the trunk (pudic, internal mammary, etc.) have venæ comites. These companion veins may lie on each side of the artery or in front and back of it, and they communicate with one another by transverse branches crossing the artery. On reaching the sheath pick up this structure with toothed forceps so as to make a transverse fold, and thus avoid catching the artery or vein; lift the fold to see that it is free, and open the sheath by cutting toward the edge of the forceps with a scalpel held obliquely with its back toward the vessel, thus making a small longitudinal incision (Pl. 3, Figs. 1, 2). Hold the edge of the incised sheath with the forceps; pass a metal dissector under the vessel and from the forceps; this clears one-half of the vessel. Grasp the other edge of the sheath and pass the blunt dissector all the way around the vessel. Pass an aneurysm needle

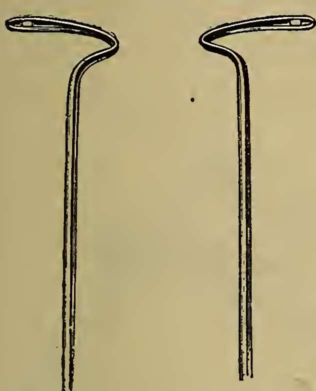


Fig. 240.—Dupuytren's aneurysm needles.

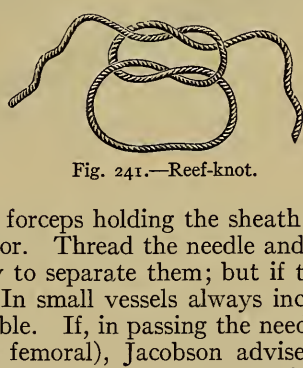

Fig. 241.—Reef-knot.

under the cleared vessel, away from the forceps holding the sheath and away from the vessel's most dangerous neighbor. Thread the needle and withdraw it. If venæ comites are in the way, try to separate them; but if this proves difficult, include them in the ligature. In small vessels always include them if they are in the way, as this saves trouble. If, in passing the needle, a large vein is severely wounded (such as the femoral), Jacobson advises the employment of digital pressure in the lower portion of the wound while the artery is being tied on a level above or below that of the vein injury, and after ligation the maintenance of pressure on the wound for a couple of days. A slight puncture in a vein merely requires a lateral ligature. A small wound can be closed with Lembert sutures of fine silk. After getting a ligature under an artery press for a moment upon the artery over the ligature, which is held taut; this pressure will arrest pulsation below if the ligature is around the main artery and there is not a double vessel. Tie the thread at right angles to the vessel with a reef-knot (Fig. 241), rupturing the internal and middle coats. As the ligature is tightened place the extended index-fingers along the ligature up to the artery (Pl. 3, Fig. 3), using the middle joints as the fulcrum of a lever by placing them against each other.

Ballance and Edmunds claim, as Scarpa and Sir Philip Crampton claimed long since, that it is not necessary to divide the internal and middle coats to

insure obliteration. If this claim be true, the danger of secondary hemorrhage can be greatly lessened. Holmes, however, thinks the older method the more certain of the two. Ballance and Edmunds use floss silk as a ligature material, because it is soft, broad, and flat, and they surround the artery with a double ligature. These surgeons thus describe the application of the stay-knot: "The best way of tying two ligatures is to make on each separately, and in the same way, the first hitch of a reef-knot, and to tighten each separately so that the loop lies in contact with the vessel without constricting it. Then taking the ends on one side together in one hand and the two ends on the other side in the other hand, constrict the vessel sufficiently to occlude it, and finally complete the reef-knot. The simplest way of completing the knot is to treat the two ends in each hand as a single thread and to tie as if completing a single reef-knot." This knot is shown in Pl. 3, Figs. 5, 6. The stay-knot applied by this method is of great value if a vessel be atheromatous.

The chief dangers after ligation are secondary hemorrhage and gangrene. Rigid asepsis usually prevents the first; rest, elevation, and heat antagonize the second.

Radial Artery.—The *line* of the radial artery is from the middle of the front of elbow-joint to the ulnar side of the styloid process of the radius. The *line* in the tabatière is from the apex of the styloid process to the posterior angle of the first interosseous space (Fig. 242).

Fig. 242.—Lines of incision for ligation of the axillary (third portion), brachial, radial, and ulnar arteries (MacCormac).

Anatomy (Pl. 4, Fig. 5).—The radial artery, though smaller than the ulnar, is the direct continuation of the brachial. It arises from the bifurcation of the brachial ½ inch below the bend of the elbow, runs down the radial side of the forearm to the front of the styloid process of the radius, passes beneath the extensor muscles of the first metacarpal bone and of the first phalanx of the thumb, and over the carpus to the first interosseous space. It is crossed by the tendon of the extensor secundi internodii pollicis, enters into the palm between the heads of the first dorsal interosseous muscle, and forms the deep palmar arch. The artery in the upper two-thirds of its course is somewhat overlaid by the supinator longus muscle; in the lower one-third of the forearm it is superficial. In the upper third of the forearm it lies between the supinator longus on the outside and the pronator radii teres on the inside; in the lower two-thirds of the forearm it lies between the supinator longus on the outside and the flexor carpi radialis on the inside. Two venæ comites attend the vessel. The radial nerve is to the outer, or radial, side of the artery, well removed from the artery in the upper third, nearer to the artery in the middle third, far external to the artery in the lower third, the nerve at this point passing beneath the supinator longus muscle. The radial artery from above downward rests upon the biceps tendon, the supinator brevis, the flexor sublimis, the pronator radii teres, the flexor longus pollicis, the pronator quadratus muscles, and the radius. The best guide to the

radial artery in the forearm is the outer edge of the flexor carpi radialis muscle or the inner edge of the supinator longus muscle.

The tabatière anatomique of Cloquet, or the anatomical snuff-box, is a triangle whose base is the lower edge of the posterior annular ligament, the ulnar side being formed by the extensor secundi internodii pollicis tendon, the radial side by the extensor ossis metacarpi and the extensor primi internodii pollicis tendons; the floor consists of the trapezium, scaphoid, their dorsal ligaments, and the base of the first metacarpal bone.

Operations.—*Ligation in the tabatière* is a dissecting-room operation of but little practical use. The patient is placed in a recumbent position, the arm is abducted, and the forearm is placed midway between pronation and supination (Barker). The surgeon stands upon the side operated upon. An incision 2 inches in length is made along the radial border of the extensor secundi internodii pollicis muscle. The skin and superficial fascia are cut and some venous branches are divided. The deep fascia is incised, and the vessel is easily found and tied before it passes between the heads of the first dorsal interosseous muscle (Barker).

Ligation of the Lower Third.—In this operation (Pl. 4, Fig. 6, and Fig. 242) the patient is placed supine, the arm is abducted, the forearm is supinated, is rested upon a table, and is held by an assistant. The surgeon stands on the side operated upon, and cuts from above downward on the right forearm and from below upward on the left forearm. The line of the vessel should be determined, and may be indicated with iodin. An incision $1\frac{1}{2}$ inches in length is made at a slight angle to this line and midway between the supinator longus and the flexor carpi radialis muscles, which incision must not extend below the level of the tuberosity of the scaphoid bone. In the superficial fascia watch for the superficial radial vein, and if it comes into view push it aside. Incise the superficial fascia and locate each guide-tendon. Open the deep fascia in the length of the first cut; try to separate the veins, but if they strongly adhere include them in the ligature. There is no special fascial sheath. The radial nerve will not be seen, but a division of the anterior cutaneous nerve is frequently found in relation with the vessel. The needle can be passed in either direction. A high origin of the superficialis volæ artery is confusing.

Ligation of the Middle Third.—In this operation the position of the patient should be the same as in the preceding. A 2-inch incision is made. Veins of the subcutaneous tissues are avoided. Lying upon the deep fascia is the anterior division of the musculocutaneous nerve. Open the fascia; find the inner edge of the supinator longus muscle and draw it outward, flexing the elbow partly if necessary. Be sure not to cut external to this muscle. Find the vessel where it is bound down by connective tissue to the pronator radii teres muscle, separate the veins, and pass the ligature from without inward. The nerve is external.

Ligation of the Upper Third (Pl. 4, Fig. 6, and Fig. 242).—For this operation the incision is as described above, only higher up. The artery is between the supinator longus and the pronator radii teres, which muscles are at once differentiated by the different direction of their fibers. The artery is usually covered by the supinator longus muscle, which must be retracted externally. The nerve is not seen. The ligature may be passed in either direction.

Ulnar Artery.—No one *line* will overlie the entire ulnar artery. The line of the upper third runs from the middle of the front of the elbow-joint to the point of junction of the upper and middle thirds of the ulna. The line of the lower two-thirds runs from the tip of the internal condyle of the humerus to the radial side of the pisiform bone (Pl. 4, Figs. 5, 6; Fig. 242).

Anatomy (Pl. 4, Fig. 5).—The ulnar artery arises from the brachial bifurcation and runs obliquely inward under the median nerve and a group of muscles from the internal condyle; it turns down the arm, being covered in the middle third of its course by the flexor carpi ulnaris muscle. In the lower third it is superficial, between the tendons of the flexor carpi ulnaris on the inside and the flexor sublimis digitorum on the outside, the vessel being a little overlapped by the flexor carpi ulnaris. This vessel rests first upon the brachialis anticus muscle, next upon the flexor profundus, to which it is bound by a distinct process of fascia, and next upon the annular ligament, which structure it crosses to become the superficial palmar arch. Two venæ comites attend the vessel. In the upper third the ulnar nerve is well internal, but in the lower two-thirds the nerve lies near the artery and to its ulnar side. The guide is the outer edge of the flexor carpi ulnaris.

Operations (Pl. 4, Fig. 6, and Fig. 242).—*Ligation of the Lower Third.*—The position in this operation is the same as for ligation of the radial artery. Make a 2-inch incision to the radial side of the tendon of the flexor carpi ulnaris, which incision should not be taken lower than a point 1 inch above the pisiform bone. Avoid the superficial ulnar vein in the subcutaneous tissue. Open the deep fascia, find the tendon of the flexor carpi ulnaris, flex the wrist and draw the tendon inward, open a second layer of fascia, clear the vessel, separate the veins, and pass the ligature from within outward to avoid the nerve. On the artery is the palmar cutaneous branch of the ulnar nerve, and this branch must not be included in the ligature.

Ligation of the Middle Third (Pl. 4, Fig. 6).—In this operation the position is the same as in the preceding one, the incision being 3 inches long. Avoid the anterior ulnar vein and the branches of the internal cutaneous nerve in the superficial fascia. Open the deep fascia a little external to the superficial cut (Treves). Find the space between the flexor carpi ulnaris and the superficial flexor, feeling with the index-finger, and when the space is discovered flex the wrist, retract the flexor carpi ulnaris inward and the flexor sublimis digitorum outward, open the fascia, find the ulnar nerve, look external to it for the artery, clear the vessel, separate the venæ comites, and pass the needle from within outward. The ulnar artery should not be ligated in continuity in the upper third of its course.

Brachial Artery.—The *line* of the brachial artery is from the junction of the anterior and middle thirds of the outlet of the axilla, the arm being abducted and the forearm supinated, to the middle of the front of the elbow-joint (Fig. 242).

Anatomy (Pl. 4, Fig. 1).—The brachial artery is the prolongation of the axillary, and extends from the lower edge of the teres major muscle to ½ inch below the bend of the elbow, where it divides into the radial and ulnar arteries. It lies first to the inner side of the arm, but passes to the front of the elbow. It is crossed by no muscle, and is, in fact, superficial, barring its being somewhat overlaid in part of its course by the edge of the biceps muscle. The median nerve is external above, crosses over the vessel about the middle of the arm, and reaches the inner side of the artery. The coracobrachialis and biceps muscles are external, and both often overlap the vessel. The ulnar nerve is internal above, and the median nerve is internal below the middle. The basilic vein is to the inner side of the artery, being outside the deep fascia to near the middle of the arm, at which point it pierces it. The artery above is separated from the long head of the triceps by the musculospiral nerve and superior profunda artery and vein; it rests from above down on the inner head of the triceps, the coracobrachialis, and the brachialis anticus muscles. The artery is covered by skin, by superficial fascia, and by deep fascia. The internal cutaneous nerve lies in front of

the artery, upon the deep fascia, until it pierces the fascia along with the basilic vein. The artery has venæ comites, and in its upper half has also the basilic vein to its inner side. The guide to the brachial is the inner edge of the biceps muscle. Just in front of the elbow-joint the artery lies in a triangle, the base of which is formed by an imaginary transverse line above the condyles, and the apex by the junction of the pronator radii teres and the supinator longus muscles. The outer line is the supinator longus, the inner line is the pronator radii teres, and the floor is formed by the brachialis anticus and the supinator brevis muscles. From within outward the triangle contains the median nerve, brachial artery, tendon of the biceps, anastomosis of the superior profunda and radial recurrent arteries, and the musculospiral nerve.

Operations.—*Ligation at the Bend of the Elbow.*—In this operation (Pl. 4, Fig. 2, and Fig. 242) the patient is placed supine, the arm is moderately abducted and extended, and is allowed to lie upon its posterior aspect. The forearm is supinated. The surgeon stands upon the side operated upon, and cuts from above downward on the right side and from below upward on the left side. The tendon of the biceps and the median basilic vein must be accurately located. An incision is made parallel to the inner edge of the biceps tendon and 2 inches in length, the center of this cut being in the crease of the elbow. On exposing the median basilic vein, retract it downward and inward, open the bicipital fascia, clear the artery of fat, separate the venæ comites, and pass the ligature from within outward to avoid the median nerve. The above operation is not frequently performed.

Ligation in the Middle of the Arm (Fig. 242).—In this operation the patient is placed supine, the arm is abducted, and the forearm is supinated. An assistant holds the forearm, but the arm should not rest upon the table, because, if it be allowed to do so, the inner head of the triceps will be forced forward and may overlie the artery, and thus complicate the operation. Locate the inner edge of the biceps, which is the guide. Make an incision 3 inches in length in the line of the artery. Incise the skin and fascia, flex the elbow slightly, retract the biceps outward, feel for the artery, open the sheath, separate its venæ comites, and, having located the median nerve, pass the ligature from it. In the middle of the arm the nerve is in front of the vessel, above the middle it is external to it, and below the middle it is internal to it. High up the arm the inner edge of the coracobrachialis is the guide, rather than the biceps. Above the middle of the arm the basilic vein is beneath the deep fascia and passes along by the inner side of the artery; hence, high up the artery has three companion veins, the venæ comites and the basilic vein, and there is seen the ulnar nerve to the inside of the artery.

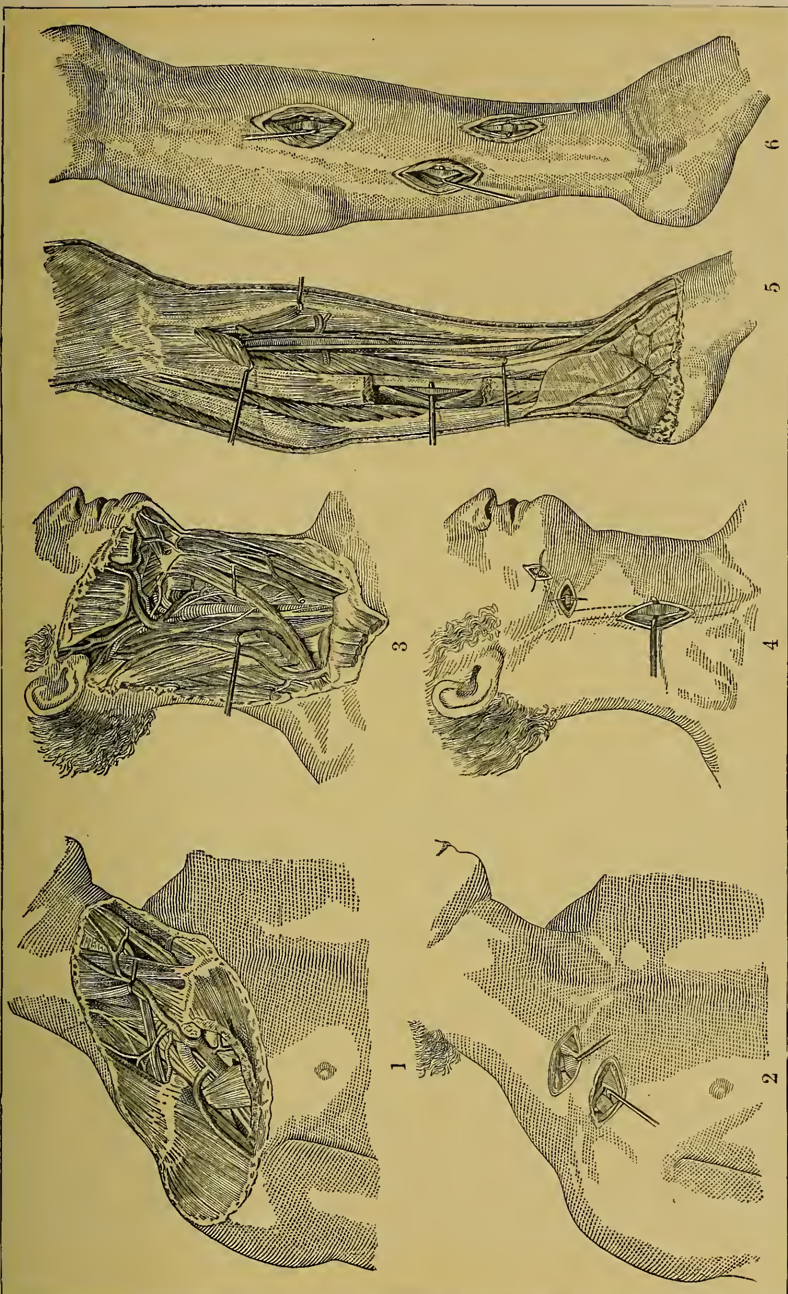
Axillary Artery.—To determine the *line* of the axillary artery place the arm at a right angle to the body, with the patient supine, and lay down a line from the middle of the clavicle to the humerus near the inner border of the coracobrachialis. The line of the third portion can be approximated by projecting the line of the brachial upward (Fig. 242).

Anatomy (Pl. 4, Fig. 3; Pl. 5, Fig. 1).—The axillary artery is the continuation of the subclavian, and runs from the lower margin of the first rib to the inferior border of the teres major muscle. It is divided into three portions by the pectoralis minor muscle. The first portion is above, the second portion is behind, and the third portion is below, the pectoralis minor. The position of the artery varies with the position of the limb. When the arm is parallel with the body the artery is far from the surface and forms a curve whose convexity is upward and outward. When the arm is at a right angle to the body the vessel is nearer the surface and straight. When the arm is raised above a right angle the artery comes near the surface and forms a curve with the convexity downward.

The first portion of the axillary artery is occasionally ligated. It lies upon the first intercostal muscle and the first serration of the great serratus muscle, and has behind it the posterior thoracic nerve; the brachial plexus is external and posterior to the vessel; on its inner side is the axillary vein; in front of it are the clavicle, the great pectoral muscle, the subclavius muscle, the costocoracoid membrane, the cephalic and acromiothoracic veins, and the external anterior thoracic nerve. The branches of the first part of the axillary artery are the superior thoracic and the acromiothoracic. The second part of the artery is not ligated. The brachial plexus surrounds the second portion. The third part is covered in front, above, by the great pectoral, but is covered below by skin and fascia; behind, it has the tendon of the subscapularis, the latissimus dorsi, and the teres major muscles; the coracobrachialis is on the outer side; the axillary vein is on the inner side. It is important to remember that there may be three veins, one external and two internal. The axillary vein is formed by the venæ comites of the brachial artery joining, and this new vein effecting a junction with the basilic vein. The median nerve lies upon the axillary artery in the upper part of the third portion of the vessel's course, and passes to the outer side. The musculocutaneous nerve is external, but it is only seen high up; the ulnar nerve is internal; the lesser internal and the internal cutaneous nerves are internal; the musculospiral and the circumflex nerves are behind. The branches of the third portion of the axillary artery are the subscapular and the anterior and posterior circumflex.

Operations.—*Ligation of the Third Portion* (Pl. 4, Fig. 4, and Fig. 242).—The position of the patient should be supine, with the shoulders raised and the arm abducted to a right angle. The surgeon stands between the patient's arm and side, with his back toward the subject's feet. An incision is made 3 inches in length. It begins half-way up the axilla opposite to the head of the humerus, and is taken downward parallel to the lower edge of the great pectoral muscle and crosses the junction of the anterior and middle thirds of the outlet of the axilla. The integuments and fascia are incised. The vein or veins will be prominent to the inner side and may ovelie the vessel. To the inner side with the veins are the ulnar and internal cutaneous nerves. The median nerve is upon, and the external cutaneous is to the outer side of, the artery. Feel for the pulsations of the artery, find the median nerve, and draw it outward, draw the nerves and veins which lie to the inner side inward, clear the artery from the venæ comites, and pass the ligature from within outward. Apply the ligature well below the circumflex branches.

Ligation of the First Part.—This operation (Pl. 5, Fig. 2, and Fig. 244) was first performed in 1815 by Chamberlaine, of Jamaica. The patient is placed supine, the upper part of the body being raised, a sand-pillow being placed between the scapulæ to insure carrying back of the point of the shoulder, and the arm being brought down along the side. In operating on the left side the surgeon stands on the outer side of the left arm; in operating on the right side he stands to the right of the subject's head and leans over his shoulder. The incision, which is slightly curved downward, begins external to the sternoclavicular joint and ends internal to the margin of the deltoid, thus avoiding the cephalic vein. The incision is ½ inch below the clavicle (Fig. 244). Incise the skin, platysma myoides muscle, and deep fascia. In the outer angle of the wound watch for the acromiothoracic artery and the cephalic vein. Incise the pectoralis major; draw the pectoralis minor downward; retract the lower margin of the wound, cut through the costocoracoid membrane close to the coracoid process and the upper border of the lesser pectoral muscle. Bring the arm to the side so as to relax the structures. Find the brachial plexus, feel for the artery internal to it, clear the vessel, draw the vein internally, and



1, Anatomy, 2, Ligation, of the Subclavian Artery and First Part of the Axillary Artery. 3, Anatomy of the Neck. 4, Ligation of the Carotid, Lingual, and Facial Arteries. 5, Anatomy, 6, Ligation, of the Anterior Tibial and Peroneal Arteries. (From Bernard.)

pass the needle from within outward. This avoids the dangerous neighbor, which is the axillary vein. This operation is difficult, dangerous, and unusual, and in its performance the axillary vein, which has a close attachment to the costocoracoid membrane, is apt to be torn.

Subclavian Artery.—The subclavian artery was first successfully tied by Post, of New York, who applied a ligature about the third portion of the vessel in 1817. In 1809 Sir Astley Cooper attempted to tie the first part of the left subclavian, but abandoned the operation because he feared he had wounded the thoracic duct. The first part of the subclavian was first tied by Colles in 1818 (Treves's "Manual of Surgery"), but the patient died. At the present day the first and second portions are rarely ligated. Professor Halsted in 1892 successfully tied the first portion of the left side for aneurysm. Schumpert tied it successfully for aneurysm. I assisted Dr. Nassau, of St. Joseph's Hospital, Philadelphia, in a ligation of the first part of the right subclavian. The man suffered from a ruptured traumatic aneurysm of the third portion of the vessel. The operation was followed by recovery. Chilton produced a cure of an aneurysm of the third portion of the subclavian of the right side by tying the first portion, and twenty-four hours later tying the first portion of the axillary. Curtis, in 1897, and Allingham, in 1899, ligated the first part successfully. Neff, of Spokane, successfully ligated the first part of the left subclavian ("Annals of Surgery," Oct., 1911). I tied the first part of the right subclavian and the first part of the common carotid for innominate aneurysm. The aneurysm was apparently cured. I also tied the third part of the right subclavian and the first part of the carotid for an innominate aneurysm. The patient apparently recovered, but many months later developed an aneurysm at the point of carotid ligation. There is no *line* for this vessel.

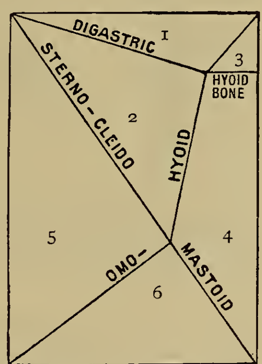


Fig. 243.—The triangles of the neck, right-sided view: 1, Submaxillary triangle; 2, "triangle of election," or superior carotid triangle; 3, submental triangle; 4, "triangle of necessity," or inferior carotid triangle; 5, occipital triangle; 6, subclavian triangle (after Keen).

Anatomy (Pl. 5, Fig. 1).—The subclavian artery of the right side arises from the innominate; that of the left side, from the arch of the aorta. The subclavian is divided into three parts: the first part runs from the origin of the vessel to the inner border of the scalenus anticus muscle; the second part lies behind the scalenus anticus muscle, and the third part runs from the outer edge of the muscle to the lower border of the first rib. The third portion is contained in the subclavian triangle (Fig. 243), and is superficial. It rises, as a rule, to ½ inch above the clavicle. The subclavian vein is below the artery, being separated from it by the scalenus anticus muscles. The brachial plexus is above and external to the artery. The vessel rests upon the first rib, and behind it is the scalenus medius muscle. The suprascapular and transversalis colli arteries and veins and branches of the cervical plexus of nerves lie in front of the artery, and the external jugular vein crosses it at its inner side. The third portion gives off no branches.

Ligation of the Third Part (Pl. 5, Fig. 2, and Fig. 244).—The patient is placed upon his back, the shoulders are raised, the head is extended and turned toward the opposite side, the arm is pulled down and held by pushing the forearm under the patient's back (Treves). This pulls down the clavicle, thus increasing the size of the subclavian triangle. The operator stands facing the shoulder, with his back toward the patient's feet. The skin over the sub-

clavian triangle, at a point ½ inch above the clavicle, is drawn down until it overlies the bone and is incised. This maneuver enables the surgeon to avoid the external jugular vein and to make an incision in the skin ½ inch above the collar-bone. The incision reaches from the anterior edge of the trapezius to the posterior border of the sternocleidomastoid (Pl. 5, Fig. 2, and Fig. 244), and is about 3 inches long. This incision divides the skin, superficial fascia, the platysma myoides, the vein running from the cephalic to the external jugular, and some superficial nerves. The deep fascia is opened. The external jugular vein is drawn into the inner angle of the wound, and is not divided unnecessarily; if forced to divide the vein, tie with two ligatures and cut between them. The surgeon seeks to find the outer edge of the anterior scalene muscle, and runs the finger down along it to the tubercle on the first rib. The posterior belly of the omohyoid muscle is drawn upward by an assistant. The surgeon, with a finger on the tubercle, recalls the facts that the vein is in front of the finger and the artery is behind it, and that the subclavian vein is on a lower plane than the artery. The artery is felt beating as it lies upon the rib. The artery is cleared and the lower cord of the brachial plexus is exposed. The vein must be guarded with the finger and the needle is passed from above downward, as the plexus, which is in more danger than the vein, is to be avoided. In this operation the transversalis colli and suprascapular arteries must not be cut, as they are necessary to the future anastomotic circulation. If the field of operation is too small, the trapezius or sternocleidomastoid, or both should be partly divided transversely.

Fig. 244.—Position of the lines of incision of temporal, facial, lingual, common carotid (above the omohyoid), subclavian, axillary (first portion), and internal mammary arteries (MacCormac).

Results.—Before the days of antisepsis ligation of the subclavian was a very fatal operation. Poland estimated the mortality at 70 per cent. In most cases death was due to secondary hemorrhage. Koenig collected 20 cases of ligation of the first part of the right subclavian, with 19 deaths. Lilienthal believes that the mortality after ligating the first portion on the right side is now only 16 per cent. (quoted by Neff in "Annals of Surg.," Oct., 1911). According to Joseph D. Bryant, there have been 134 deaths in 250 ligations at various points of the subclavian ("Operative Surgery"). I have twice tied this vessel with success. Gangrene seldom follows ligation of the subclavian. In 42 recoveries after ligation of various points there was 1 case of gangrene of the arm (Poiret's statistics, quoted by Neff in "Annals of Surg.," Oct., 1911). In Von Bergmann's 90 ligations for gunshot-wounds there was not a case of gangrene of the arm and only 3 of gangrene of the fingers.

The **vertebral artery** was first successfully ligated by Smythe, of New Orleans, in 1864. He had ligated the innominate for aneurysm of the subclavian and at the same time tied the common carotid. Secondary hemor-

rhage occurred, the blood coming from the brain. He arrested it by tying the vertebral.

Anatomy.—This vessel is the largest branch of the subclavian, and is the first branch coming from the first portion of the subclavian. The vertebral artery ascends and enters the foramen in the transverse process of the sixth cervical vertebra (in rare cases the fifth or the seventh), and ascends through foramina in the cervical vertebræ, passes behind the articular process of the atlas and over the posterior arch of this first vertebra, pierces the posterior occipito-atloid ligament, and enters the skull by way of the foramen magnum ("Gray's Anatomy"). It joins its fellow of the opposite side to form the basilar artery. At its point of origin the vertebral artery has in front of it the internal jugular vein and inferior thyroid artery. Near the spine it lies between the longus colli and scalenus anticus muscles, and on the left side has the thoracic duct to the left and in front.

Ligation.—The position of the patient is the same as for ligation of the carotid artery. Alexander thus describes the operation: "An incision 3 or 4 inches long is made in an upward and outward direction along the hollow which exists between the scalenus anticus and the sternomastoid muscles. The incision should begin just outside and on a level with the point where the external jugular vein dips over the edge of the sternomastoid muscle, or, if the vein is invisible, about $\frac{1}{2}$ inch above the clavicle. The external jugular vein is drawn inward with the sternomastoid muscle. The connective tissue now appearing, the wound is opened by a blunt dissector until the scalenus anticus muscle, the phrenic nerve, and the transverse cervical artery are seen. It cannot be too well remembered that the pleura is at the inner side of the wound, while below lies the subclavian artery. It is now only necessary to separate the edges of the scalenus anticus and the longus colli muscles to see the vertebral artery lying in the space between them. The artery is generally completely covered by the vein, which is drawn aside, and the artery is then ligatured" (quoted in Bryant's "Operative Surgery"). When the vessel is cleared and tied, branches of the inferior cervical ganglion are damaged and possibly included in the ligature, and as a consequence the pupil contracts. Jacobson tells us to remember that the phrenic nerve lies on the scalene muscle, the pleura is internal, the internal jugular, inferior thyroid, and vertebral veins are over the vessel, and the thoracic duct on the left side crosses it from within outward.

Results.—In 36 ligations of the vertebral artery there were 3 deaths (Joseph D. Bryant).

The Inferior Thyroid Artery.—**Anatomy.**—The inferior thyroid artery is a branch of the thyroid axis. It ascends the neck, passes back of the carotid sheath and the sympathetic nerve, and reaches the thyroid gland. The recurrent laryngeal nerve lies behind the artery. The phrenic nerve is external to the artery and near to it in the first part of its course (up to the point of origin of the ascending cervical branch). The ascending cervical branch takes origin just before the artery begins to dip behind the carotid. In front of the beginning of the inferior thyroid artery of the left side the thoracic duct crosses. The artery is ligated in the second part of its course (between its distribution and the origin of the above-named branch).

Ligation.—The position of patient and the incision are the same as for the ligation of the common carotid artery in the triangle of necessity (see page 480). After exposing the sternocleidomastoid muscle retract it outward, and then draw outward the common carotid artery and also the internal jugular vein. The inferior thyroid artery will be found a little below the carotid tubercle. It is cleared and ligated. Treves advises ligation close to the level of the carotid, so as to avoid the recurrent laryngeal nerve.

Innominate Artery.—First successfully ligated by Smythe, of New Orleans, in 1864.

Anatomy.—The innominate artery arises from the beginning of the transverse portion of the arch of the aorta, passes to the back of the right sterno-clavicular joint, and divides into the common carotid and subclavian vessels. It rests upon the trachea. It has upon its outer side the pleura, the right innominate vein, and the pneumogastric nerve. Upon its inner side are the remnant of the thymus gland and the beginning of the left carotid artery. In front of it are the inferior thyroid veins of the right side, the left innominate vein, the sternohyoid and sternothyroid muscles, the remnant of the thymus gland, and sometimes a branch from the right pneumogastric nerve.

Ligation.—Place the patient supine, with the shoulders a little raised, and the head thrown back. Carry an incision from the upper margin of the sternum for 3 inches along the anterior margin of the sternomastoid. Make another cut of the same length along the upper border of the clavicle to meet the first cut. Dissect up the flap of skin and fascia. Divide the sternal origin and a part of the clavicular portion of the sternocleidomastoid muscle, and cut the sternohyoid and sternothyroid muscles just above their sternal origins (Joseph Bell). Retract the inferior thyroid veins. Divide the dense leaflet of cervical fascia. Find the common carotid artery, and trace back along this vessel until the innominate comes into view. Retract the left innominate vein downward. The needle is passed from without inward to avoid the right innominate vein and right pneumogastric nerve. If the needle is kept close to the artery the pleura and trachea will not be injured.[1]

Results.—Burns, of Memphis, collected 45 cases and added 1 of his own, making 46 cases, with 9 recoveries ("Jour. Am. Med. Assoc.," 1908). To these should be added Percy Sargent's successful case ("Lancet," May 6, 1911), making 47 cases and 10 recoveries. Burrell's case in 1895 is counted as a success, although death occurred on the one hundred and fourth day. Smythe's case lived ten years. Sargent's case lived seventeen months and then died of pneumonia and pericarditis. He tied the common carotid as well as the innominate. The case of Coppinger, of Dublin, was alive and well two years after operation. Mitchell Banks's case lived over three months.

Region of the Neck.—**Anatomy.**—The side of the neck is that space between the median line in front and the anterior edge of the trapezius muscle behind, which space is limited below by the clavicle and above by the body of the jaw and an imaginary line running from the angle of the jaw to the mastoid process. The sternocleidomastoid muscle divides this space into an anterior and a posterior triangle, and each of the triangles is subdivided by other structures, the anterior into four spaces and the posterior into two (Fig. 243).

The *anterior triangle* is bounded in front by the median line of the neck, behind by the anterior margin of the sternocleidomastoid muscle, and above by the body of the lower jaw and an imaginary line drawn from the angle of the jaw to the mastoid process. This space is subdivided into four smaller triangles—namely, the inferior carotid, the superior carotid, the submaxillary, and the submental.

The *inferior carotid triangle* is called the "triangle of necessity," because the common carotid artery in this region is ligated, not from choice, but through force of necessity. It is bounded in front by the median line, above by the anterior belly of the omohyoid muscle and the hyoid bone, and below by the anterior edge of the sternomastoid muscle. The floor of this triangle is com-

[1] See the exceedingly clear and terse account in that excellent book, "A Manual of Surgical Operations," by Joseph Bell.

posed of the longus colli, the scalenus anticus, the rectus capitis anticus major, the sternohyoid, and sternothyroid muscles.

The *superior carotid triangle* is known as the "triangle of election," because, if the carotid artery must be tied, the surgeon, whenever possible, elects or chooses to tie it in this triangle. In this region the carotid is superficial, and there can be tied either the external, the internal, or the common carotid artery, as the surgeon elects. The triangle is bounded behind by the anterior edge of the sternocleidomastoid, above by the posterior belly of the digastric, and below by the anterior belly of the omohyoid muscles. Its floor is composed of the inferior and middle constrictors of the pharynx, the thyrohyoid and hyoglossus muscles.

The *submaxillary triangle* is bounded above by the body of the jaw and an imaginary line drawn from the angle of the jaw to the mastoid process, behind by the posterior belly of the digastric muscle and the stylohyoid muscle, and in front by the anterior belly of the digastric muscle. Its floor is composed of the mylohyoid and hyoglossus muscles.

The *submental triangle* is bounded on either side by the anterior belly of one digastric muscle; its base is the hyoid bone and its floor is the mylohyoid muscle.

The *posterior triangle* is bounded in front by the posterior border of the sternocleidomastoid muscle, behind by the anterior edge of the trapezius muscle, and below by the clavicle. The posterior belly of the omohyoid muscle subdivides it into two smaller spaces, the occipital and subclavian triangles.

The *occipital triangle* is bounded in front by the posterior edge of the sternocleidomastoid muscle, behind by the anterior border of the trapezius muscle, and below by the posterior belly of the omohyoid muscle.

The *subclavian triangle* is bounded above by the posterior belly of the omohyoid muscle, below by the clavicle, and in front by the posterior border of the sternocleidomastoid muscle. Its floor is formed by the first rib and the first serration of the serratus magnus muscle.

Common Carotid Artery.—The common carotid was tied to arrest bleeding by Abernethy in 1798, and was first ligated successfully for aneurysm by Sir Astley Cooper in 1806. The *line* of the common carotid artery is from the sternoclavicular articulation to midway between the angle of the jaw and the mastoid process, the head being turned toward the opposite side.

Anatomy (Pl. 5, Fig. 3).—The right common carotid arises from the innominate opposite the sternoclavicular joint; the left common carotid arises from the arch of the aorta. In the neck the two carotids possess identical relations. The common carotid runs upward and outward from behind the sternoclavicular articulation to a level with the upper border of the thyroid cartilage, at which point it divides into the external and internal carotid. The common carotid is contained in a sheath derived from the cervical fascia. This sheath also contains, in separate compartments, the internal jugular vein on the outer side of the artery and the pneumogastric nerve between the vein and artery, but more deeply placed. The anterior edge of the sternocleidomastoid muscle lies over the artery and is a guide. Low in the neck the common carotid is deep, being covered by skin, superficial fascia, platysma, deep fascia, and the sternocleidomastoid, sternohyoid, and the sternothyroid muscles. Above the omohyoid muscle the vessel is more superficial, being covered by the skin, superficial fascia, platymsa, deep fascia, and the anterior edge of the sternocleidomastoid muscle. Upon the sheath (occasionally within it), above the crossing of the omohyoid muscle, lies the descendens noni nerve—the descending branch of the ninth pair of Willis (the hypoglossal). This nerve is a valuable guide to the sheath in the triangle of election.

The *sternomastoid* branch of the superior thyroid artery crosses the carotid artery a little below its bifurcation, and the superior thyroid vein also crosses it in this region; the middle thyroid vein crosses the artery near its middle, and the anterior jugular vein crosses low down. The common carotid rests upon the longus colli and rectus capitis anticus major muscles, the sympathetic nerve lying between the last-named muscle and the vessel, outside the carotid sheath. The recurrent laryngeal nerve passes behind the carotid below the omohyoid muscle, and the inferior thyroid artery passes behind the carotid just above the omohyoid muscle. The common carotid is in relation internally with the trachea, thyroid gland, larynx, and pharynx. To the outer side are the pneumogastric nerve (which is on a posterior plane) and the internal jugular vein. On the left side, low down in the neck, the jugular vein often lies in front, or partly in front, of the artery.

Ligation in the Triangle of Necessity.—In this operation the patient is placed supine, with the shoulders raised, a sand-pillow under the neck, and the head turned to the opposite side, with the chin raised. The operator stands upon the side operated upon. The incision, 3 inches long, at a slight angle to the arterial line, runs from the level of the cricoid cartilage downward and inward toward the sternoclavicular joint, following the inner border of the sternocleidomastoid muscle. The surgeon opens the deep fascia, draws the sternocleidomastoid outward, retracts the sternohyoid and sternothyroid muscles inward, and feels for the carotid tubercle of Chassaignac. This tubercle is the costal process of the sixth cervical vertebra, and lies directly under the artery. The tubercle is found about the point at which the omohyoid crosses the carotid. When the tubercle is found we know the situation of the artery, and that the triangle of necessity is below, and the triangle of election above, the tubercle. The operator draws the omohyoid muscle upward, opens the sheath of the artery on its inner side, clears the vessel, and passes the needle from without inward to avoid the internal jugular vein, remembering that the pneumogastric nerve is in the same sheath as the artery and vein, posterior and external to the artery. In this operation the inferior thyroid veins are much in the way, the anterior jugular vein crosses low down, and on the left side, at the root of the neck, the internal jugular vein may be in front of the carotid artery. If the incision is not sufficiently wide, partially divide the sternocleidomastoid or the sternohyoid and thyroid muscles. In the triangle of necessity the descendens noni nerve does not serve as a guide to the sheath of the vessels. (See Pl. 5, Fig. 4.)

Ligation in the Triangle of Election (Fig. 244).—The *position* of the patient for this operation is the same as in the preceding one. An incision, 3 inches in length, is made along the anterior edge of the sternocleidomastoid muscle in the line of the artery, the middle of this incision being opposite the cricoid cartilage (Fig. 244). In cutting the superficial fascia the surgeon avoids the external jugular vein, the course of which should be outlined before making the incision. The line of the external jugular is from the angle of the jaw to the middle of the clavicle. The operator opens the deep fascia, retracts the sternocleidomastoid muscle outward, feels for the carotid tubercle, draws the omohyoid muscle downward, finds the descendens noni nerve upon the sheath, opens the sheath at its inner side, and passes the needle from without inward. This incision permits ligation of either the superior thyroid or the external, internal, or common carotid, and if it be extended up a little there can be tied through it the lingual and even the facial and occipital arteries. (See Pl. 5, Fig. 4.)

Results.—In from 20 to 25 per cent. of cases after ligation of the common carotid artery there is cerebral softening or some other intracranial complication. Crile states that of the cases that develop cerebral trouble, one-

half die. The direct operative mortality, according to Crile, is only 3 per cent. Some modern operators regard the mortality as much higher than this. I was obliged to tie the common carotid during an operation for tumor of the carotid gland; the patient developed hemiplegia.

External Carotid Artery.—Burke ligated the external carotid in 1827 (Treves, from Chelius). The *line* of the external carotid artery is the upper portion of the common carotid line.

Anatomy (Pl. 5, Fig. 3).—The external carotid artery, which is one of the terminal branches of the common carotid, arises on a level with the upper border of the thyroid cartilage and runs to the level of the neck of the condyle of the lower jaw. At its point of origin it is covered only by skin, platysma and fascia, and the edge of the sternomastoid, but as it ascends it passes beneath the digastric and stylohyoid muscles and into the parotid gland. The glossopharyngeal nerve, styloid process, and stylopharyngeus muscle lie between the external and internal carotid arteries. The hypoglossal nerve crosses the vessel just below the digastric muscle, and the facial and lingual veins cross it a little below the nerve. The first branch is the superior thyroid, which arises from the very beginning of the trunk. The lingual arises on a level with the greater cornu of the hyoid bone. The facial and occipital take origin above the lingual. Each of them can be ligated through the incision made for ligation of the external carotid.

Operation.—Place the patient in the same *position* as for ligation of the common carotid. The point of election is between the superior thyroid and the lingual arteries. Make an incision 3 inches in length at a slight angle to the arterial line, from near the angle of the jaw to opposite the middle of the thyroid cartilage. Cut through the skin, superficial fascia, platysma and deep fascia, and retract the sternocleidomastoid muscle outward. Watch for the digastric muscle, find the hypoglossal nerve, and feel for the greater cornu of the hyoid bone. Open the sheath a little below the hyoid cornu and pass the needle from without inward. Ligation of the external carotid has been neglected because ligation of the common carotid is easier.

Results.—Crile believes the operative mortality to be 2 per cent.

Internal Carotid Artery.—The internal carotid was tied by Keith, of Aberdeen, in 1851 (Ashhurst's "International Encyclopedia of Surgery"). The *line* of the internal carotid is parallel with and $\frac{1}{2}$ inch external to the line of the external carotid.

Anatomy (Pl. 5, Fig. 3).—The internal carotid artery, the other terminal branch of the common carotid, arises on a level with the upper border of the thyroid cartilage and enters the carotid canal. The first inch of the artery is the only point where a ligature is ever applied, this point being covered only by skin, platysma, fascia, and the sternocleidomastoid muscle; higher up the artery is more deeply placed. It rests upon the vertebræ and the rectus capitis anticus major muscle. The internal jugular vein is in the same sheath and external to the artery; the pneumogastric is in the same sheath, between the artery and the vein, but posterior to both. The superior cervical ganglion of the sympathetic lies behind the origin of the internal carotid, and between the ganglion and the artery is the superior laryngeal nerve.

Operation.—In this operation the *position* of the patient is the same as for ligation of the external carotid. The incision is of the same length and direction as that for ligation of the external carotid, and is $\frac{1}{2}$ inch external. The sternocleidomastoid muscle is drawn outward, the external carotid artery is found and drawn inward, the internal carotid is found and cleared, and the needle is passed from without inward. The internal carotid is known by its more external position and by the fact that it gives off no branches.

Results.—There is the same danger of cerebral complications after this operation as after ligation of the common carotid. The operative mortality is probably as great.

Superior Thyroid Artery (Pl. 5, Fig. 3).—This branches off from the external carotid below the level of the greater cornu of the hyoid bone, in the triangle of election. It is primarily superficial, runs first upward and inward, next downward and forward, passes underneath the omohyoid, sternohyoid, and sternothyroid muscles, and reaches the thyroid gland.

Ligation.—The position of the patient and of the surgeon is the same as for ligation of the carotid. The artery may be reached through the incision employed for ligation of the external carotid. Gross made an incision beginning at the edge of the hyoid bone, and running downward and outward to the sternomastoid muscle. The skin and superficial and deep fasciæ are divided, and the artery is found deeply placed in the triangle of election between the carotid sheath and the thyroid gland.

Lingual Artery.—Charles Bell ligated the first part of the lingual artery in 1814. The operation beneath the hyoglossus muscle was devised by Pirogoff in 1836 (Treves's "Manual of Operative Surgery").

Anatomy (Pl. 5, Fig. 3).—The lingual artery arises from the external carotid opposite the greater cornu of the hyoid bone, passes beneath the digastric and stylohyoid muscles, reaches the margin of the hyoglossus muscle, passes under that muscle, and emerges from beneath it to run along the under surface of the tongue. The place of election for ligation is where the artery is beneath the hyoglossus muscle. Its guide is the hypoglossal nerve, which lies upon the muscle, but at a slightly higher level than the artery.

Operation.—In this operation the patient is placed recumbent with the shoulders raised and the face turned away from the side to be operated upon. The surgeon stands upon the affected side. A curved incision is made from a little external to the symphysis of the lower jaw, downward and outward, to just above the greater cornu of the hyoid bone, and upward and outward to just in front of the facial artery at the lower edge of the lower jaw. The skin, the superficial fascia and platysma, and the deep fascia are incised. The submaxillary gland is cleared and retracted well upward. The fascia beneath the gland is divided by a transverse incision. The posterior edge of the mylohyoid muscle and the bellies of the digastric muscle are sought for and identified. One of the digastric tendons is retracted down and out (Treves). The hyoglossus muscle is cleared with a dissector; the hypoglossal nerve and ranine vein are found and drawn a little upward. The hyoglossus muscle is divided transversely a little above the hyoid bone and below the level of the hypoglossal nerve. The artery is found under the muscle and the needle is passed from above downward.

Facial Artery.—**Anatomy** (Pl. 5, Fig. 3).—It arises from the external carotid a little above the lingual, runs upward and forward beneath the body of the inferior maxillary bone, passes along a groove in the posterior and upper surface of the submaxillary gland, crosses the body of the lower jaw at the lower anterior edge of the masseter muscle, and passes forward and upward to the angle of the mouth and side of the nose.

Ligation (Pl. 5, Fig. 4).—The facial artery is rarely ligated in the cervical portion, but may be reached through the incision employed for ligation of the external carotid. The vessel may be tied before it crosses the submaxillary gland, the stylohyoid and digastric muscles being drawn aside. The vessel is reached in the facial portion of its course by a 1-inch cut at the anterior edge of the masseter muscle (Fig. 244). Branches of the facial nerve are pushed aside. The needle is passed from behind forward to avoid the vein (Jacobson).

Temporal Artery.—The line of the temporal artery passes "upward over the root of the zygoma, midway between the condyle of the jaw and the tragus" (Jacobson).

Anatomy.—The temporal artery arises from the external carotid behind the condyle of the jaw and in the parotid gland, passes over the zygoma, and divides into two terminal branches.

Ligation.—The patient is placed recumbent and the head is turned to the opposite side. An incision 1 inch in length is made (see Fig. 244), the superficial structures and dense fascia are divided, the vein is retracted backward, and the needle is passed from behind forward.

The **occipital artery** takes origin from the posterior surface of the external carotid, below the digastric muscle and opposite the point of origin of the facial artery. It ascends beneath the digastric and stylohyoid muscles and parotid gland; the hypoglossal nerve hooks around it from behind forward. It crosses the internal carotid artery, the internal jugular vein, the pneumogastric and spinal accessory nerves; passes between the mastoid process of the temporal bone and the atlas; grooves the temporal bone; penetrates the trapezius muscle, and ascends over the occiput.

Ligation.—This vessel can be ligated near its origin through the same incision as is employed to reach the external carotid. The hypoglossal nerve is avoided. To tie back of the mastoid process, place the patient in the same position as for ligation of the carotid. Carry an incision from the tip of the mastoid upward and backward, reaching a point midway between the mastoid and the occipital protuberance (Jacobson). Cut the skin, the fascia, the sternocleidomastoid, the splenius capitis, and possibly a portion of the trachelomastoid muscles. Bring the head toward the operator in order to relax the structures, retract the edges of the wound, and clear the artery where it lies between the mastoid process and the transverse process of the atlas (Jacobson). An electric forehead light is of great assistance in finding the vessel. Pass the needle away from the vein or veins (there are often several).

Dorsalis Pedis Artery.—The *line* of the dorsalis pedis artery is from the middle of the front of the ankle-joint to the middle of the base of the first interosseous space.

Anatomy (Pl. 6, Fig. 1).—The dorsalis pedis is a continuation of the anterior tibial artery, and it runs from the bend of the ankle to the proximal extremity of the first interosseous space, where it divides into the dorsalis hallucis and the communicating arteries. The artery rests, from above downward, upon the astragalus, scaphoid, and internal cuneiform bones, and at its point of bifurcation lies between the heads of the first dorsal interosseous muscle. It may lie in some persons a little external to this course. It is held upon the bones by a distinct layer derived from the deep fascia. This artery is covered by skin, by superficial and deep fascia, and by the annular ligament above, and is sometimes partly overlaid by the extensor proprius pollicis muscle, and is crossed, just before its bifurcation, by the innermost tendon of the extensor brevis muscle. The inner tendon of the extensor communis digitorum is to the outer side of the vessel; the tendon of the extensor proprius pollicis is to the inner side, and is a guide. The artery is ligated in the dorsal triangle of the foot—a space which is bounded above by the lower edge of the annular ligament, externally by the inner tendon of the extensor brevis, and internally by the tendon of the extensor proprius pollicis. The artery has venæ comites; the anterior tibial nerve lies, as a rule, to its inner side, but may be found upon the artery or to its outer side, and the inner division of the musculocutaneous nerve is external to the vessel in the superficial parts.

Operation (Pl. 6, Fig. 2).—In this operation the patient is placed supine with the leg and foot extended. Heath flexes the leg partly and rests the sole

of the foot directly upon the table. The surgeon stands below the extremity and cuts from above downward. Make an incision 2 inches in length along the arterial line, beginning opposite the lower edge of the annular ligament and running along by the tendon of the extensor proprius pollicis; cut through the skin and superficial and deep fascia; have the toes extended; retract the tendon of the extensor proprius pollicis inward, and the tendon of the extensor communis digitorum outward; clear the artery, find the nerve, try to separate the venæ comites, and pass the needle from the nerve.

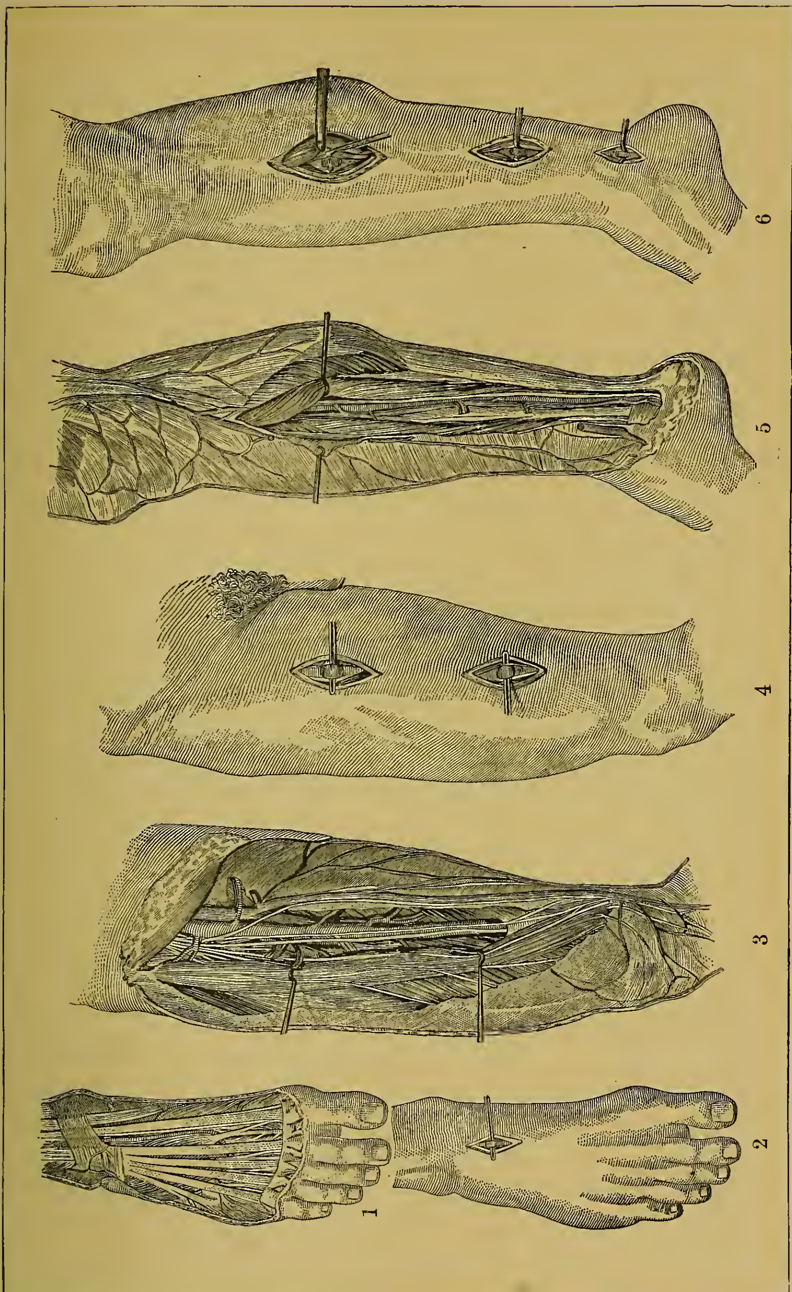
Anterior Tibial Artery.—To locate the *line* of the anterior tibial mark a point midway between the head of the fibula and the tuberosity of the tibia, drop 1 inch, and draw a line from the second point to the middle of the front of the ankle-joint.

Anatomy.—The anterior tibial artery is one of the terminal branches of the popliteal. It arises opposite the lower border of the popliteus muscle, passes forward between the two heads of the posterior tibial muscle, comes to the front of the leg through an opening in the interosseous membrane, and runs down to the middle of the front of the ankle-joint. In the upper two-thirds of its course it rests upon the interosseous membrane, to which it is fastened by firm fascia; in the lower third it lies first upon the front of the tibia and then upon the anterior ligament of the ankle-joint. For its upper two-thirds the artery has the tibialis anticus muscle just external to it; at the junction of the middle and lower thirds the extensor proprius pollicis comes from the outside and lies either upon the artery or to its inner side for the rest of its course. Externally in its upper third is the extensor communis digitorum; in the middle third is the extensor proprius pollicis; in the lower third, the proprius pollicis having crossed to the inner side, the extensor communis digitorum again becomes the outer boundary. The artery is covered by skin and by superficial and deep fascia. In its upper third it is deeply placed between the muscles; in its middle third it is less overlaid by muscle; in its lower third it is superficial except where it is crossed by the extensor proprius and where it is covered by the annular ligament. The artery has venæ comites. In the lower three-fourths of its course it is accompanied by the anterior tibial nerve, which in its course in the upper third of the leg is external to the artery; in the middle third it is external and a little in front of the artery; and in the lower third it is external to or upon the artery (Pl. 5, Fig. 5).

Operations.—The ligations of the anterior tibial (Pl. 5, Fig. 6) are: (1) of the lower third; (2) of the middle third; (3) of the upper third. In all these ligations the patient is placed recumbent with the leg extended, and the surgeon stands to the outer side of the extremity, cutting from above downward on the right side and from below upward on the left side.

Ligation of the Lower Third.—Make an incision 3 inches long in the line of the artery and over the annular ligament. This incision is external to the tibialis anticus muscle and ½ inch from the outer border of the tibia (Barker). Divide the skin and fascia, retract the tendon of the tibialis anticus inward, and the tendon of the extensor proprius pollicis outward, along with the tendons of the extensor communis. Flex the ankle-joint to relax the tendons and clear the artery. Draw the nerve external and pass the ligature from without inward. In order to recognize the muscles in this as in other ligations, rely largely upon the finger while the muscles are being moved.

Ligation of the Middle Third.—In this operation the procedure is similar to the above. Remember that the nerve lies in front of the vessel and that the extensor proprius pollicis muscle is external. The nerve is retracted outward and the needle is passed from the nerve. A good rule for detecting the artery is to find the outer edge of the tibia and by this locate the inter-



1, Anatomy, 2, Ligation, of the Dorsalis Pedis Artery. 3, Anatomy, 4, Ligation, of the Femoral Artery. 5, Anatomy, 6, Ligation, of the Posterior Tibial Artery. (From Bernard.)

osseous membrane, and then, by passing out along this membrane, discover the artery.

Ligation of the Upper Third.—Make an incision 3 inches long in the arterial line. On opening the deep fascia, do not rely on the eye for finding the muscular interspace, as often the latter cannot be seen, and neither a white nor a yellow line is reliable. Place the index-finger deep in the wound and have the tibialis anticus and extensor communis digitorum muscles successively rendered tense by an assistant. In opening the interspace use the handle of the knife. Relax the muscles, retract the tibialis anticus inward and draw the extensor communis digitorum outward. Find the interosseous membrane where it is attached to the edge of the tibia, and the artery will be found upon this membrane, between the tibia and the nerve. Clear the vessel and pass the ligature from without inward to avoid the nerve.

Posterior Tibial Artery.—The *line* of the posterior tibial is from the middle of the popliteal space to a point midway between the tip of the inner malleolus and the point of the heel (Pl. 6, Figs. 5, 6).

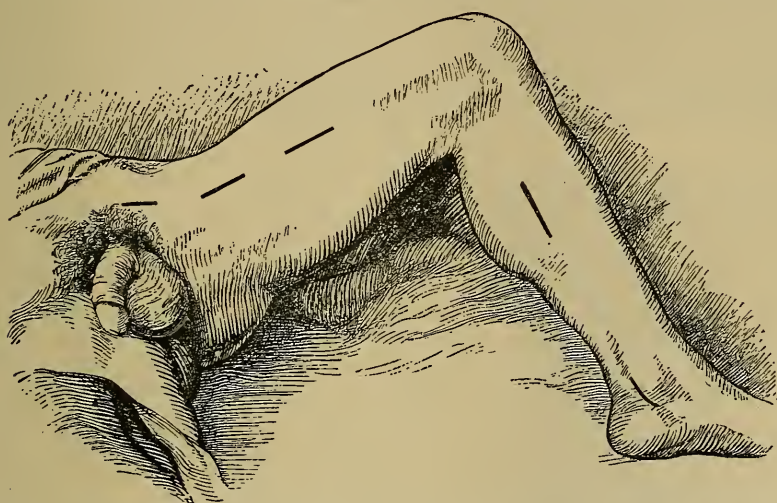


Fig. 245.—The lines indicate the incision to be made for the ligature of the common femoral, of the femoral in Scarpa's triangle and in Hunter's canal, and of the posterior tibial in the calf and behind the malleolus (MacCormac).

Anatomy.—The posterior tibial is the larger of the two terminal branches of the popliteal. It arises opposite the lower border of the popliteus muscle, passes down between the deep and superficial flexor muscles to midway between the tip of the malleolus and the point of the heel, and divides into the external and internal plantar vessels. In the upper third of its course it is very deeply placed midway between the tibia and fibula; in its middle third it is less deep, having passed inward; and in its lower third it is superficial. At the ankle the artery is beneath the annular ligament. From above downward the posterior tibial artery rests upon the posterior tibial muscle, the flexor longus digitorum muscle, the posterior surface of the tibia, and the internal lateral ligament of the ankle-joint. For the first inch or two of the course of the artery the posterior tibial nerve is to the inner side; the nerve then crosses to the outer side, and remains in that relative position throughout the rest of the course of the artery. When the knee is partly flexed and the leg is laid upon its outer surface the artery is between the operator and the nerve, and the nerve is between the artery and the table. Back of the malleo-

lus, in the first compartment, lies the posterior tibial muscle; in the next compartment is the flexor longus digitorum muscle; in the next compartment are the artery and nerve; and in the most posterior is the flexor longus pollicis muscle.

Operations.—*Ligation Back of the Malleolus.*—In this operation the patient is placed recumbent, with the thigh abducted and the leg flexed and resting upon its outer surface. The surgeon stands to the outer side. Make a 2-inch semilunar incision corresponding in its curve to the malleolus and $\frac{1}{2}$ inch posterior to its margin (Fig. 245). Cut down to the annular ligament, incise the ligament, and find the artery and venæ comites. Clear the vessel and pass the needle from behind forward (to avoid the nerve, which is here posterior and external). Do not make the preliminary incision nearer the malleolus than $\frac{1}{2}$ inch, as the sheath of the tibialis posticus muscle will then surely be opened. In closing the wound, suture the ligament by buried sutures of catgut before closing the superficial parts (Pl. 6, Fig. 6).

Ligation in the Middle of the Leg.—In this operation the patient is placed in the same position as for the ligation back of the malleolus. Feel for the inner border of the tibia, and make an incision 4 inches long 1 inch behind the osseous border, parallel with it, and extending through skin and superficial and deep fascia (Fig. 245). Draw the gastrocnemius muscle outward. Incise the soleus muscle, but not the fascia beneath the soleus; cut this fascia,

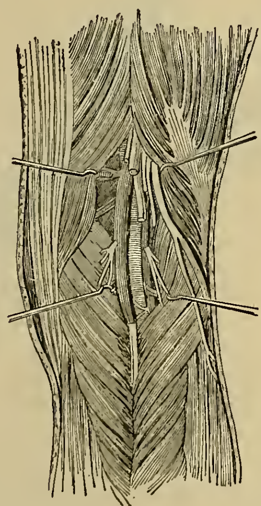

Fig. 246.—Anatomy of popliteal artery (Bernard and Huette).

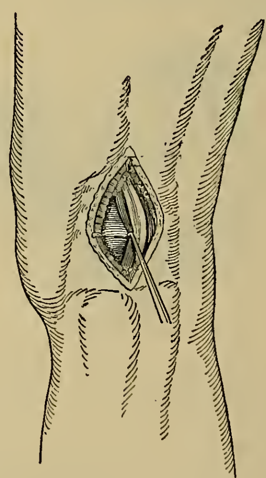

Fig. 247.—Ligation of popliteal artery in its upper third (Bernard and Huette).

after dropping the handle of the knife so that the blade is at right angles with the plane of the tibia. Clear the artery; pass the needle from without inward (Pl. 6, Fig. 6).

The **popliteal artery** is almost never ligated in continuity. It can be tied at the upper portion of the popliteal space, at the lower portion of the popliteal space, or at the inner side of the thigh.

Anatomy (Fig. 246).—The popliteal artery is the continuation of the femoral, and runs from the opening in the adductor magnus muscle to the lower margin of the popliteus muscle. This vessel runs downward and outward behind the knee-joint and in the popliteal space. The ham, or popliteal space, is a lozenge-shaped space, which above the joint is bounded on the

outer side by the biceps muscle, and on the inner side by the semitendinosus, semimembranosus, gracilis, and sartorius muscles, while below the joint it is bounded externally by the plantaris and outer head of the gastrocnemius muscles, and internally by the inner head of the gastrocnemius muscle. The floor of this space is formed by the surface of the femur, the posterior ligament of the knee-joint, the head of the tibia, and the popliteus fascia. The internal popliteal nerve passes down the middle of the popliteal space; it is superficial to the vessels in the upper half of the space, and is external to them; it is internal to the vessels in the lower half of the space. The external popliteal nerve is in the outer side of the space. The popliteal vein is between the nerve and the artery. Above the knee-joint it is to the outer side of the artery, but below the knee-joint it is to the inner side. The artery lies deeply in the space.

Ligation in Upper Third.—Place the patient prone. The surgeon stands to the outer side of the limb and makes a vertical incision 3 inches in length along the outer margin of the semimembranosus muscle, exposes the popliteal nerve, retracts the muscle inward and the nerve outward, exposes the artery, separates it from the other structures, and passes the needle from without inward (Fig. 247).

Ligation in Lower Third.—Make a 3-inch vertical incision between the heads of the gastrocnemius muscle. Avoid the external saphenous vein and nerve, and retract them with the popliteal nerve. Separate the artery from the vein and pass the needle from within outward.

Femoral Artery.—The *line* of the femoral artery is from midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, the thigh being abducted and resting upon its outer surface (Pl. 6, Fig. 3).

Anatomy.—The femoral artery is the continuation of the external iliac trunk; it extends from the lower border of Poupart's ligament to the opening in the adductor magnus muscle, and hence occupies the upper two-thirds of the thigh. The artery for its first 5 inches is superficial, lying in Scarpa's triangle, a space which is bounded externally by the sartorius muscle and internally by the adductor longus, its base being Poupart's ligament and its floor being composed of the psoas, iliacus, pectineus, and adductor longus muscles, and often the adductor brevis. The artery enters the triangle as the common femoral, but after a 2-inch course it divides into the profunda (which passes deeply) and the superficial femoral. The latter vessel is the one alluded to in this section.

At the base of Scarpa's triangle the vein is internal, the artery is between, and the nerve is external (V. A. N.). At the apex of the triangle the vein is internal and a little posterior. At the apex of the triangle the superficial femoral passes under the sartorius muscle and enters into Hunter's canal, which occupies the middle third of the thigh and which terminates at an opening in the adductor magnus muscle. Hunter's canal is bounded externally by the vastus internus muscle, internally by the adductors longus and magnus, and its roof is fascia which stretches from the adductor longus to the vastus internus. In Hunter's canal the vein is behind the artery in the upper part, but external to it in the lower part, and is firmly attached to the artery. There may be two veins. Inside Hunter's canal, but outside the femoral sheath, is the long saphenous nerve, which crosses the artery from without inward.

A way to remember the relation of the femoral vein to the femoral artery is to recall the fact that the relation of the vein to the artery is always contrary to the relation of the sartorius muscle to the artery: when the sartorius muscle is external to the artery the vein is internal, as at the base of Scarpa's

triangle; when the sartorius muscle is crossing in front toward the inside of the artery, the vein is passing at the back to the outside, as at the apex of Scarpa's triangle; when the muscle is over the artery the vein is back of it, as in the upper third of Hunter's canal; and when the muscle is to the inside of the artery the vein is to the outside, as in the lower two-thirds of Hunter's canal. In a ligation at the apex of Scarpa's triangle the inner edge of the sartorius is the guide. In a ligation in Hunter's canal the long saphenous nerve is the guide.

Operations.—*Ligation of the Superficial Femoral at the Apex of Scarpa's Triangle.*—In this operation the *position* of the patient is supine, with the thigh and leg partly flexed, and the thigh abducted, everted, and rested upon its outer surface on a pillow. The operator stands to the outer side of the extremity. From a point corresponding to the middle of Scarpa's triangle, and 2½ inches below Poupart's ligament, make a 3-inch incision in the arterial line (Fig. 245). Cut the skin and superficial fascia. The saphenous vein will not be seen unless the incision is internal to the arterial line; if this vein is seen, draw it inward. Open the fascia lata, find the inner border of the sartorius muscle, and draw it outward. The fibers of this muscle run downward and inward, thus distinguishing it from the adductor longus, whose fibers run downward and outward. Open the common sheath for the artery and vein, and then incise the individual arterial sheath. Clear the artery and pass the ligature from within outward (Pl. 6, Fig. 4).

Ligation of the Superficial Femoral in Hunter's Canal.—This operation was first performed for aneurysm by John Hunter in 1785. In this operation the *position* of the patient is the same as in the ligation at the apex of Scarpa's triangle. Make a 3-inch incision in the middle third of the thigh, parallel with the arterial line and ½ inch internal to it (Barker) (Fig. 245). Incise the skin and superficial fascia, look out for the internal saphenous vein, open the fascia lata, find the sartorius muscle, and retract it inward, thus exposing the roof of Hunter's canal, which is to be opened for 1 inch or more. Within the canal is seen the long saphenous nerve, usually upon the sheath. Open the sheath of the artery, clear the vessel, and pass the needle from without inward.

Results: Ligation at the apex of Scarpa's triangle is a method for treating popliteal aneurysm. It is a very successful procedure. I have performed it 3 times with success and have assisted other operators in 3 successful cases. Syme successfully ligated the femoral about its middle 23 consecutive times, and in Guy's hospital the same operation was done 24 times, with 1 death ("Practice of Surgery," by Thomas D. Bryant).

Iliac Arteries.—The *line* of the common and external iliac arteries is from a point ½ inch below and ½ inch to the left of the umbilicus to midway between the anterior superior spine of the ilium and the pubic symphysis. The upper third of this line represents the common iliac, and the lower two-thirds the external iliac (Pl. 3, Fig. 4).

Anatomy.—The common iliac arteries arise from the aorta opposite the left side and lower border of the fourth lumbar vertebra, and extend to the upper margin of the right and left sacro-iliac joints, where they each bifurcate into an external and an internal iliac. The common iliac arteries lie upon the fifth lumbar vertebra, are covered with peritoneum, and are crossed by the ureters. In women the ovarian arteries cross the common iliacs. Each common iliac vein lies to the right side of its associated artery. The right common iliac artery has in front of it, besides the peritoneum and ureter (in women also the ovarian artery), the ileum, branches of the superior mesenteric artery, and branches of the sympathetic nerve. The left common iliac artery has in front of it, in addition to structures common to both sides (ureter,

ovarian artery, sympathetic branches), branches of the inferior mesenteric artery, and the sigmoid flexure with its mesocolon. The internal iliac artery runs from the sacro-iliac joint to the upper margin of the great sacrosciatic foramen. It is very rarely ligated (only for gluteal aneurysm, for uncontrollable hemorrhage from the gluteal or sciatic arteries, or to produce atrophy of the prostate gland). The external iliac artery runs from the sacro-iliac joint along the pelvic brim, upon the inner edge of the psoas muscle, to Poupart's ligament. The external iliac vein is internal to the artery. On the right side, high up, it passes behind the artery. The external iliac artery has in front of it peritoneum and subserous tissue (Abernethy's fascia). The ileum crosses the right, and the sigmoid flexure crosses the left, external iliac artery. The genital branch of the genitocrural nerve crosses the artery low down, and the circumflex iliac vein crosses it just before it terminates in the femoral. The spermatic vessels and the vas deferens in the male, and the ovarian vessels in the female, lie upon the artery near its termination. Sometimes the ureter crosses the vessel near its point of origin.

Ligation of the Iliac Arteries After Abdominal Section.—The best method for ligating the common, the internal, and sometimes the external iliac is by abdominal section. The patient is placed in the Trendelenburg position. The abdomen is opened in the midline below the umbilicus or in the semilunar line of the diseased side. The intestines are lifted toward the diaphragm, and are held up by gauze pads. The edges of the incision are retracted. The vessel to be tied is located and the point for ligation is selected. The posterior layer of the peritoneum is opened over the selected point, the vessel is cleared, and the threaded Dupuytren's aneurysm needle is passed in a direction away from the vein. In ligating either common iliac pass the needle from right to left. In ligating the external iliac pass the ligature from within outward. It is not necessary to suture the posterior layer of peritoneum. The abdomen is closed without a drain. In these operations be sure to push the ureter out of the way. This operation has been performed by Dennis, Hearn, Marmaduke Shield, Mitchell Banks, the author, and others.

Results: Bryant ("Operative Surgery") alludes to 5 reported cases of transperitoneal ligation of the common iliac artery, with 1 death.

Ligation of the Common Iliac Artery by the Extraperitoneal Method.—The common iliac artery was tied unsuccessfully by Dr. Wm. Gibson in 1812. It was first successfully ligated by Valentine Mott in 1827. The patient is placed recumbent or in the Trendelenburg position. The body is then turned a little to the opposite side and the thighs are partly flexed. Bryant says there are two linear guides for this artery. *Crampton's line* is drawn from "the apex of the cartilage of the last rib downward and a little forward nearly to the crest of the ilium, then carried forward parallel with it to a little below the anterior superior spine" ("Operative Surgery," by Joseph D. Bryant). *McKee's line* is "drawn from the tip of the cartilage of the eleventh rib to a point 1½ inches within the anterior superior spine, then curved downward, forward, and inward, and terminating abruptly above the internal abdominal ring" (Ibid.).

The incision can be begun just external to the internal abdominal ring and be curved upward and outward as in ligation of the external iliac, but Crampton's incision gives more room. The superficial tissues are divided down to the transversalis fascia, this structure is nicked and divided, and the exposed and unopened peritoneum is rolled upward and inward. The muscular guide is the inner border of the psoas magnus muscle. By its side an artery is felt. If the sacrovertebral prominence is above the vessel touched, the artery is the external iliac; otherwise it is the common iliac. If the external iliac is the vessel first exposed, follow it up to find the common trunk.

When the common iliac is found, separate the fatty tissue about it and pass the ligature from the right toward the left in order to avoid the associated vein.

Results: Jos. D. Bryant tells us that this vessel has been ligated by the extraperitoneal method 69 times, with only 16 recoveries, but it is to be remembered that many of these operations were in pre-antiseptic days. The artery has been tied 80 times, with 56 deaths (70 per cent.).

Twenty-one of these operations were done since 1880; there were 10 deaths (mortality of nearly 48 per cent.). In these 21 cases gangrene occurred 7 times. (See Wm. J. Gillette, in "Annals of Surgery," July, 1908.)

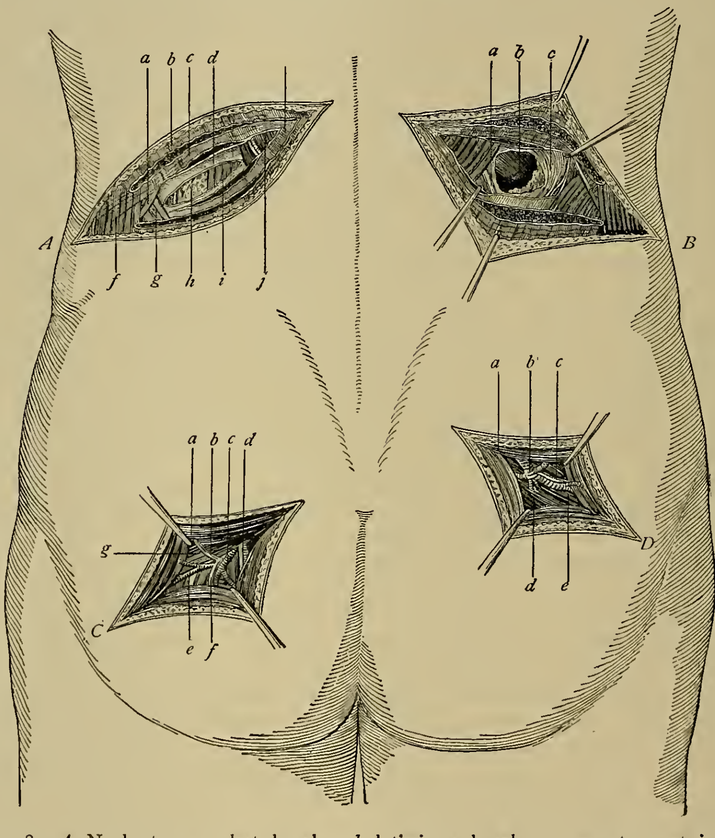

Fig. 248.—*A*, Nephrotomy: *a*, last dorsal n.; *b*, latissimus dorsal m.; *c*, serratus post. inferior m.; *d*, middle layer of lumbar fascia; *e*, outer layer; *f*, ext. oblique m.; *g*, int. oblique m.; *h*, perinephritic (extraperitoneal) fat; *i*, quadratus lumborum m.; *j*, erector spinæ m. *B*, Nephrotomy: *a*, first lumbar n.; *b*, kidney; *c*, transversalis fascia. *C*, Ligature of the sciatic and internal pudic arteries, and exposure of the great sciatic, small sciatic, and internal pudic nerves: *a*, gluteus maximus m.; *b*, inf. gluteal n.; *c*, sciatic a.; *d*, int. pudic a. and n.; *e*, great sciatic n.; *f*, small sciatic n.; *g*, pyriformis m. *D*, Ligature of the gluteal artery and exposure of the superior gluteal nerve: *a*, gluteus maximus m.; *b*, gluteal a.; *c*, superior gluteal n.; *d*, pyriformis m.; *e*, gluteus medius m. (Kocher).

Extraperitoneal Ligation of the Internal Iliac Artery.—This operation was first performed by Stevens, of Vera Cruz, in 1812 ("Practice of Surgery," by Thomas Bryant). The incision and the method of exposing the vessel are identical with like steps in the ligation of the common iliac.

Results: Of 26 ligations of this vessel recorded, 18 were fatal, but only a few of the cases were done antiseptically (Joseph D. Bryant's "Operative Surgery").

Ligation of the External Iliac by Abernethy's Extraperitoneal Method (Pl. 3, Fig. 4).—The external iliac artery was first ligated by Abernethy in 1796. The operation failed, but he did the first successful operation in 1806. The patient is placed recumbent with the thighs extended during the first incisions; but in the later stages of the operation the thighs are flexed a little to relax the abdominal structures. The operator stands to the outer side. The surgeon will find the artery by the side of the psoas muscle. Mark a point 1 inch above and 1 inch external to the middle of Poupart's ligament, and another point 1 inch above and 1 inch internal to the anterior superior iliac spine (Barker). Join these two points by a curved incision 4 inches long and convex downward. Cut the skin, the fat, the two oblique muscles, and the transversalis muscle; open the transversalis fascia, separate the peritoneum toward the vessels, and draw it inward by a broad retractor, and look for the artery along the pelvic brim. The anterior crural nerve is seen to the outer side of the artery, the external iliac vein is to the inner side of the artery, and the genitocrural nerve is upon the artery. Clear the artery near its middle and pass the ligature from within outward. In Sir Astley Cooper's method of ligation the inguinal canal is opened; in Abernethy's method the inguinal canal is not opened.

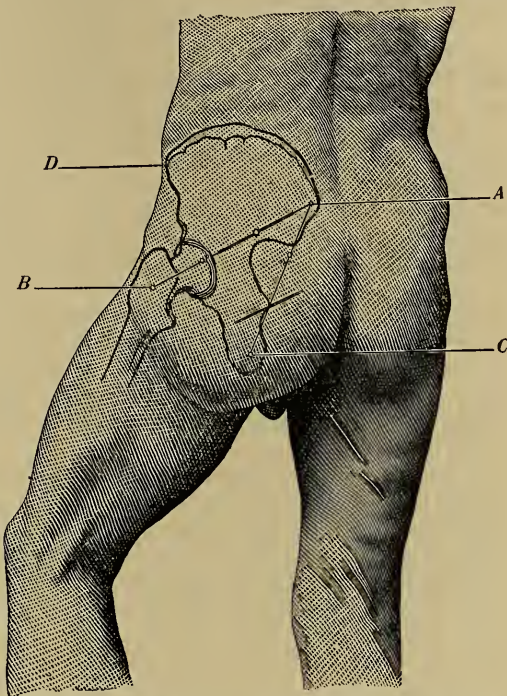

Fig. 249.—Position and direction of the superficial incisions which must be made in order to secure the gluteal artery and the sciatic and pudic arteries: *A*, Posterior superior iliac spine; *B*, great trochanter; *C*, tuberosity of the ischium; *D*, anterior superior iliac spine; *A–B*, iliotrochanteric line, divided into thirds. This line corresponds in direction with the fibers of the gluteus maximus muscle. The incision to reach the gluteal artery is indicated by the darker portion of the line. Its center is at the junction of the upper and middle thirds of the iliotrochanteric line, and exactly corresponds with the point of emergence of the gluteal artery from the great sciatic notch. *A–C*, ilio-ischiatic line. The incision to reach the sciatic artery and internal pudic is indicated by the lower dark line. It is also to be made in the direction of the fibers of the gluteus maximus muscle. The center of the wound corresponds to the junction of the lower with the middle third of the ilio-ischiatic line (MacCormac).

The Gluteal Artery.—This vessel is a continuation of the posterior division of the internal iliac. It emerges from the great sacrosciatic foramen at the upper border of the pyriformis muscle. It rests upon the gluteus minimus, divides into three branches, and is covered by the gluteus maximus muscle. The superior gluteal nerve lies inferior to the artery (Fig. 248).

Ligation.—The patient should be prone. The surgeon stands to the outer side. The incision corresponds to a line drawn from the posterior superior iliac spine to the upper border of the great trochanter (Fig. 249). Divide the skin, fascia, gluteus maximus muscle, and the fascia over the gluteus medius muscle, and retract the gluteus medius upward. Feel for the great sacrosciatic foramen, and at this point the artery is found above the pyriformis

muscle. Clear the vessel and pass the needle from below upward (Kocher's "Operative Surgery"). There is practically no mortality from this operation.

The Sciatic Artery.—This artery is the larger of the terminal branches of the anterior division of the internal iliac artery. It passes to the lower portion of the great sacrosciatic foramen, lying back of the internal pudic artery, and resting upon the sacral plexus of nerves and pyriformis muscle (Gray). It leaves the pelvis between the pyriformis and coccygeus muscles, and passes downward between the ischial tuberosity and great trochanter. It is covered by the glutæus maximus muscle, rests upon the gemelli, internal obturator, and quadratus femoris muscles, has the great sciatic nerve external to it, and the small sciatic nerve external and posterior (Fig. 248).

Ligation.—The patient lies prone. The surgeon stands to the outer side. The incision "corresponds to the middle two-thirds of a line extending from the posterior inferior iliac spine to the base of the great trochanter."[1] MacCormac advises the incision shown in Fig. 249. Divide the skin, fat, fascia, and the glutæus maximus muscle. Find the artery at the lower border of the pyriformis muscle and trace it to its point of emergence from the pelvis. Pass the ligature from without inward. There is practically no mortality from this operation.

Internal Pudic Artery.—This artery is one of the terminal branches of the anterior trunk of the internal iliac. It passes to the lower margin of the great sacrosciatic foramen, and leaves the pelvis between the pyriformis and coccygeus muscles, crosses the ischial spine, and again enters the pelvis by the lesser sacrosciatic foramen. The vessel is accompanied by the internal pudic nerve (Fig. 248).

Ligation.—The position of the patient and the incision are the same as for ligation of the sciatic artery (Fig. 249). The artery is found below the ischial spine. Pass the needle from below upward to avoid the nerve. There is practically no mortality from this operation.

Ligation of the Abdominal Aorta.—This operation was first performed by Sir Astley Cooper in 1817. The patient lived but a few hours. The aorta has been ligated twenty times and there have been twenty deaths. Nine of these cases were aseptic operations. The patient of Monteiro, of Rio Janeiro, lived for ten days. The circulation was entirely restored in the limbs, and the man died from hemorrhage resulting from the ulceration produced by a septic ligature. Keen's case lived for forty-eight days after ligation just below the diaphragm. The urinary secretion was plentiful and the circulation in the lower extremities was restored, death resulting from cutting through of the ligature. Robert T. Morris performed distal ligation below an aneurysm. He encircled the aorta with a soft-rubber catheter and clamped it with forceps. Twenty-two hours after operation the aneurysm began to shrink, and in three hours more had apparently disappeared. Twenty-seven hours after operation the clamp and catheter were removed. The patient died of septicemia fifty-three hours after operation. The necropsy disclosed gangrene of a bit of intestine which had been in contact with the forceps, but the dissecting aneurysm was filled with solid clot, the aorta was patent, and the circulation in the extremities was re-established ("Amer. Jour. of Med. Sciences," Sept., 1900). These cases prove that under certain circumstances the operation is feasible, and in desperate cases it must be considered as a possible means of treatment. Halsted and Matas prefer a metal band to the ligature (see page 429). Gradual occlusion and partial occlusion of the aorta are much safer than sudden closure.

Murray Operation.—This procedure aims to avoid opening the peritoneum. An incision is made from just below the tip of the tenth rib to a point 1 inch internal to the anterior superior iliac spine. The peritoneum is separated

[1] Kocher's "Operative Surgery," by Stiles.

from the abdominal wall until the vessel is reached. Cooper's operation by abdominal section is the preferable procedure.

Operation by Abdominal Section (Cooper's Operation); Instruments Required.—Those used in any ligation, with the addition of an aneurysm needle with a large curve and a very long handle. With an ordinary instrument it is extremely difficult to pass the ligature. It would be a great advantage to use an instrument which, after being passed under the vessel, could have a central eyed shaft projected, as is the center shaft of a Bellocq cannula. Floss silk is probably the best ligature material.

If the patient is much exhausted, an assistant should infuse salt solution in a vein during the operation. In Keen's case there was profound shock, but the moment the ligature was tightened it passed away.

The patient should be placed upon his back. The surgeon stands to the right of the patient and opens the abdomen in the median line, a little above the level of the aneurysm. The intestines are packed aside, the posterior layer of the peritoneum is divided, the surface of the aorta over a small area is cleared of nerves, the plexuses being separated with a blunt dissector.

The needle is passed from right to left. A double ligature of floss silk should be passed and the ends should be tied with a stay-knot. The wound is closed and dressed.

It has been suggested—I think by Wyeth—that it might be wise to only partially tighten the ligature at first, completing the occlusion of the artery after a day or two. Such a procedure would certainly give a better chance for the collaterals to dilate and restore circulation in the legs (see page 429).

Unfortunately, in an aneurysm, the vessel will usually be extensively diseased, and ligation will be out of the question. If, however, a normal region is found, the chance of success in a case of aneurysm will be greater than in a case of hemorrhage from a branch of the aorta, because, in a case of aneurysm, the probabilities are that the collaterals are somewhat distended before a ligature is applied.

XX. DISEASES AND INJURIES OF BONES AND JOINTS

Diseases of the Bones

Atrophy of bone is a diminution in the amount of bony matter without change in osseous structure. It arises from want of use (as seen in the wasting of the bone of a stump) or from pressure (as seen in the destruction of the sternum by an aneurysm of the aorta). *Eccentric* atrophy is the thinning of a long bone from within, the outer surface being perhaps unchanged. It is usually a senile change. *Concentric* atrophy means a thinning of the outer surface of the shaft, causing a lessened diameter. It is usually linked with eccentric atrophy.

Hypertrophy of bone may be due to increased blood-supply (as seen in chronic epiphyseal inflammation), the bone growing much more than does its fellow. It may arise from excessive use or from strain (as seen in the increased size of the fibula when the tibia is congenitally absent).

Tumors of Bone.—Bones give origin to both innocent and malignant tumors. Myeloid sarcoma takes origin in the endosteum and expands the bone. The fasciculated sarcoma is a periosteal growth. Besides these growths there may develop an osteoma, a chondroma, and secondary deposits of cancer and sarcoma. A bone may become cystic, and occasionally the cysts are due to hydatids. Gummata are frequently met with.

Cysts and Cystomata of Bone.—One variety of cyst is found in the jaws (dentigerous cysts, see page 361). The other variety occurs usually in the medullary canal of long bones and very seldom in short bones and flat bones. "It differs from the dentigerous cyst in the absence of a connective-tissue capsule. The fluid is usually hemorrhagic. Islands of cartilage may be found in the bone capsule" (Bloodgood, in "Progressive Medicine," Dec. 1, 1907).

A bone-cyst slowly expands and thins the shaft of the bone, and in some cases fracture of the bone is the first evidence of the trouble. Union takes place after fracture, but the enlargement remains. The *x*-ray picture does not enable us to make the diagnosis, because it exactly resembles the picture of any medullary growth possessed of a bony capsule and producing osseous absorption.

The diagnosis is proved by exploratory incision and the condition is treated by curettement and drainage.

Many bone-cysts are produced by softening of solid neoplasms (sarcoma, myxoma, medullary fibroma, chondroma). Occasionally cysts form in osteomalacia and osteitis deformans, the condition arising from softening. Hydatid cysts and dermoid cysts are sometimes encountered. A true cystoma of bone, except in one of the jaws, is a surgical rarity. In the jaws cystomata are not very uncommon.

Syphilis of Bone.—Secondary syphilis may attack the bones (see page 326). Tertiary syphilitic lesions are considered on page 330.

Actinomycosis of bone is most usual in the jaw, but may attack the orbit, ribs, sternum, or limbs (see page 309). Actinomycosis of bone may arise secondarily after infection of superficial parts by the streptothrix. In the jaw the fungus obtains entrance to the interior of the bone through a tooth socket. In some cases of bone actinomycosis the fungus reaches the bone by the blood. Actinomycosis leads to the production of granulation tissue, the bone is expanded and becomes carious, and a quantity of new bone is sometimes produced. In vertebral actinomycosis, although the condition resembles tuberculosis, angular deformity does not occur.

Tuberculosis of bone (*tuberculous osteomyelitis*) tends especially to appear in the cancellous ends of long bones. In about one-fifth of the cases it is primary, that is, only one focus can be found. In such cases the point of entry shows no lesion, or the lesion at that point may have healed. In some cases the bacilli enter through the tissue. Trauma may be an exciting cause. Long after apparent healing the disease process may awaken into activity and trauma is often the cause of the awakening. In one of König's cases trouble began anew after sixty years. The disease is especially apt to attack the epiphysis and spread to the joint, although in some cases it spreads to the shaft. Primary tuberculosis is rare in the shafts of long bones, but is not uncommon in the shafts of short bones. A bone focus leads to the formation of a bone cavity which may contain tuberculous granulations or bone sequestra. The sequestra in tuberculous osteomyelitis are not completely loose, but are still attached at some point. The bone may sclerose or may undergo alterations of an osteoporotic nature, making it soft. Sclerotic bone means a healing process. Softened bone means a spreading process. A sequestrum in tuberculous osteomyelitis is usually wedge shaped, the base being toward the joint. A sequestrum is due, König thinks, to the obstruction of a terminal artery by a tuberculous embolus or by the intra-arterial growth of bacilli ("Die Tuberculose der Menschlichen Gelenke, swiel der Brustwand und des Schaedels"). In a certain number of cases tuberculosis infiltrates a spongy bone with great rapidity because of rapid caseation. This condition is known as *infiltrating progressive bone tuberculosis*.

Osteitis, Periostitis, and Osteoperiostitis.—**Osteitis, or inflammation of bone,** may be due to traumatism, to a constitutional malady or diathesis, to the extension of inflammation from some other structure, to certain fevers, to cold, to phosphorus or mercury, to infection, or to working in pearl button factories. In inflammation of bone the exudate and leukocytes pass into the Haversian canals, spaces, and canaliculi. The bone corpuscles proliferate and the bone undergoes thinning (rarefaction), not because of pressure, but because of absorption by voracious leukocytes and osteoclasts. This process of rarefaction enlarges all the bony spaces, and by destroying septa throws many of the spaces into one. If the surface of a bone inflames, the periosteum will be separated more or less by exudation, and the bone will be covered with little pits or erosions made by the leukocytes. Inflamed bone is so soft that it can readily be cut with a knife.

Pearl workers' osteitis occurs particularly in youths before fusion of the epiphyses. It arises in the diaphysis by the epiphysis. The bones of the limbs are most apt to suffer, but the bones of the face or chest may be attacked. The attack begins with pain and moderately elevated temperature and the fever may persist for several weeks. The condition may apparently get well and yet begin again when the patient returns to work. The lesions are often symmetrical and always multiple (Broca). It is a condensing osteitis and undergoes spontaneous cure if the patient gives up the occupation (Deturk, in "Archives Génerales de Chirurgie," Nov., 1908).

Osteitis may terminate in *resolution* or it may terminate in *sclerosis*, the mass of proliferating cells being converted first into fibrous tissue and next into dense bone which contains a very few small cancellous spaces. If the exudation is under the periosteum, the bone will be thickened at this point, bone stalactites marking the points of passage of the vessels. Osteitis may terminate in *suppuration*, this condition being often called *caries*. In tuberculous osteitis caseation of the inflammatory products is very apt to arise (*tuberculous caries*, the *strumous caries* of our predecessors). Acute osteitis may terminate in *necrosis*, the inflammatory exudate compressing the vessels in their bony canals, a portion of the bone being, in consequence, deprived of nutritive material. The portion cut off from nutritive fluid dies *en masse* (necrosis). Osteitis is usually associated with more or less periostitis. A simple acute periostitis without involvement of the bone may arise from traumatism or strain; but in all severe cases of periostitis, in all chronic cases, in all cases due to syphilis, rheumatism, measles, scarlatina, or enteric fever the bone is involved at the same time or subsequently. In syphilitic states gummatous degeneration frequently ensues.

Symptoms of Osteitis and Osteoperiostitis.—As a chronic process, *osteitis* is most commonly found in the femur. The history may exhibit a record of an antecedent injury or chilling of the body. Pain is severe, boring or aching in character, deep seated, worse at night, and aggravated by a dependent position of the part. The symptoms closely resemble those of periostitis, with which disease it is almost sure to be linked. Tenderness exists on percussion, and sometimes on pressure. Subperiosteal swelling, fusiform in shape, is noted; cutaneous edema and discoloration are observed if a superficial bone is inflamed. In syphilis atrophic osteitis may attack the cranial bones and produce softening or even perforation, or osteophytic osteitis may arise, exostoses being formed. *Osteoperiostitis* may be acute or chronic, circumscribed or diffused, and may terminate in resolution, organization, or suppuration. It arises from cold, blows, wounds, strains, the spread of adjacent inflammation, specific febrile maladies, pyogenic infection, syphilis, rheumatism, or tuberculosis. The symptoms are pain (which is worse at night and which is aggravated by motion, pressure, or a dependent position), swelling, edema, and

discoloration of the soft parts. Pain in the syphilitic form is not so severe as in other varieties. *Acute necrosis* or *diffuse osteoperiostitis*, a pyogenic inflammation of bone and periosteum, is commonest in boys about the age of puberty. It is usually awakened by cold, a specific fever, or injury, and most often affects the tibia or femur; the symptoms locally are redness, swelling, and severe pain; constitutionally there are rigors, fever, and sometimes convulsions. Necrosis is apt to result. Pyemia is common. In *simple acute periostitis* a swelling is felt upon the osseous surface. The swelling is firmly fixed and is very tender, but the bone itself is not enlarged. There is some local heat, discoloration, often fever, and the patient complains of an aching pain, which is worse at night.

Periostitis due to strain demands some special attention. Sir James Paget, years ago, pointed out that muscular exertion might cause periostitis. C. T. Dent has written a valuable article upon this subject.[1]

It is common to hear football players complain of some swelling of the knee-joint. Examination finds tenderness over the tubercle of the tibia with slight swelling of the joint. Dent points out that pain is felt on straightening the leg, not on rotating it. The same observer states that omnibus drivers suffer from periostitis of the fibula, due to pressing forcibly against the foot-board; those who ride may develop periostitis of the adductor insertion (riders' bone); the victims of flat-foot may labor under periostitis of the inner tuberosity of the os calcis; bar-keepers, from working a beer-pump, may get periostitis of the scapula, pain being marked on contracting the biceps; a housemaid may develop periostitis at the points of bony origin of the great pectoral from the chest, the condition being due to sweeping and scrubbing.[2]

Treatment of Osteitis and Osteoperiostitis.—In syphilitic forms the local treatment consists in rest, elevation of the part, the application of iodin and mercurial ointment, and bandaging. Specific treatment is given by the stomach or hypodermatically. Operation is rarely justifiable. In other forms, if the case be recent and severe, put the patient to bed, place the limb in a splint and elevate it, employ cold, apply a bandage, and give salines and iodid of potassium internally. Later use ichthyol inunctions locally and apply a hot-water bag. Morphin is administered for pain. If these means fail, order counterirritation by iodin and blue ointment or blisters, and apply heat locally. In severe cases take a tenotome and slit the periosteum subcutaneously to relieve tension; this procedure often quickly relieves the pain. Some cases demand longitudinal osteotomy, which is performed by taking Hey's saw and dividing the bone longitudinally into the medullary canal. If pus forms, drain at once.

Diffuse osteoperiostitis requires early and free incisions through the periosteum, antiseptic irrigation, drainage, rest and elevation of the limb, and strong supporting and stimulating treatment. Amputation is sometimes demanded, as when the patient grows weaker and weaker even after incision, and when a joint is seriously involved. If the necrosis affects the entire shaft, which separates from its epiphyses, and new bone has not yet formed from the periosteum, make a subperiosteal resection of the shaft.

Chronic periostitis is usually syphilitic. A *node* is a chronic inflammation of the deep periosteal layers. Nodes occurring early in the secondary stage remain soft and soon pass away under treatment, but those occurring two years or more after infection are apt to cause a bony deposit. A node may soften, leaving a sinus, at the bottom of which is a piece of dead bone. Gumma of the periosteum is one form of node which is apt to produce caries or necrosis.

Osteoplastic periostitis accompanies chronic osteitis and causes the deposit of new bone, which undergoes sclerosis. The chief *symptom* is aching

[1] "Practitioner," Oct., 1897. [2] Ibid.

pain, which is worse when the patient is warm in bed, and is aggravated by damp and wet. A hard swelling is found at the seat of pain (often over the tibia, ulna, clavicle, or sternum). The soft parts are uninflamed and move freely unless softening or suppuration has occurred. Tenderness is manifest.

Treatment of Chronic Periostitis and Osteoplastic Periostitis.—For the nodes of early syphilis administer mercury by the plan usually followed in secondary syphilis; for the nodes of late syphilis give mercury and large advancing doses of iodid of potassium. Blisters, blue ointment, and iodin are applied to the skin over the area of periostitis in both forms, and subcutaneous division of the periosteum is of value. If suppuration occurs, incise antiseptically and drain.

Chronic Abscess of Bone, or Brodie's Abscess.—This condition is sometimes due primarily to tuberculous infection, symptoms being absent for a longer or shorter time and arising because of secondary infection with staphylococci. It is always chronic, never acute. A very acute inflammation, such as is induced by virulent pyogenic organisms, causes acute necrosis rather than an acute abscess. After typhoid fever an area of suppuration may slowly form in the head of a long bone, due to action of typhoid bacilli. Non-virulent staphylococci may be responsible, and the condition may follow long after a staphylococcus osteomyelitis. In 84 per cent. of cases of Brodie's abscess this is the history (Alexis Thomson). The same author says the latest period between the osteomyelitis and the abscess varies from one to fifty-seven years. Chronic abscess of bone was first described by Sir Benjamin Brodie, and is often called *Brodie's abscess.* It occurs in the cancellous structure of the ends of bones—usually in the head of the tibia, sometimes in the femur (Fig. 250) or humerus. It seldom occurs in the shaft of a long bone. A tuberculous abscess of bone may follow a slight injury, which constitutes a point of least resistance. Bacteria lodge and multiply; bone rarefaction leads to the formation of a cavity, the inflammatory products caseate, suppuration arises, and the surrounding bone thickens and hardens because of growth from the periosteum. The abscess is apt to break and often breaks into a joint, as the joint surface is not covered by periosteum and no barrier of bone is there formed. Brodie's abscess may induce necrosis.

Fig. 250.—Chronic abscess in the great trochanter ("American Text-Book of Surgery").

Alexis Thomson thus describes Brodie's abscess ("Edinburg Med, Jour.," April, 1906):

In the first or quiescent stage there is a cavity filled with serum and lined with a membrane like the periosteum of young bones. The outer layer of the membrane is forming new bone of a spongy nature, "further away the old bone is sclerosed and the medullary canal obliterated."

When the mature stage or abscess stage arises the lining membrane is converted into granulation tissue, and the cavity becomes filled with staphylococcus pus. The outer layer of granulations erodes the bone and the abscess progressively enlarges. As the bone is eroded within, new bone is formed by the periosteum and the bone enlarges. If pus formation is more rapid than bone erosion there is tension and pain, but if bone erosion is suffi-

ciently rapid to prevent tension there is little or no pain. Finally, the abscess perforates the bony shell "on the periosteal surface or into an adjacent joint."

Symptoms.—There are attacks of boring pain, worse at night and aggravated by motion and pressure and a dependent position. The pain is intermittent, and may be absent for many days at a time. These pains are frequently thought to be rheumatic. The tenderness is marked, even when pain is absent, and is not in the joint, as the patient believed the pain was, but is over the site of infection. If the head of the tibia or the great trochanter is the seat of disease, percussion over that region develops pain most certainly. At times pain in the bone becomes excruciating and tenderness acute. There is more or less loss of function in the limb and in far advanced cases the bone is enlarged. There may be thickening of the bone and soft parts, edema and discoloration of the skin over the seat of trouble, and attack after attack of synovitis in the nearest joint. Irregular fever and sweats are usually noted, but there may be no fever. The harrassing pain causes sleeplessness, exhaustion, and emaciation. When the pus breaks through the bone abscess develops in the soft part, and if this bursts or is opened pain ceases (Thomson). The x-rays aid greatly in making the diagnosis.

Treatment.—In treating bone-abscess, trephine the bone at the point of greatest tenderness, and if the abscess is missed, follow the advice of Holmes and perforate the wall of bone with the trephine, opening in several directions, to discover the pus. It is often easy to open into the abscess with a chisel or gouge. After opening the cavity scrape its walls, remove dead bone, thoroughly dry with gauze, touch with pure carbolic acid, and pack with iodoform gauze. If the abscess opens into a joint, trephine the bone, and also open, irrigate, and drain the joint.

Caries was a term once used universally to signify suppuration or molecular death of bone. In some cases caries means suppurative osteitis; in others, tuberculous osteitis; in still others, gummatous osteitis. Typhoid fever is occasionally followed by a carious condition of bone. Osteitis is apt to become purulent when the bone is exposed to the air, when rest is not secured, when the health of the individual is below normal, when a foreign body such as a bullet is in the bone, or when tubercle or syphilis exists. The term is seldom used to-day except loosely, and then usually to signify tuberculous disease of bone. When caries arises the softened and granulating bone breaks down and is eventually discharged through a sinus. After drainage is secured, organization, sclerosis, and healing may result. In these cases new bone may form and a cure follow.

Tuberculous or *strumous caries* (*caseous osteitis*), a condition produced by the caseation of the products of a tuberculous osteitis, seldom shows any tendency to self-cure, neither organization nor sclerosis takes place, and new bone seldom forms unless an operation is performed. The interior of bones, especially of the carpus and tarsus, is entirely softened and destroyed and thin shells only are left.

Caries necrotica is a condition in which small but visible portions of soft and dead bone are cast off; *caries sicca* is molecular death of bone without liquefaction or suppuration.

The caseating masses in tuberculous caries contain tubercle bacilli. If a tuberculous collection is evacuated and infection with pus organisms occurs, genuine suppuration takes place, and constitutional infection causes septic fever and may cause death. Pyogenic osteitis may affect any part of any bone; but caseous osteitis (tuberculous caries) tends to arise, especially in cancellous structure (heads of long bones, vertebral bodies, ribs and sternum, and bones of the carpus and tarsus). Tuberculous osteitis of the shaft

of a long bone occasionally, but rarely, arises. Tuberculous osteitis is apt to cause tuberculous disease in an adjacent joint. Tuberculous osteitis may be followed by the formation of a cold abscess.

Symptoms.—In the beginning the evidences of caries are usually those of osteitis, but the first sign noted may be a fluctuating swelling due to pus or to caseated tubercle. After a time, at any rate, a fluctuating swelling is discovered. If not opened, the softened mass breaks externally, voids its contents, and leaves a sinus from which flows caseated matter which after a time becomes thin, reddish, and irritating to the skin, contains small portions of gritty bone, and has a foul smell. The opening of the sinus fills up with edematous granulations. A probe carried to the bottom of the sinus finds bone which is sieve-like (worm-eaten), and which on being struck gives a muffled note rather than the clear, sharp note of necrosis; the bone is rough, is bared, and is so soft that the probe can usually be stuck into it. In old cases of caries amyloid disease may arise.

Treatment.—If syphilis exists, give iodid of potassium in advancing doses and a mild mercurial course. If tuberculosis exists, give iodid of iron, arsenic, cod-liver oil, and nourishing foods, and recommend ocean air and living in the open air. Locally, in all cases, insist on rest and at once secure drainage, enlarging the opening, if necessary, and inserting a tube, and even making additional openings; syringe often with antiseptic fluids and dress antiseptically. If the case is seen before spontaneous evacuation has occurred, open under strict antiseptic precautions. When a chronic sinus exists there arises the question of operation. Incomplete operations are worse than useless, for they may be followed by diffuse tuberculosis or pyemia. If the gouge is used, try to remova *all* carious bone. The diseased bone is white, crumbles, and does not bleed; the non-carious bone is pink and vascular. Scrape away all granulations, swab the cavity with pure carbolic acid, and pack it with iodoform gauze. Instead of gouging away bone, there may be used the actual cautery, sulphuric acid, or hydrochloric acid. In severe cases excision is required, and in some rare cases amputation may be necessary. Caries of the spine is considered under Diseases of the Spine.

Necrosis is the death of visible portions of bone from circulatory impediment or the direct action of bacterial toxins. It is analogous to gangrene. One cause of necrosis is traumatism (such as the tearing off of periosteum) which deprives the bone of blood. Inflammation of the periosteum further lessens the nutrition. Acute inflammation in bone causes necrosis, the excessive exudation in the canals and spaces occluding the blood-vessels by pressure. The occlusion of vessels by bacterial thrombi or emboli may lead to necrosis, or the direct action of toxins may first inflame and finally destroy a portion of the bone. A thin shell of bone only may necrose from periosteal separation, or an entire shaft may die from acute pyogenic osteomyelitis or diffuse infective periostitis. Osteomyelitis is the most usual cause of necrosis. Necrosis is most frequently met with in the diaphyses of the long bones, caries in the cancellous tissue of bones. The ribs may become carious, but very rarely become necrotic. A sequestrum may, but does not often, form in a vertebral body, in the cancellous head of a long bone, in the carpus, or in the tarsus. If a sequestrum arises from tuberculous osteomyelitis it is seldom found completely detached, but still retains some vascular connection. In tuberculous osteomyelitis of a long bone the sequestrum is wedge shaped with its base toward the joint, and is due to infarction of terminal arteries. A fragment of dead bone is a foreign body; the healthy bone adjacent to it inflames and softens; granulations form, and this line of granulation, like the line of demarcation of gangrene, tends to separate the dead part from the living, the white dead bone being surrounded by the red zone of granulation tissue. A bit of dead bone is

called a *sequestrum*, and Nature tries to cast it off. A superficial sequestrum is known as an *exfoliation*.

Nature's method of casting off a sequestrum is as follows: Suppuration takes place at the line of demarcation, osteitis extends for a considerable distance around this line, the periosteum shares in the inflammation, and new bone forms. A cavity is made within by suppuration, and a box or case is formed without by ossification, the now entirely loosened sequestrum being so encased that it cannot escape. The pus finds its way through the new bone, and there is presented the condition so often seen by the surgeon—namely, a case of new bone known as the *involucrum*, a *cavity* containing pus and the dead fragment or *sequestrum*, and a discharging sinus or *cloaca* (Fig. 251). Nature may eventually cast off the fragment, but the surgeon should not wait for the completion of this slow process.

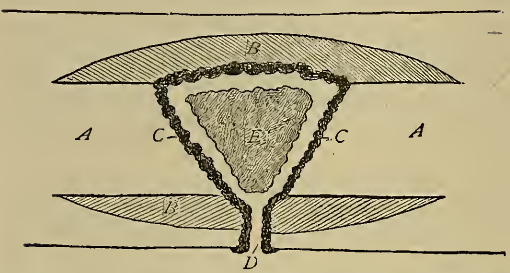

Fig. 251.—Diagram illustrating the formation of a sequestrum: *A*, *A*, Sound bone; *B*, *B*, new bone; *C*, *C*, granulations lining involucrum; *D*, cloaca; *E*, sequestrum.

When a portion of the bone surrounding the medullary canal dies, the condition is called *central necrosis*. In some rare cases necrosis occurs without apparent suppuration, a painless swelling of bone simulating sarcoma. This condition is known as *quiet necrosis*, and has been described by Sir James Paget and Mr. Morrant Baker. Mercury is an occasional cause of necrosis. The fumes of phosphorus may cause necrosis of the lower jaw in those with decayed teeth. Necrosis may be produced also by frost-bites and burns. Many fevers (measles, typhoid, scarlet fever, etc.) are occasionally followed by necrosis. Syphilis and tuberculosis are occasional causes.

The **symptoms** of necrosis are at first those of osteitis or osteomyelitis. The abscess, when formed, opens itself or is opened by the surgeon, and a sinus or sinuses form in the soft parts, as happens in caries. As a matter of fact, were cases of acute osteomyelitis operated on early, extensive necrosis would be rare. If surgeons followed the rule of removing hopelessly damaged bone at the primary operation for osteomyelitis it would seldom be necessary to do extensive operations for dead bone at a later period. When a sequestrum exists a probe introduced into the sinus strikes upon hard bone with a clear, ringing note, and often finds a sinus or sinuses in the bone. In superficial necrosis the discharge is slight and the probe shows the limitations of the disease. In extensive necrosis the discharge is profuse, much new bone forms, several sinuses appear far apart, and the probe must pass through a considerable thickness of new bone before it finds the bit of dead bone. In a chronic case in which there is an involucrum the surgeon may not operate until the dead bone is separated from the living by a line of demarcation unless there is general sepsis. He may wait until the sequestrum is loose unless the patient is being poisoned during the wait. The tendency of thought is against such long delay as was formerly the custom. In youth dead bone loosens quickly, but in old age slowly. An exfoliation becomes loose sooner than the sequestrum of central necrosis. In diffuse periostitis the necrosed shaft loosens quickly. Necrosed portions of the upper extremity loosen more rapidly than those of the lower. In a young adult two or three months will be required to loosen a necrosed fragment in the lower extremity and from six weeks to two months in the upper. A loose sequestrum may be moved by the probe,

and when struck gives a hollow note. In protracted cases of necrosis there is always danger that amyloid disease may arise.

Quiet necrosis is a rare condition which has led to some deplorable but pardonable mistakes, because it resembles ossifying sarcoma. It follows injury, particularly fracture. The bone enlarges greatly. There is little or no pain and no fever. The diagnosis can only be made by exploratory incision, and it may even be necessary to remove portions for microscopic study before a conclusion can be reached.

Postfebrile necrosis is most usually caused by typhoid fever. The bacilli of typhoid cause chronic osteomyelitis, and this may be followed by necrosis. Scarlet fever, measles, and other febrile processes may also induce necrosis. It is certain that bacilli accumulate in the bones during typhoid fever. They may promptly induce disease; they may remain for long periods apparently inactive and finally pass away; or after a slight strain or injury these organisms may induce bone disease months or even years after the primary infection. *Typhoid bone disease* is often multiple, many bones being involved successively.[1] Not unusually after typhoid fever muscle strain causes periostitis and osteitis, and at such a point necrosis may occur. Either exfoliation or central necrosis may follow typhoid fever. The tibia is involved more often than other bones.

Treatment.—An exfoliation should be removed as soon as it becomes loose, the seat of trouble should be touched with pure carbolic acid, and packing of iodoform gauze should be inserted. The treatment of central necrosis comprises free incisions for drainage, removal of the sequestrum and disinfection, antiseptic dressing, frequent cleansing, rest, nourishing food, stimulants, and tonics. When a sequestrum exists the operation of *sequestrectomy* should be performed. The extremity is drained of blood, an Esmarch band is applied, the bone is exposed by a longitudinal incision, the periosteum is reflected on each side, the involucrum is broken through, and the opening is enlarged with the chisel, gouge, and rongeur. The dead bone should be removed by sequestrum forceps, the cavity scraped by a sharp spoon, the lateral edges of the involucrum cut down until the cavity which formerly contained the sequestrum is very shallow, the wound is irrigated with hot salt solution, dried, painted with pure carbolic acid and then with alcohol, again irrigated with salt solution, and firmly packed with iodoform gauze. Remove the Esmarch band, tie the vessels in the soft parts, suture the wound, and apply dressings. It was long the rule of surgery to remove a sequestrum only when loose, and wait if necessary for it to become loose. This rule has been largely abandoned in favor of early operation. The simple removal of a sequestrum—*i. e.*, the operation of *sequestrectomy*—often fails to effect a cure, and even in the most satisfactory cases healing requires a very long time. "The involucrum always contains pyogenic germs that may live in its small foramina and crevices almost indefinitely. For this reason, and on account of the denseness of bony structure, it is well-nigh impossible to disinfect it" (Dr. J. Shelton Horsley, in the "Medical Record," Oct. 20, 1900). Because of the difficulty of curing a case when an involucrum has formed, Dr. Cushing has warmly advocated early operation in osteomyelitis; that is, operation before an involucrum has formed, and when the osteoblasts of the periosteum are extremely active. He points out that if an involucrum has formed, the sequestrum and involucrum should be removed after stripping the periosteum from this region. If the periosteum is found not to be infected, it may be stitched together at the gap where the bone has been removed, so that a periosteal cord exists between the two ends of the bone; and the soft parts above this may be closed. If the periosteum is found to be infected, we agree with Cushing that the cavity should

[1] Keen's "Surgical Complications of Typhoid Fever."

be packed with gauze. The cavity that is left by the removal of a sequestrum and the chiseling of the walls of the involucrum, if large, may be filled by various methods more or less satisfactory. In some cases of widespread necrosis due to diffuse infective osteoperiostitis or to osteomyelitis, extensive resection, or even amputation, may be necessary. If the entire shaft of the tibia requires removal the length of the limb may be maintained by implanting the head of the fibula into the head of the tibia. Otherwise extension must be used during repair.

Treatment of Bone-cavities.[1]—Before filling a bone-cavity try to disinfect it. This can be done only relatively. It may be swabbed with pure carbolic acid, followed in one minute by alcohol, or can be mopped with pieces of gauze wet with boiling water. Schede does not pack the bone-cavity, but allows it to fill up with blood-clot after the wound in the soft parts has been closed by sutures. The blood-clot obliterates the dead space in the bone, acts as a support for granulations from the margins, and is slowly eaten by phagocytes. Unfortunately, it is an excellent culture-medium and it often fails of its purpose. Sherman arrests hemorrhage, fills the gap with normal salt solution, and sutures the soft parts without drainage. The surgeon may try to fill the cavity by taking flaps of skin from the sides of the wound, separating them freely from the fascia beneath, and holding them within the bone-cavity by inversion sutures or fastening them to the bottom with tacks (*Neuber's operation*). Another operation consists in breaking the edges of the involucrum and turning them in. Some surgeons insert decalcified bone-chips. The cavity in the bone is made as sterile as possible and is well dusted with iodoform, the bone-chips are dried and inserted into the cavity, a capillary drain is employed, the periosteum is stitched over the opening, and the soft parts are sutured; but if this cannot be done, iodoform packing is used to keep the chips in place. This method we owe to the genius of Senn. Senn's method often fails because of the impossibility of completely sterilizing the walls of the bone-cavity. Attempts have been made to fill bone-cavities as a dentist fills teeth—with gutta-percha, plaster-of-Paris, copper amalgam, etc., but each of these materials acts as a foreign body in the bone (James E. Moore, on "The Treatment of Bone-cavities," "Jour. Amer. Med. Assoc.," May 20, 1905). Schleich uses formalin-gelatin to fill bone-cavities. The difficulty in every case is the impossibility of completely sterilizing the walls of the cavity. Dressman has advised for this purpose the use of boiling oil, but it is apt to cause superficial necrosis. In some cases the cavity has been healed by the insertion of a Thiersch skin-graft. This method has been advocated by J. P. Lord ("Jour. Amer. Med. Assoc.," May 31, 1902). Von Mosetig-Moorhof's method is one of the best ("Zeitschrift für Chirurgie," lxxi, No. 5). He pours into the cavity a melted material which completely fills the cavity, which will not act as a culture-medium or as a foreign body, which is gradually absorbed, and which "possesses the inhibitory and medicinal properties of iodoform without causing iodoform intoxication" (James E. Moore, Loc. cit.). Mosetig-Moorhof's material consists of 60 parts of iodoform, 40 parts of spermaceti, and 40 parts of oil of sesame. These materials are mixed by heating gradually up to 100° C. On cooling, a solid mass is formed. When the surgeon wishes to use it he heats it up to 50° C. and stirs it while heating (Moore), and pours it into the cavity in the bone. On entering the cavity it at once solidifies. A capillary drain is introduced, the periosteum is sutured with catgut, and the other soft parts are sutured with silkworm-gut. Usually union by first intention is secured. Even if the wound gaps the wax is apt to hold. Mosetig-Moorhof has used this material in 4000 cases without ill effect. Cases of poisoning and at least 1 case of death have been reported

[1] The views of Macewen and Murphy on repair of bone will be found on pages 126 and 127.

(Durvergey, in "Presse Médicale," July 1, 1911). Many attempts have been made to fill the defect by *bone-grafting*. The first case of satisfactory transplantation from one of the lower animals with the retention of a vascular attachment was reported by A. W. Morton, in "American Medicine," July 12, 1902. The patient suffered from a compound comminuted fracture of both bones of the right leg. The fracture in the fibula united, but the tibia underwent necrosis, and it was necessary to remove 5 inches of the lower end of the bone. Some days later the periosteum was raised from the ends of the bone and these ends were freshened. The left leg of a dog was amputated just above the tarsus, the bones being sawed so that the ulna was 1 inch longer than the radius. The lower end was partly bared of periosteum, and the ulna of the dog was forced into the cavity of the tibia of the man, and wired to that bone with silver wire. The incision in the man's leg was then sutured, and powerful tendons in each leg of the dog were divided. Each of the dog's other legs was wrapped separately in a plaster-of-Paris bandage, and the entire animal and the leg of the man were then put up in a plaster-of-Paris dressing. Five weeks later the cast was removed, and the bones were sawed and placed in contact with the astragalus. Union took place, and the man was fortunate enough to obtain a useful leg. In some cases a bone defect may be supplied by transference of another bone. Nichols reported 11 cases and insisted on the necessity of preserving the periosteum ("Jour. Amer. Med. Assoc.," Feb. 3, 1904). Huntington has reported a case similar to case No. 2 in Nichols's list. The patient was a boy of seven. A large piece of the entire thickness of the tibia was lost as a result of acute osteomyelitis. There was a gap of 5 inches between the ends of the bone, and the leg was a mere flail. Eight months after the beginning of the osteomyelitis the fibula was sawed opposite the lower end of the upper fragment of the tibia and the upper end of the lower fragment of the fibula was fixed in a cup-shaped depression in the lower end of the upper fragment of the tibia. Six months later union was solid, but in order to improve the weight-bearing power of the limb, nine months after the first operation, the lower end of the upper fragment of fibula was fastened to the upper end of the lower fragment of tibia. The result was excellent. The shortening is only $\frac{3}{4}$ inch ("Annals of Surgery," Feb., 1905).

Osteomyelitis.—By this term we mean inflammation arising in and about the blood-vessels and attacking the marrow of bone. It may attack the soft tissues and cells in the Haversian canals, in the cancellous spaces, or in the medullary cavity. It may be acute or chronic, localized or diffused. Simple osteomyelitis is not due to bacteria. If localized it usually depends upon a traumatism (fracture, contusion, wrench of an epiphysis). Simple diffuse osteomyelitis may arise in a victim of rickets or osteitis deformans. An acute simple inflammation may cause softening and permit bending. A chronic inflammation causes sclerosis.

Acute infective or **pyogenic osteomyelitis** is an acute and diffuse inflammation of the bone-marrow due to pyogenic organisms. Infection from staphylococci may be limited to a portion of one bone. Streptococcus infection causes widespread involvement of a bone or of several bones. Acute osteomyelitis may be due to mixed infection with bacilli of typhoid and pyogenic organisms, or bacilli of tubercle and pyogenic organisms, a typhoid process or a tuberculous process serving to establish a point of least resistance. The gonococcus and the pneumococcus occasionally produce acute osteomyelitis. In a case of gonorrheal arthritis in which I resected the wrist-joint cultures of gonococci were obtained from the interior of the bone removed.

It was at one time believed that osteomyelitis was due to a specific organism, but Pasteur proved that micrococci are the cause, and Ogston demonstrated pyogenic bacteria in pus obtained from cases of osteomyelitis. In some cases

there is pure staphylococcus infection (aureus or albus), both aureus and albus may be present, there may be mixed infection with streptococci and staphylococci, streptococci and several sorts of bacilli, or staphylococci and bacilli. Mixed infections with streptococci are more malignant than staphylococcus infections. Most cases of osteomyelitis are due to staphylococci. Trauma is a common predisposing cause. It creates an area of tissue damage which captures bacteria from the blood. Ullman was unable to experimentally induce osteomyelitis without first creating by bone injury a point of least resistance. When he applied a ligature to a rabbit's leg for fourteen hours distinct changes were found to occur in the marrow of the bones. These changes consisted chiefly in extravasation and localized hemorrhages. When the marrow was in this condition, if virus were injected into the animal, osteomyelitis resulted, because the bones presented points of least resistance, vulnerable points in which pus cocci lodged and multiplied.

The pyogenic organisms may gain entrance directly by way of a wound (a gunshot-wound, a compound fracture, an amputation). The causative organisms may reach the bone by way of the blood, having entered the blood originally through the lymphatic system or from a focus of suppuration in the skin, the subcutaneous tissue, or a deeper part. Staphylococcus infection commonly depends on cutaneous suppuration.

Pus organisms may pass into the blood from the tonsils or respiratory organs (Kraske); the intestinal canal (Kocher); the genito-urinary tract; or from excoriations, bruises, small wounds, or suppurations in the skin. Certain fevers strongly predispose to the disease by preparing the soil, as it were, for the growth of pyogenic bacteria. Typhus fever, small-pox, malarial fever, scarlet fever, measles, and diphtheria lessen the vital resistance of bone-marrow. Typhoid fever is not unusually followed by chronic osteomyelitis, due solely to typhoid bacilli. If mixed infection with pus organisms occurs, acute osteomyelitis arises. Vital resistance of marrow is lessened by exhausting diseases, overexertion, unhealthy and, especially, putrid food. We know that various infections produce various reactions in marrow, and in this changed marrow vital resistance is probably lessened or even seriously impaired. Longcope made a study of the marrow in 26 fatal cases of enteric fever, and he invariably found numerous lymphoid cells, phagocytes of large size, and multiple foci of distinct necrosis. The cells whose function is to form blood were noted to be undergoing hyperplasia. In persons dead of perforation and general peritonitis there were numerous foci of necrosis, and also widespread degenerative changes in the blood-making cells and pronounced edema and congestion of the marrow ("A Text-Book of Pathology," by Alfred Stengel). When organisms gain entrance directly by a wound (as in a compound fracture), the endosteum, the medulla, and the cancellous tissue inflame and suppurate, and the entire length and thickness of the bone may be involved. The periosteum becomes infiltrated, detached from the bone, and retracted from the edges of the wound in the bone. The soft tissues around the bone may inflame, suppurate, or slough. More or less necrosis inevitably occurs.

Acute pyogenic osteomyelitis without a wound is often called *acute epiphysitis.* This condition is most common in infants or children of one or two years of age, but is not uncommon in older children (from ten to seventeen years), and even occurs in adults. It is vastly more common among males than females. The tibia is the bone most prone to attack. It is most common during the period of active growth of bone. It is frequently preceded by one of the predisposing causes before mentioned. In some cases a strain or bruise is followed by pyogenic infection, because the damaged tissue extends a hospitable welcome to micro-organisms which are traveling in the body-fluids and pass through the injured area. The most usual antecedent

injury is a twist. As Ollier showed, a twist damages the weakest structure, which is the soft, new bone. In at least half of the cases a history of trauma can be obtained. In some cases there doubtless was trauma, even though we can obtain no history of it. In some cases chilling of the surface of the body is a predisposing cause. In others no predisposing cause is discoverable.

The compact bone suffers secondarily, but is never attacked primarily. New tissue is more susceptible to infection than old tissue, and the disease, as a rule, begins near the epiphyseal line, where new bone is being formed. This point was spoken of by Ollier as "the zone of election of pathological processes." Warren points out that in a growing bone near the epiphyseal cartilage there exists a newly formed spongy tissue, very vascular and connected with the cartilage by a spongy layer of tissue, which is not yet bone, but which does not possess a cartilaginous structure. It is in this portion of the skeleton that the most active changes take place during the period of growth. The medullary substance is very vascular at this point; it is red and without fatty tissue. It communicates with the medullary canal and with the periosteum by a number of vascular channels. The epiphyseal cartilage itself is intimately blended with the periosteum. The diaphyseal side of the cartilage produces much more bone than is found in the epiphyseal margin. There is also an active growth of bone in the periosteum, and it is in these regions and in the medullary canal that the inflammatory process originates.[1] The end of the diaphysis is very vascular, but the blood-stream is sluggish because of the large size of the capillary loops ("Practice of Surgery" by Spencer and Gask). The lower end of the femur and the upper end of the tibia are the regions most commonly attacked; but the upper end of the femur and the lower end of the tibia may suffer, and other bones may be attacked, especially

Fig. 252.—Fracture of femur after acute osteomyelitis.

Fig. 253.—Osteomyelitis, showing sequestrum formation.

[1] Warren's "Surgical Pathology."

the humerus, radius, ulna, and inferior maxilla. The adjacent joint not unusually becomes involved. Though the inflammation begins in the spongy tissue or medulla, it passes to the canals and spaces of the compact bone. The inflammatory exudate in the canals compresses the vessels and cuts off nutrition from certain areas. Suppuration begins, clots form in the medulla from thrombophlebitis, and the clots in the vessels of the Haversian canals become septic. A small sequestrum forms at the seat of origin of the disease, and the pus about the sequestrum is apt to empty into the medullary canal, causing diffuse osteomyelitis, or into the adjacent joint, causing suppurative inflammation of the articulation.

Marked constitutional symptoms arise from absorption of toxins (suppurative fever), and sometimes true septic infection or even pyemia arises.

Very extensive necrosis may follow osteomyelitis if the patient recovers. Fracture of the bone may occur (Fig. 252). An acute pyogenic osteomyelitis may involve the medulla, may break into the adjacent joint, or may remain localized in the head of a bone and cause an abscess containing fragments of bone or a distinct sequestrum (Fig. 253). The walls of such an abscess are composed of sclerosed bone.

When the medullary canal is involved in a pyogenic inflammation, a part or the whole of the medulla may suffer. The condition may result in central necrosis or in suppurative periostitis and death of the shaft of the bone. The mortality of acute osteomyelitis is high. In the 309 cases collected by Kennedy the mortality was 34 per cent. ("Brit. Med. Jour.," July 20, 1912). The earlier the operation, the less the mortality. Operation within forty-eight hours of the initial chill has a mortality of less than 10 per cent.

Symptoms.—Osteomyelitis secondary to a wound of the bone may occur in a person of any age. If a wound exists,—for instance, a compound fracture,—the diagnosis is evident. The constitutional symptoms of septic absorption are positive: there is a profuse, offensive, purulent discharge containing bone-fragments and tissue-sloughs; the periosteum is red, thick, and separated; there are swelling over the bone, great tenderness, and violent boring, gnawing, or aching pain. Osteomyelitis occurring without a wound, the condition often known as acute epiphysitis, occurs in the young, and particularly in children under three years of age.

The symptoms of acute osteomyelitis without a wound of the bone usually come on suddenly and especially at night, and the attack may be so acute as to cause death by systemic poisoning before a diagnosis is arrived at. The disease is generally ushered in by a chill, which is followed by septic febrile temperature. The history will sometimes contain the statement that a blow had been received, that a febrile process had existed, or that the patient had been suddenly chilled after having been overheated (sitting in a draft or in a cellar on a hot day, possibly swimming when very warm, etc.). There is violent aching pain in the bone and acute tenderness near the joint. Within seventy-two hours of the initial chill there will usually be pus in the medullary cavity and a quantity of hopelessly damaged bone if operation has not been performed. The soft parts, which at first are healthy in appearance, after a time discolor, swell, and present distended veins, and may become glossy and edematous because pus is gathered below. The medullary cavity becomes filled with pus. An abscess sometimes reaches the surface and may break spontaneously. The neighboring joint swells, and may become filled with pus; the periosteum and the shaft are involved for a considerable distance; each epiphysis may become affected, the shaft between being comparatively uninvolved, and the epiphyses may separate, displacement and shortening taking place. Extensive necrosis may occur. This disease is often mistaken for rheumatism because of the joint swelling, occasionally for typhoid fever because of

the fever, and in some cases for erysipelas because of the redness of the skin. It gives a very grave prognosis. Sometimes an epiphysitis shows milder symptoms and is slower in progress (subacute). These cases are very often mistaken for rheumatism. But in rheumatism the joint is the part involved from the beginning, while in epiphysitis the joint is involved secondarily after obvious evidence of inflammation well clear of the articulation. Further, the symptoms of rheumatism will be rapidly improved by the use of the alkalis or the salicylates.

Treatment.—If osteomyelitis arises secondarily to a wound, apply a tourniquet, sterilize the parts, enlarge the wound, expose and curet the medullary cavity, remove loose fragments of bone, irrigate the medullary cavity with a hot solution of corrosive sublimate or hot salt solution, scrape it with bits of gauze held in the bite of a forceps, paint with pure carbolic acid, pack lightly with iodoform gauze, dress with hot antiseptic fomentations, and secure rest for the parts by splints and bandages. The constitutional treatment is the same as that for septicemia. In some cases amputation is necessary. Acute osteomyelitis without a wound is a most serious condition, rapidly progressive, apt to be quickly fatal, and requiring prompt and radical treatment. Operation should be done as soon as possible after the initial chill. Murphy has insisted upon this for years. Cushing, Le Conte, and others warmly advocate it. I always practice it when possible. Within seventy-two hours, perhaps within forty-eight hours of the initial chill, there will be pus in the medullary cavity and a quantity of bone will be hopelessly damaged. Operation consists in opening the medullary cavity by means of a burr, trephine, or chisel. At such an early stage drainage is all that is necessary, as dead bone has not as yet formed. Very early operation anticipates pus formation. It is not desirable to curet the cavity. A delay of a very few hours will be responsible for pus and dead bone. The medullary cavity must then be freely opened, curetted, and disinfected with pure carbolic acid. The former custom was to pack with iodoform gauze and wait for the formation and loosening of a sequestrum. It is safer and wiser to freely remove dead bone at the primary operation (Le Conte, "Boston Med. and Surg. Jour.," June 1, 1911). In any case if the joint is involved it must be drained. In all cases employ rest, anodynes, strong supporting treatment, and other remedies advised in septicemia. Amputation may be required. In a neglected or prolonged case very extensive necrosis occurs and a formidable operation may be required. Even amputation may be necessary. The entire shaft may have to be removed, a bloody and dangerous operation.

Fig. 254.—Chronic osteomyelitis of the tibia.

Chronic osteomyelitis is usually linked with osteitis. Pus may or may not form. There may be only thickening of and pain in the bone. Such

a condition can be caused by attenuated bacteria or by bacteria of ordinary power acting on tissue possessed of a very high vital resistance. It may eventuate in osteosclerosis with filling up of the medullary canal, in limited suppuration, in chronic abscess of the cancellous tissue (Brodie's abscess), or in necrosis. A tuberculous inflammation is one form of chronic osteomyelitis (see page 249). Syphilis, typhoid fever, etc., may cause it, and it can be caused by glanders, leprosy, and actinomycosis.

The typhoid bacillus under certain conditions is pyogenic. Fränkel taught this some years ago, and Keen proves it in his work on "The Surgery of Typhoid Fever." Osteomyelitis due purely to typhoid bacilli is chronic. When the medulla contains typhoid bacilli pus infection is apt to take place, and if such a mixed infection arises acute osteomyelitis develops.

Fig. 255.—Chronic osteomyelitis of the femur.

In chronic osteomyelitis there are pain, tenderness, and swelling, but no marked constitutional symptoms. In some cases the real trouble is not identified until an abscess forms (see Necrosis). There is a form of chronic osteomyelitis which is nearly always mistaken for rheumatism. J. C. Stewart describes it fully ("N. Y. Med. Jour.," March 25, 1911). It is sometimes preceded by a fever, sometimes by a trivial traumatism, but usually comes on insidiously and endures indefinitely as a chronic condition. Stewart shows that the bone enlarges because of subperiosteal production of new spongy bone. The marrow cavity fills with tissue resembling red marrow. The thick bone is tender at points, there is aching pain, and a trivial rise of temperature toward night.

Treatment.—If an abscess exists, at once evacuate it by incising the soft parts and chiseling the bone. Do not wait for an involucrum to form, but promptly incise, disinfect, and drain. If dead bone is present it must be removed. In the insidious form, so often mistaken for rheumatism, expose and cut through the new bone formation and open the marrow cavity.

Osteomalacia, or Mollities Ossium.—In this disease the bones are partly decalcified, and consequently soften and bend. Masses of new uncalcified bone-tissue are formed. Many bones are usually involved, but the bones of the head are not obviously affected. It is commoner beyond than before middle age, though it may occur in infancy, and a case has been reported in which the disease arose at the age of seventy. It is more frequently met with in women than in men, and pregnancy seems to bear more than a casual relation to its production. The disease is particularly apt to arise when pregnancies are rapidly repeated (Marquis, "L'Obstetrique," June, 1910). In osteomalacia the medulla increases in bulk and becomes more fatty, and the

osseous matter is absorbed gradually, first from the cancellous tissue and then from the compact tissue. Some observers believe that this curious condition is due to lactic acid in the blood, an abnormal amount of acid having been produced and absorbed because of disorder of the primary assimilation. Volkmann maintained that some inflammatory condition disturbs the blood-supply of the medulla, and von Recklinghausen asserted that arterial hyperemia is responsible. Hönnicke suggests that the disease is due to hypersecretion of the thyroid gland.

Fehling, influenced by finding that improvement may follow removal of the ovaries, set forth the view that the disease is due to overaction of the ovaries, causing reflex dilatation of the blood-vessels of bone. The answer to this theory is the fact that the disease can occur in the male. Some have thought that the disease is of bacterial origin. It is most common in those who dwell in damp or dark habitations. It may arise after a soaking and "taking cold." It is a rare disease in England and America, but is much more common in Germany.

The **symptoms** of osteomalacia are as follows: many points of pain which are often thought to be due to rheumatism; deformities from twisting and bending of bone; sometimes lactic acid and occasionally an excess of calcium salts in the urine. There is no fever early in the case, but later there may be a hectic fever. When the disease comes on after childbirth the iliac bones suffer first. Severe pain arises in the pelvis and back and the pain radiates into the thighs, the pain is worse at night, and is greatly aggravated by pressure or movements. Finally, standing and walking become unbearably painful. The earliest pain may be in the sacrum and be felt only when supine. Pains eventually become generalized throughout the skeleton. Pain in the bony walls of the thorax makes respiration difficult. Great deformity occurs because the partly decalcified bones bend.. Many of these patients become fat. Fractures occur from very slight force. In the majority of cases the disease is not cured, but grows progressively worse until the patient dies, after many years, from exhaustion. In some cases the process is arrested and the osteoid tissue is calcified.

Treatment.—In treating osteomalacia in women insist that pregnancy must not occur. In all cases put braces and supports upon distorted limbs to prevent further bending and fracture. Advise hygienic surroundings and nourishing food, and insist on the value of fresh air. Among the medicines that can be used may be mentioned cod-liver oil, lime salts, extract of the pituitary body, preparations of phosphorus, and bone-marrow. In women the removal of the ovaries sometimes produces great improvement. It has been asserted that the production of anesthesia by means of chloroform may be of benefit.

Acromegaly.—In 1886 Marie reported 2 cases with acquired and symmetrical enlargement of the face, hands, and feet. He named the condition acromegaly. This curious disease is, in all probability, due to hypersecretion or perverted secretion of the anterior portion of the pituitary body. There is a hypertrophy or a hyperplasia of this body. As a result of the perverted secretion or accentuated secretory activity there is accelerated growth of the skeleton. It was once thought that tumor was always the cause of acromegaly, but it is now known that whereas tumor may be a cause, many cases occur without tumor. Cases of adiposis dolorosa may show hypophyseal symptoms. Gigantism is probably acromegalic. (For a masterly discussion of this subject see "The Pituitary Body and its Disorders," by Harvey Cushing.) Acromegaly is a disease which causes progressive and often great enlargement of both the bones and soft parts of the extremities, which enlargement is symmetrical. The cranium becomes triangular in shape, with the base below, at the lower jaw.

The lower jaw projects in advance of the upper jaw, the nose becomes prominent and thick, the supra-orbital ridges are accentuated (Fig. 256), and the costal cartilages and inner ends of the clavicles become protuberant. Later the larynx, ribs, shoulder-blades, and vertebræ become involved, and the back becomes markedly humped (cervicodorsal hump). The hands and feet are affected in advanced cases. As a rule, the thyroid gland is enlarged, and a postmortem examination may detect a diseased pituitary gland. Severe and uncontrollable headache is sometimes a distressing feature of the disease. In some cases there is marked somnolence. A fireman who suffered from acromegaly would go to sleep almost the moment he sat down. Early there is low assimilation of carbohydrates, often with glycosuria. The disease is not regularly progressive, but exhibits periods of rapid increase, a stationary condition, or perhaps retrogression. In a prolonged case signs of pituitary insufficiency are noted, viz.: such high assimilation of carbohydrates that it is difficult or impossible to cause alimentary glycosuria, adiposity, subnormal temperature, and atrophy of the sexual organs. In all suspected cases an *x*-ray picture should be taken. If a tumor is present or if the gland is hypertophied the plate will show an enlarged sella turcica. A tumor causes rapid blindness. The disease slowly but surely causes death. Medical treatment is of no avail in cases of pituitary overactivity (*hyperpituitarism*). If there is evidence of hypophyseal insufficiency (*hypopituitarism*) administer hypophyseal extract.

Fig. 256.—Face in acromegaly. Note enlarged superciliary ridge, thickened lips, massive jaw, and general grossness. (Church and Peterson).

If there is hyperpituitarism it is justifiable to partially extirpate the gland, on the same principle as we partially extirpate the thyroid in a case of exophthalmic goiter. In Cushing's case the operation of partial extirpation of the pituitary body relieved subjective discomforts and modified acromegalic conditions. If there are evidences of tumor of the hypophysis it is justifiable to undertake its removal by operation. This has been accomplished successfully by Hochenegg, Von Eiselsberg, Brochardt, Cushing, Sir Victor Horsley, and others. In the cases of Hochenegg and Cushing not only were pressure symptoms relieved, but acromegalic conditions were greatly benefited.

Leontiasis Ossea or Hyperostosis Cranii (*Virchow's Disease*).—This is a symmetrical hypertrophy limited to the facial and cranial bones, and which begins, as a rule, in the superior maxillæ. The hypertrophy progressively increases, causes difficulty of mastication, and is accompanied by headache. It produces distinct deformity of the jaw like a tumor, whereas acromegaly enlarges all of the proportions of a bone (Fig. 257). It may produce blindness, new bone pressing upon the optic nerves. Treatment is very unsatisfactory. Horsley has obtained some degree of amelioration by operating and removing masses of bone.

Osteitis Deformans (*Paget's Disease*) (Fig. 258).—This disease was first described by Paget in 1877. Higbee and Ellis state that up to January, 1911, 158 cases have been reported ("Jour. Med. Research," vol. xxiv, No. 1). Packard and Steel were of the opinion that many reported cases were not genuine instances of the disease, some being ordinary osseous tumors, others being cases of enlargement after fracture, and still others being instances of mollities ossium ("Amer. Jour. Med. Sciences," Nov., 1901). Many of the reports are purely

clinical. The disease does not appear to be hereditary. It is usually associated with widespread arterial sclerosis. There is no evidence that gout, rheumatism, or disease of the nervous system play any part in causation. Some consider the condition parasyphilitic, but there is no real evidence of such origin. It has been asserted that heat or cold may be causal and that the condition has begun after injury of a long bone. A possible cause is disturbance of some internal secretion. The enlarged thyroid in Askanazy's case led him to suggest the theory. No parathyroids were found at autopsy in the patient of Higbee and Ellis. These two observers suggest that Paget's disease may be due to absence of parathyroid secretion and the consequent formation of substances which abstract calcium from the bones. In this disease great quantities of new bone are formed, but calcification does not occur. The material undergoes absorption, and the medullary substance of the bone becomes extremely vascular and filled with white blood-cells, and also with giant-cells. The bones lengthen and thicken. The long bones bend

Fig. 257.—Leontiasis ossium.

Fig. 258.—Paget's disease.

and the bones of the skull bulge. The bending of the long bones has been believed to depend upon the weight of the body acting on uncalcified new bone, but fracture is not particularly apt to occur. It is now maintained that the bending and bulging are active processes, "since the bending is always well marked in those bones which are fixed at both ends by muscles and ligamentous attachments, *e. g.*, the clavicle, radius, and tibia, the accompanying bone (fibula or ulna) acting as the string to the bow" (Gruner, Scrimger, and Foster, in "Archives of Internal Medicine," June, 1912). It is extremely rare before the age of forty, and usually begins between forty and fifty or later. The enlargement of the bones is usually accompanied by pain which may be severe. Enlargement may be first detected in the cranium, but is more often first seen in some other bone—for instance, the clavicle, the tibia, the spine, or the radius. The tibia in most cases suffers first, and other bones become involved later. In

fact, in some cases the bones of the head do not enlarge at all; but, taking all the reported cases, the skull is affected more frequently than any of the other bones. In some cases the enlargement of the bones seems to be symmetrical; in others it is not. In the disease known as leontiasis ossea the chief enlargement is manifested in the face; in Paget's disease there is no enlargement of the bones of the face, or else these bones are trivially involved. Packard and Steele point out that the diagnosis is extremely difficult when but a single bone is involved; but that if two or more bones are involved, we should think of Paget's disease as the condition, especially if we are able to exclude syphilis, cancer, and sarcoma. In mollities ossium the head is not involved at all, and there is not nearly so much thickening of the bone. The two authors before quoted show that in acromegaly the cranium is a triangle with its base below at the lower jaw, the orbital arches being distinctly involved, but that in Paget's disease the involvement is chiefly of the calvarium. The patient actually diminishes in height. The chest becomes deformed. There is angular curvature in the dorsocervical region. The lower extremities are usually bent, and the pelvis, as a general thing, is broadened. Paget says: "The most characteristic features are the loss in height, indicated by the low position of the hands, the stooping with round shoulders, the head held forward with the chin raised and the chest sunken toward the pelvis, the abdomen pendulous, the curved lower limbs held apart and usually with one advanced in front of the other and both with knees slightly bent, the ankles overhung by the legs, and the toes turned out. The enlarged cranium, square looking and bossed, may add distinctness to these characteristics, and they are completed in the slow and awkward gait of the patients." In some of the cases there is a tendency to tumor formation. In the 67 cases collected by Packard and Steele, 3 suffered from cancer and 5 from sarcoma. In the 158 cases collected by Higbee and Ellis ("Jour. Med. Research," vol. xxiv, No. 1) there were 14 instances of tumor growth. In a case reported by Gruner, Scrimger, and Foster ("Archives of Internal Medicine," June, 1912) sarcoma appeared in the radius, head of the humerus, and other places. Some cases are associated with goiter. It has been suggested that there is a bacterial cause for Paget's disease. An Italian investigator claimed to have discovered a bacterium and made a serum for use in treatment. In 2 cases I exposed areas of new bone, removed portions, and took cultures. One set of cultures remained sterile. A tube of the other was found contaminated by the skin staphylococcus.

Fig. 259.—Paget's disease.

Treatment is practically useless. No known remedy diminishes the size of the bones, although iodid of potassium is said occasionally to mitigate pain.

Osteo-arthropathie Hypertrophiante Pneumique (*Marie's Disease*).—(See page 644.)

Multiple Myeloma.—By this term we mean a new growth in the bone-marrow which occurs particularly in the ribs, sternum, and vertebræ. It may occur also in the bones of the cranium and in other bones. The multiplicity is not due to metastasis, but the growths start as separate foci. The nature of the cells in the growths is uncertain. They almost certainly spring from marrow cells. Some consider them myelocytes, some bone-marrow plasma cells. The effect of the growth is to thin the bones and make them very brittle. This condition was first described by Rustitzky in 1873. Stumm, who reports 2 cases, estimates that about 50 cases have been reported.

The condition begins insidiously, in either sex, during middle age, sometimes in advanced life. It begins usually with attacks of aching in the limbs and weakness. Such attacks may come and go over a considerable period of time. Eventually the back, chest, and ribs become the seats of pain and tenderness. Finally, the pain becomes constant and the patient is confined to bed. In many cases a sternal tumor can be palpated. Spontaneous fractures are apt to occur. Usually the Bence-Jones body is found in the urine. Death is due usually to exhaustion. Treatment is futile.

Fractures

Definition.—A fracture is a solution, by sudden force, of the continuity of a bone or of a cartilage. Clinically, under this head are placed epiphyseal separations and the tearing apart of ribs and their cartilages.

Varieties of Fractures.—The varieties of fractures are as follows:

Simple fracture is a subcutaneous fracture, or one in which there is no wound extending from the surface to the seat of bone injury. This corresponds to a contusion of the soft parts.

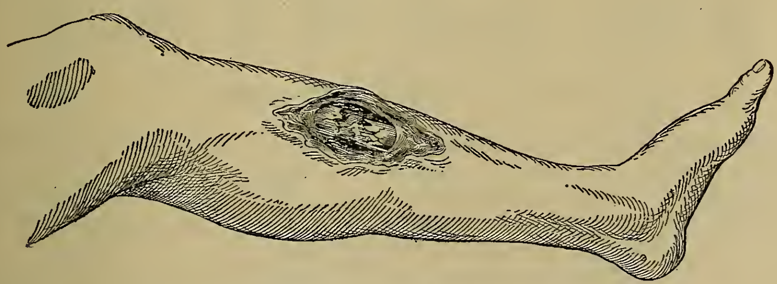

Fig. 260.—Compound comminuted fracture of the tibia.

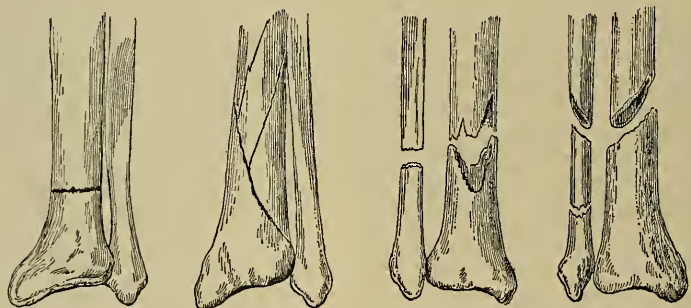
Compound fracture (Figs. 260 and 270) is an open fracture, or one in which an open wound extends from the surface to the seat of bone injury or in which a wound opens up a passage from the fracture to the surface. This corresponds to a contused or lacerated wound of the soft parts. The opening may be through the skin; through a mucous membrane, as in some fractures of the base of the skull and pelvis; through the drum of the ear, as in some fractures of the middle fossa of the base of the skull; through the lung, as when a broken rib penetrates that organ; or through the bowel or bladder, as in some fractures of the pelvis.

A *primary compound fracture* is one in which the breach in the soft parts is produced at the time of the accident, either by the direct violence of the injury or by the forcing of a bone or bones through the tissues.

A *secondary compound fracture* is one in which the breach in the soft parts occurs after the accident, either from sloughing of damaged tissues, from ulceration because of the pressure of ill-adjusted fragments, or from the forcing of a bone or bones through the soft parts because of rough handling, neglect, or the tossing of delirium.

Complicated fracture is a fracture plus the complication of a joint injury, arterial or venous damage, or injury to the nerves or soft parts. When a fractured rib injures the lung or when a broken vertebra damages the cord a complicated fracture exists. The term is unfortunate, as it conveys no definite meaning, and its use is no more justifiable than it would be to speak of "complicated pneumonia" or "complicated typhoid," for the complication should be named in any case. It must be remembered that damage to the soft parts not sufficiently severe to produce a wound reaching from the surface to the seat of fracture does not make the case a compound fracture, but rather complicates a simple fracture. Remember also that even superficial areas of tissue destruction must be treated antiseptically, otherwise absorption of pyogenic bacteria and their deposition at the seat of injury may cause diffuse osteomyelitis.

Complete fracture is that which extends through the whole thickness of a bone or entirely across it (Fig. 261).



a b c d

Fig. 261.—Complete fractures: *a*, Transverse; *b*, spiral; *c*, dentated; *d*, oblique or multiple.

Incomplete fracture is that which extends only partially through the thickness of a bone or only partially across it (Fig. 262).

A *linear*, *hair*, *capillary*, or *fissured fracture*, or a *fissure*, is a crack in a bone with very little separation of the edges. This is an incomplete fracture, but may be associated with a complete break (Fig. 261, *b*).

A *green-stick*, *hickory-stick*, *willow*, or *bent fracture* is a true incomplete break (Fig. 262). The bones most frequently so broken are the radius, ulna, clavicle, and ribs. It arises from indirect force, and it is very rare after the age of sixteen. In rickets green-stick fractures are very common. It is called "green-stick" because the bone breaks like a green stick when forced across the knee, first bending and then breaking on its convex surface. The bone, being compressed between two forces, bends, and the fibers on the outer side of the curve are pulled apart, while those on the concavity are not broken, but are compressed. In correcting the deformity such fractures are often made complete. The permanent bending of a bone without a break may possibly occur in youth. In children a portion of a bone of the skull may be bent inward, causing depression. In some cases such a depression is permanent; in others it is temporary, the bone returning to its proper level.

Depression-fracture occurs when a portion of the thickness of a bone is driven in by crushing. Fracture by depression is a result of the bending in

of a bone (as the parietal), a fragment breaking off from the side toward which the bone is bending. A *depressed fracture* is complete, not incomplete, and by this term is meant an injury in which a fragment of the entire thickness of the bone is driven below the level of the surrounding surface.

Splinter- and Strain-fracture.—The breaking off of a splinter of bone (splinter-fracture) or of an apophysis constitutes a form of incomplete fracture. A strain upon a ligament or a tendon may tear off a shell of bone, and this injury is the "strain-fracture" or "sprain-fracture" of Callender.

Longitudinal fracture is a fracture whose line is for a considerable distance parallel, or nearly so, with the long axis of the bone. Such fractures are common in gunshot injuries (Fig. 263).

Oblique fracture is a fracture the direction of which is positively oblique to the long axis of the bone. Most fractures from indirect force are oblique (Fig. 261, *d*).

Transverse fracture is a fracture the direction of which is nearly transverse to the long axis of the bone (no fracture is mathematically transverse) (Fig. 261, *a*). The cause is often, but not invariably, direct force. The *fracture en rave* (radish-fracture, so called because the bone breaks as does a radish) is transverse at the surface, but not within.

Fig. 262.—Green-stick fracture.

Fig. 263.—Longitudinal and oblique fracture.

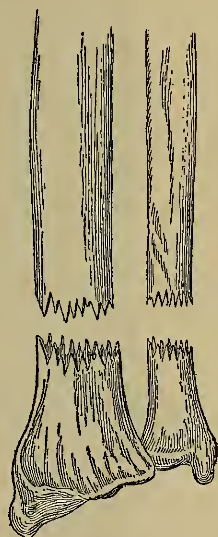


Fig. 264.—Appearances of the ends of fragments.

Toothed or *dentate fracture* is a form of fracture in which the end of each fragment is irregularly serrated and the fragments are commonly locked together; hence it is difficult to correct the deformity (Fig. 261, *c*, and Fig. 264). Most simple fractures from direct force are serrated.

Wedge-shaped, *V-shaped*, *cuneated*, or *cuneiform fracture* ("fracture oblique spiroïde," "fracture en V" of Gosselin, "fracture en coin") is one the lines of which take the shape of a V, which may be entire or may lack the point. It occurs at the articular extremity of a long bone, and a fissure usually arises from its point and enters the joint. If complete, it is a "comminuted fracture."

T-*shaped fracture* is a fracture which presents a transverse or oblique line and also a longitudinal or vertical line. It occurs at the lower end of either the

humerus or femur, the transverse line being above, and the vertical line (intercondyloid) between, the condyles. If complete, it is, in reality, a form of comminuted fracture.

Multiple or *composite fracture* is a condition in which a bone is broken into more than two pieces, the lines of fracture not intercommunicating, or a condition in which two or more bones are broken. Multiple fractures of one bone are divided into double, treble, quadruple, etc. Multiple fractures involving more than one bone are seldom seen, and represent less than 2 per cent. of fracture cases. The reason of their rarity in hospitals is that they result from severe force and many of the victims die before they can be brought to an institution. The mortality in cases which reach the hospital is large, over 27 per cent. (Astley P. C. Ashhurst, in "Annals of Surgery," August, 1907).

Comminuted fracture is a condition in which a bone is broken into more than two pieces, the lines of fracture intercommunicating (Figs. 265 and 266). The bone may be broken into many small fragments, there may be much splintering, or the osseous matter may actually be ground up.

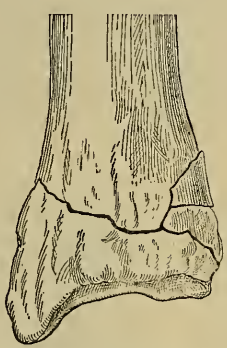

Fig. 265.—Comminuted fracture of the lower extremity of radius.

Fig. 266.—Comminuted fracture of the upper part of femur.

Impacted fracture is one in which one fragment is driven into the other and solidly wedged (Figs. 267, 268, and 269).

Fig. 267.—Impacted fracture of the neck of the femur.

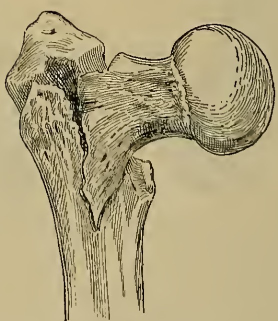

Fig. 268.—Impacted fracture of the neck of the femur.

Fracture with crushing or *penetration* is a fracture in which one bone is driven into the other, the encasing bone being so splintered that the impacting bone is not firmly held.

Pathological, *spontaneous*, or *secondary fracture* is one occurring from a very insignificant force acting on a bone rendered brittle by disease.

Ununited fracture is a fracture in which bony union is absent long after the passage of the period normally necessary for its occurrence.

Direct fracture is one occurring at the point at which the force was primarily applied.

Indirect fracture is one occurring at a point distant from the area of primary application of force.

Stellate or *starred fracture* (fracture par irradiation) is one in which several fissures radiate from a center. If the fracture be complete, the condition is, in reality, a form of comminuted fracture.

Helicoid, spiral, or *torsion fracture* is a fracture resulting in a long bone from twisting.

Fracture by contrecoup is a fracture of the skull which is on the opposite side of the head to that which was the recipient of the force.

Epiphyseal Separation or Diastasis.—This injury occurs only before the age of twenty-five. In order of frequency, the bones chiefly subject to epiphyseal separation are: the upper end of the humerus, the lower end of the radius, the lower end of the femur, and the lower end of the tibia (John Poland, in the "Practitioner," Sept., 1901). This injury induces deformity, which is often

Fig. 269.—Impacted fracture of neck of femur (Conner).

difficult to reduce, and by damaging the cartilage may retard or inhibit a further lengthening of the limb by growth. Occasionally after damage to an epiphysis suppuration will occur, sometimes thickening takes place. Non-union is very rare. After a sprain of an epiphysis tuberculous disease sometimes develops, but very rarely after a separation.

Intra-uterine fractures are usually due to injuries of the mother's abdomen sustained toward the end of pregnancy. Some hold that they can arise as a consequence of the force of violent uterine contractions. Many so-called "intra-uterine" fractures are wrongly named, as they result from injury during delivery. In sporadic cretinism the bones are fragile and ill-ossified, and many fractures may occur *in utero.*

Designation According to Seat of Fracture.—A fracture may be designated according to its anatomical seat; for instance, fracture of the upper third of the shaft of the femur, fracture of the olecranon process of the ulna, fracture of the middle third of the clavicle, and fracture of the body of the lower jaw. *Intra-articular* fracture is one within or extending into a joint; *intracapsular* fracture

is one within the capsule of either the shoulder- or hip-joint; and *extracapsular* fracture is one just without the capsule of either the shoulder- or hip-joint.

Causes of Fracture.—The causes of fracture are: (1) exciting, immediate or direct, and (2) predisposing or indirect.

Exciting causes are: (*a*) external violence and (*b*) muscular action.

External violence is the most usual exciting cause. Two forms are noted: (1) direct violence and (2) indirect force.

Fractures from direct violence occur at the point struck, as when the nasal bones are broken with the fist. In such fractures the soft parts are injured; they may be destroyed at once in part, they may be damaged so severely that a portion sloughs, or they may be damaged so slightly that they do not lose vitality; hence fractures by direct violence may be compound from the start, may become so, or may remain simple. In fractures by direct force discoloration, due to effused blood, usually appears at the point struck soon after the accident. In compound fractures by direct violence the soft-part injury is so great that primary tissue union cannot occur.

Fractures from indirect force do not occur at the point of application of the force, but at a distance from it, the force being transmitted through a bone or a chain of bones, as when the clavicle is broken by a fall upon the extended hand. Such fractures tend to occur in regions of special predilection. If they are not compound, there is no injury of the surface over the fracture. If they become compound by projection of fragments, primary union may still occur. Discoloration over the seat of fracture is usually not present soon after the accident, but may occur later. Discoloration rapidly appears in soft parts at the point where the force was first applied.

Muscular action is rather an unusual cause except in the patella. Fractures thus produced result from sudden or violent muscular contraction. Bones so broken are usually diseased. Violent coughing may fracture the ribs; attempting to kick may fracture the femur; saving one's self from falling backward may fracture the patella; throwing a stone may fracture the humerus; and sudden extension of the forearm may fracture the olecranon process of the ulna.

Predisposing Causes.—There are two classes of predisposing causes, namely: (1) physiological, natural or normal, and (2) pathological or abnormal.

Natural Predisposing Causes.—Under this head is considered the liability to fracture possessed by individual bones because of their shape, structure, function, or position. Those predispositions occasioned by special ages are also considered. In youth epiphyseal separation is commoner than fracture and a fracture is apt to be incomplete. Fractures are commonest between the ages of twenty-five and sixty. From two to four years of age a child is more liable to fracture than later, because he is then learning to walk (Malgaigne). The bones of the old are easily broken, but the normal lack of activity of the aged saves them from more frequent injury. Thus, the predispositions of age are in part due to habits and in part to bony structure. The bones of the young, being elastic, bend considerably before they break; the bones of the old, being brittle and inelastic, break easily, but do not bend. In old age the bones become lighter and more porous, though they do not diminish in size. Absorption takes place from the interior of a bone, particularly at its articular head, the medullary canal increases in size, the cancellous spaces become notably larger, and portions of the remaining bone of the interior show a fatty change. There is no increase in the amount of mineral salts present, as was long taught. These alterations occur earlier in women than in men.[1] The change of age is a diminution in the amount of bone present, and sometimes a fatty change in a portion of what remains. If the atrophy of bone is other than that normal to senility, it constitutes a pathological predisposing

[1] Humphrey on "Old Age."

cause of fracture. Normal predisposing causes include the person's weight (which determines the force of a fall), muscular development, habits, sex, occupation, and the season of the year.

Pathological Predisposing Causes.—Hereditary fragility, a form of *fragilitas ossium*, is a condition commonest among women, often existing in generation after generation, and in this condition fractures occur from a very slight force. There exists in these cases bony rarefaction—in fact, a premature senility. *Fragilitas ossium* (*osteopsathyrosis*) may be congenital or may come on later in life. It may result from senility, wasting diseases, scurvy, scarlatina, bone-cyst, malignant disease of the bone, certain nervous disorders, rickets, osteomalacia, and atrophy due to disuse.

Nervous Diseases.—Bony nutrition is dependent on the spinal cord, and the trophic influence is probably exerted through the posterior nerve-roots. In diseases of the anterior cornua bony growth is much interfered with; in diseases of the posterior columns, as in locomotor ataxia, a true bony atrophy bespeaks trophic disorder. Syringomyelia causes brittleness of the osseous structures, and in paralysis agitans bones are thought to break easily. Trophic changes may occur in the bones of the insane, most commonly when insanity is linked to organic disease. About one-quarter of paretic dements show undue brittleness or unnatural softness of bones.[1] The bones of maniacs are frequently fragile. Fractures among the insane are not necessarily an indication of abuse.

Rickets predisposes to fracture because of altered bone structure and the great liability to falls.

Osteomalacia predisposes to fracture of the long bones, sternum, and ribs.

Atrophy of Bone.—This condition, as has been stated (see page 518), is normal in senility. It may arise from want of use, as is observed in the bedfast, in the wasted femur of hip-joint disease, and in the bones of a stump. It may arise from pressure, as when an aneurysm compresses the ribs, sternum, or vertebræ. Among other of the pathological predisposing causes are to be mentioned cancer, sarcoma, hydatid and solitary cysts of bone, caries, necrosis, gout, scrofula, syphilis, mollities ossium, and scurvy.

Symptoms of Fractures.—*History of An Injury.*—In spontaneous fracture there may be no record of violence; for instance, a bone may break while an individual is turning in bed. In investigating the history, not only seek for a record or for evidences of violence, but try to determine exactly how the accident happened.

A *sound of cracking* is occasionally audible to a bystander at the time of the injury. The patient may have heard it, but very rarely does. A rupture of a tendon or a ligament produces a similar sound.

Pain is usually, but not invariably, present (absent often in rickets). In some fractures the pain is slight, in some there is no pain, in others pain is torturing, and in most it is severe for a time after the injury, but gradually abates unless reinduced by movement. Pain developed at the time of the accident is far less important as a symptom than that which can subsequently be produced by movement. In indirect fracture there is an area of pain at the point of application of the force, and another at the seat of fracture. Pain at the seat of fracture can be greatly aggravated by pressure or movement and is rather narrowly localized.

Deformity or *alteration in length or outline* is due in part to swelling and in part to a change in the mutual relation of the fragments (displacement). The deformity due to swelling is no aid to diagnosis, as the same condition occurs in contusion, and often hides some positive symptomatic distortion. The swelling is due first to blood and next to inflammatory products and

[1] "Manual of Insanity," by Spitzka.

pressure-edema, and is very great in joint fractures. Swelling due to bleeding is early and rapid. Swelling due to inflammatory exudation is later and gradual. Swelling due to pressure-edema may be rapid. The greater part of the swelling is due to hemorrhage and exudation from the damaged soft parts, a portion of it is due to hemorrhage and exudation from the bone. The swelling is usually in direct ratio to the mobility, the greater the mobility, the greater the swelling. "The swelling in fractures of the skull is inconsiderable, notwithstanding that the total area of bone surface involved is commonly more than in fractures of the leg or arm, and the vascularity greater. The reason for this is the natural immobility of fractures of the skull" (James P. Warbasse, in "Jour. Amer. Med. Assoc.," March 13, 1909). The deformity of displacement may be produced by the violence of the injury (as is the depression in a skull fracture), by the weight of an extremity (as is the falling of the shoulder in a fracture of the clavicle), or by muscular action (as is the pulling upward of the fragment of a fractured olecranon process).

The **varieties of displacement** are: (1) *transverse* or *lateral*, where one fragment goes to the side, front, or back, but does not overlap the other; (2) *angular*, the bony axis at the point of fracture being altered and the fragments forming with each other an angle; (3) *rotary*, one fragment rotating in the bony circumference, the other remaining stationary. As a rule, it is the lower fragment which turns on its long axis, the limb below the level of the break rotating with it; (4) *overlapping* or *overriding*, when the upper level of one fragment is above the lower level of the other fragment. It is usually the lower fragment which is drawn by the muscles above the upper, but in a fracture of the lower extremity the body-weight and sliding down in bed may push the upper below the lower fragment. In overriding the ends are near together and the bones are usually in contact at their periphery. It is obvious that overlapping is associated with transverse displacement, as one fragment must go front, back, or to the side; (5) *penetration* or *impaction* when one fragment is driven into the other, thus producing shortening; (6) *separation of the two fragments* occurs in fracture of the patella, olecranon, os calcis, certain articulations, and in some breaks of the humerus when the arm is not supported.

It is important to remember that a dislocation as well as a fracture may produce displacement, but these two conditions may be differentiated by the observation that the displacement of fracture tends to reappear even after complete reduction, while the displacement of dislocation does not reappear after correction. A displacement is difficult of detection in a flat bone and when one of two parallel bones is broken.

Loss of function may be shown by inability to move the limb because of the break, but it is not always markedly present, though some degree invariably exists. It is slight in "green-stick" and impacted fractures (unless the loss of power arises from pain or nerve injury). A person can walk when the fibula alone is broken, and likewise in some cases of intracapsular fracture of the femur, and can often put the hand on the head in fractured clavicle (Malgaigne). The pain of an injury or the loss of power from nerve traumatism may cause loss of movement in the limb. This symptom is of slight diagnostic value in most fractures.

Extravasation of Blood.—A contusion of the surface accompanied by skin abrasion indicates merely the point of application of direct external violence. If contusion is extensive over a superficial bone, as the tibia or parietal, after a few hours it often stimulates fracture by presenting a soft, compressible center surrounded by a ring of hard, condensed tissues and coagulated blood. Direct external violence may merely occasion ecchymosis, and in fracture from indirect force ecchymosis may occur throughout a considerable area.

In regard to this symptom, note that even great external violence may occasion no evident contusion or ecchymosis, and in any fracture this symptom may be present or absent. In old people, anemic subjects, fat individuals, alcoholics, and opium-eaters extravasation of blood is frequently marked and persistent. By suggillation is meant an extravasation of blood which slowly invades wide areas of tissue and which appears at the surface only after some time, and then usually as a yellowish discoloration, red hemoglobin having been changed to yellow hematoidin. Linear ecchymosis has been esteemed by some as a sign of fissure, and it is often noted after fracture of the fibula. Linear ecchymosis over the line of the posterior auricular artery was shown by Battle to be a valuable sign of fracture of the posterior fossa of the base of the cranium.

Preternatural mobility is a most important symptom, which is pathognomonic when surely found. The unbroken bone is nowhere mobile in continuity. By preternatural mobility is meant that a bone is mobile in continuity or that there is abnormality in the direction or extent of joint mobility. In some fractures this symptom does not exist (impacted, green-stick, and locked serrated fractures); in others it cannot be found (fractures of tarsus, carpus, vertebral bodies); in others it is difficult to obtain, but at times can be developed (fractures near or into many joints). To develop this symptom try, when the case admits, to grasp the fragments and to move them in opposite directions. In a fracture of the shaft of the femur or humerus fix the upper fragment and carry the knee or elbow in various directions to develop bending at the point of fracture. In fracture of the clavicle push the shoulder downward and inward. In fractures of either bone of the forearm grasp the parallel bone with four fingers of each hand and make pressure on the suspected bone alternately with either thumb, and the same procedure can be used in fractures of the leg. In fracture of the neck of the femur the altered rotation-arc of the great trochanter demonstrates preternatural mobility (Desault). In fracture of the lower end of the radius bend the hand back, and in a break of the lower end of the fibula evert the foot (Maisonneuve). In seeking preternatural mobility remember that the elastic ribs when forced in give a sense of bending, and that the fibula at its middle is "normally flexible" (Dupuytren). Some rachitic bones may be bent.

Crepitus or *crepitation* is both a sensation and a sound, which indicates the grating together of the two rough surfaces of a broken bone. This symptom is of great value, but it is not always present. It is absent in locked serrated fractures, in impacted fractures, in cases where the broken ends cannot be approximated (as in overlapping), is rare when a fractured surface is against the side, and not the broken face, of the other fragment, and is unusual in incomplete fractures. Crepitus is often absent in epiphyseal separation, in softened bones, and in fractures in or near joints, and it may be prevented from occurring by blood-clot, fascia, synovial membrane, periosteum, or muscle between the broken surfaces. The grating found in tenosynovitis must not be mistaken for the crepitus of fracture; the former is diffuse, large, soft, and moist; the latter is limited, small, harsh, and dry. The clicking of an inflamed or eroded joint and the crackling of emphysema must also be separated from bony crepitus. Crepitus of fracture may be present at one moment, but absent the next. It is often not detected during the time swelling is marked, and cannot be discovered after organization of the callus begins. In but few fractures is it needful to try to hear crepitus with the unaided ear or with a stethoscope upon the part, but in doubtful cases of fractures of ribs and joints this evidence should be sought for.

The above-named symptoms are known as "direct." There are other symptoms known as "circumstantial," such as the flow of blood and cere-

brospinal fluid from the ear after some fractures of the middle fossa of the base of the skull; emphysema of the face and epistaxis after fracture of the nasal bones; hemoptysis and emphysema after crushes of the chest; discoloration following the line of the posterior auricular artery after fracture of the posterior fossa of the skull, and subconjunctival ecchymosis after fracture of the anterior fossa of the base of the skull.

Diagnosis.—Examine as soon as practicable after the injury—before the onset of swelling, if possible. Expose the part completely, taking off the clothing, if necessary, by clipping it along the seams. Attentively scrutinize the part and compare it with the corresponding part on the opposite side. If any deformity be present, it must be ascertained that it did not exist before the accident. If the nature of the injury be uncertain, if the patient be very nervous, or if the part be acutely painful, it is better to give ether to diagnosticate, set, and dress. In injuries of the elbow-joint anesthetize before examination, unless an x-ray apparatus is accessible to settle the diagnosis, and even then it is usually well to anesthetize in order to facilitate reduction and dressing. In every case of suspected fracture get an x-ray picture if possible. A correct diagnosis is of the first importance and on a correct diagnosis proper treatment primarily depends.

A fracture is distinguished from a dislocation by its preternatural mobility, its easily reduced but recurring displacement, and its crepitus, as contrasted with the preternatural rigidity, the deformity, difficulty to reduce but remaining reduced, and the absence of crepitus of a dislocation. Further, in dislocation the bone, when rotated, moves as one piece, whereas in fracture it does not so move; in dislocation the bony processes are felt occupying their proper relations to the rest of the same bone, while in fracture some of them present altered relations. In dislocation the head of the bone is found out of its socket, but in fracture it is felt in place. It is important to remember, moreover, that a fracture and a dislocation may occur together, and that the rubbing of a dislocated bone against an articular edge, when the joint has been roughened by inflammation, simulates crepitus.

Great contusion, by inducing extreme tumefaction, may mask characteristic deformity and obscure crepitus. When only a contusion exists, pain is apt to be widespread; but if a fracture has occurred, the pain is accentuated at some narrow spot. In many cases, before he can give a certain opinion, the surgeon must wait some days until the swelling has largely subsided. In such a case it is best to assume in our treatment that a fracture exists until the contrary is known. Combat swelling by rest, the use of evaporating lotions, and moderate compression.

In impaction the diagnosis is difficult. The moderate deformity is concealed by swelling; crepitus and preternatural mobility do not exist unless the fragments are pulled apart, and there is not necessarily much loss of function. A conclusion is reached largely by considering the nature, direction, and extent of the violence, the seat of the pain, and by a careful study of the most minute deformity. It is difficult to recognize fissures. They rarely present any evidence of their existence except a localized pain, and possibly a linear ecchymosis appearing after a few days.

In green-stick fractures the age, the deformity, and possibly crepitus during reduction help in the diagnosis, although in many cases no crepitus is obtained. Epiphyseal separations are diagnosticated by the age, the preternatural mobility, the pain, the swelling, the ecchymosis, the deformity, the situation of the injury, and the absence of crepitus or the presence only of a soft crepitus. It is important, however, to remember that an epiphyseal separation is sometimes incomplete, and even when it is complete there may be no displacement. In cases without displacement the x-rays will not enable

us to make a diagnosis. In many cases of complete separation soft crepitus is obtainable, but in not a few cases it is not to be found. In incomplete separation crepitus is absent. If absent in complete separation, probably some tissue is caught in the opened area between the fragments. Fractures are often difficult to recognize when occurring in a group of bones (which are firmly joined by dense ligaments) like those of the carpus and tarsus, or in one of two parallel bones. There is not always a certainty that a fracture exists (see below), and when, after a careful examination, there is still uncertainty, do not prolong the efforts or use great force, but treat the case as a fracture until a cure ensues or the diagnosis becomes apparent.

In a child the diagnosis of fracture is sometimes difficult. Pain may be trivial. Children are liable to a form of fracture in which the periosteum is but slightly torn or is not torn at all, the disability and pain are often slight, and the fracture may be easily overlooked (Cotton and Vose).

We have recently had added to our resources a method of incalculable value in diagnosticating fracture; that is, the use of the force known as the *x*-ray or the Röntgen ray. We can look through a part with a fluoroscope and see the bones as shadows, or we can take a negative of the shadows and print skiagraphs from it. This method is applicable even when the parts are swollen, and even when a limb is clothed or wrapped in dressings. It is possible to obtain a picture of a fractured skull; fractured ribs and vertebræ can be detected; and the process is of the greatest use in detecting fractures of the limbs. It is not infallible. An epiphyseal separation may not be detected, and a slight angling of the plate may give a deceptive apperance of distortion. An *x*-ray picture, to be useful, must be taken by an expert and should be interpreted by a surgeon in association with the *x*-ray expert. It is imperative to employ this method in doubtful cases if an *x*-ray apparatus is accessible. It is advisable to use it in all recognized cases and in all suspected cases.

Complications and Consequences.—Some of the consequences and complications of fractures are—sloughing of the soft parts, thus making the fracture compound; extravasation of blood, causing swelling or even gangrene; rupture of the main artery or vein of the limb; dislocation; edema from pressure of extravasated blood, from inflammatory exudation, from tight bandaging, from thrombosis, or, later, from the pressure of callus; stiffness of joints from synovitis with adhesion, from displaced fragments, or from intra-articular callus; stiffness of tendons from adhesive thecitis or from the pressure of callus; paralysis from traumatic neuritis, the pressure of callus upon nerve-trunks, or from division of a nerve; muscular spasm; painful callus; exuberant callus; embolism; fat-embolism; pulmonary congestion; pulmonary embolism; gangrene; shock; septicemia; pyemia; tetanus; delirium tremens; urinary retention; extensive laceration of the soft parts; rupture of large nerves, and involvement of joints. A fracture may fail to unite, fibrous union or cartilaginous union only being obtained. An epiphyseal separation may arrest the future growth of the limb.

Repair of Fractures.—**Simple Fracture.**—In a simple fracture the bone is broken, the medullary contents are lacerated, the periosteum is torn, and the overlying soft parts are damaged to a considerable degree. The periosteum is stripped more or less from each fragment, but it is rarely completely torn through, an untorn portion known as the *periosteal bridge* remaining. The amount of blood effused is usually considerable, and it forms a decided prominence at the seat of fracture; it gradually gathers because of oozing, and soon clots. This clot lies in the medullary canal, between the fragments, under the periosteum at the ends of the fragments, and in the tissues outside of the periosteum. Very rapidly after the accident the dam-

aged parts inflame (bone, endosteum, periosteum, and the torn periosseous structures). The inflammatory exudate enters into the blood-clot and the leukocytes eat up and destroy the clot. The clot is simply dead material and in no way contributes to repair. The cells of the damaged tissue proliferate and the young proliferating cells (fibroblasts) enter into the spaces in the clot which were eaten out by the leukocytes. Finally, the entire clot is replaced by fibroblasts and much of this cellular mass quickly becomes vascularized (granulation tissue).

The osteoblasts which exist in the deeper layers of the periosteum and, in the tissue of the medulla itself, begin to proliferate actively soon after the fracture has taken place. The fibroblasts have been formed by the proliferation of the ordinary connective-tissue cells, and the proliferating osteoblasts soon enter into and become widely distributed through this mass of fibroblasts. Some observers maintain that the fibroblasts themselves are directly transformed into bone; others deny this, and think that all bone formation comes from the osteoblasts. Osteoblasts may form bone directly, or may form cartilage first and then bone. When a fracture takes place, a bridge of periosteum is usually left untorn, and this bridge holds the fragments in contact at some point, just as a strap nailed to a trunk and also to its lid holds these two objects in contact at some point. The new tissue about the periosteal bridge always

Fig. 270.—Compound fracture.

becomes cartilaginous for a time, but the rest of the callus rarely shows the development of cartilage, and passes directly into bone. If, however, osteoblasts fail to proliferate with sufficient activity, the mass of granulation tissue becomes fibrous tissue; bone is not formed at all, or is very scantily formed, and fibrous union occurs. If the osteoblasts lack activity, but are more active than in the case just cited, they form cartilage extensively—but cartilage only; consequently, cartilaginous union occurs. During the process of the repair of a fracture the ends of the bony fragments are always softened, and some of the bone is absorbed by the osteoclasts. The osteoclasts are really large osteoblasts that have lost the power of producing bone and that furnish a secretion to absorb bone (the elder Senn). After bony union has been accomplished the osteoclasts absorb the superfluous callus. The mass of new tissue around and between the bone-ends is called *callus*. It will be observed that the name is applied successively to fibroblastic tissue, granulation tissue, fibrous tissue, and bone. Warren tells us that callus has no well-defined outline, and "involves not only the bone and periosteum, but also the connective tissue and some of the surrounding muscular tissue." Within a few days after the injury the inflammatory mass is much firmer than follows inflammation involving other structures, and the bone ends have become deeply embedded in a dense mass.

During the second week the callus is greatly strengthened by the formation of dense fibrous tissue in and below the periosteum, of less dense fibrous tissue outside the periosteum, and of cartilage from the periosteal bridge. The newly formed tissue contracts decidedly. During the third week ossification begins at the points farthest from the fracture, and in the course of a short time (from three to six weeks) is complete. The mass of ossified callus, or new bone, is spindle shaped and spongy.

The terms *intermediate*, *definitive*, or *permanent* callus are used to describe the material which forms between the ends of the broken bone. The names *provisional* or *temporary* callus are given to the material within the canal (central callus) and external to the bone (ensheathing callus). The amount of provisional callus depends directly on the extent of separation and the amount of motion between the fragments. It is Nature's splint, and when the break is not well immobilized a large amount is formed. The greater the amount of motion, short of a degree sufficient to cause non-union, the larger the amount of provisional callus.

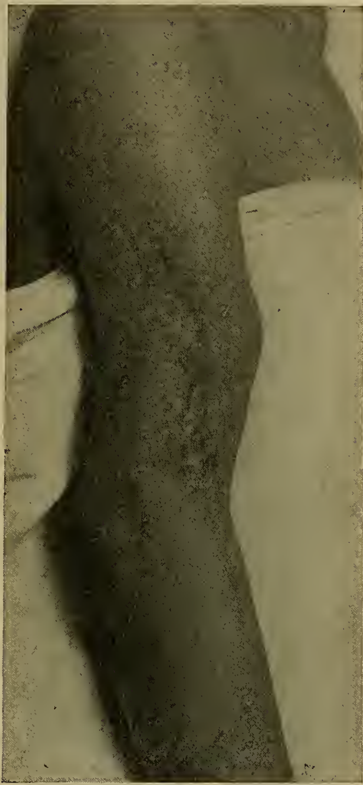

Fig. 271.—Ununited fracture of humerus; unsuccessful wiring.

The ensheathing callus is after a time largely absorbed, and the central callus in the course of a long time may also be absorbed, with the restoration of the medullary canal, although this latter result is rare. An excessive amount of provisional callus may ossify nearby tendons, may unite parallel bones (radius to ulna, tibia to fibula, a rib to its neighbors), may block a joint just as a stone in the crack of a door will block a door, or may absolutely abolish a joint. Fragments, even if entirely detached, often unite, but they may be surrounded by provisional callus; sometimes they do not cause trouble, but sometimes suppuration takes place. It takes about one year for Nature to remove the temporary callus. The definitive or permanent callus after a time ceases to be porous and becomes very dense bone.

Compound fractures (Fig. 270) without much destruction or bruising of soft parts, if treated antiseptically, soon become simple fractures and unite as such. If the wound is not drained and asepticized and septic inflammation occurs, pus forms, and union by granulation is the best that can be obtained. Compound fractures by direct violence will not heal by first intention because of the loss of vitality of a large area of the soft parts.

Delayed union is usually due to imperfect approximation or unstable fixation of the fragments. Imperfect approximation may result from failure to reduce the fracture (muscle, ligament, or synovial membrane being caught between the bone-fragments); the use of unsuitable splints; too tight application of bandages; pregnancy; and general causes of ill health, for instance, anemia, scurvy, Bright's disease, rickets, and syphilis. In delayed union there is pain on passive motion; in non-union there seldom is. In delayed union there

is loss of voluntary motion; in non-union there is power of voluntary motion (A. H. Tubby, in "Brit. Med. Jour.," Dec. 7, 1901). In delayed union there is apt to be tenderness on pressure and often a quantity of callus can be palpated. Delayed union is not non-union, but may eventuate in non-union. The exact time requisite for the solidification of a particular fracture cannot be predicted. The average, taken from a large majority of patients, is not true in a minority. For no apparent reason consolidation may require two or three weeks more than the average, but be accomplished at last. Mr. Jones, of Liverpool, well says that ununited fracture is often the result of "surgical impatience," the surgeon frequently examining a part in which union is slow, and that "non-union would rarely occur if delayed union obtained proper attention" ("Brit. Med. Jour.," Dec. 7, 1912).

Fig. 272.—Vicious union of fractured bones of the leg. View from inner side of limb.

Fig. 273.—Ununited fracture of the femur.

Bending of Callus.—Sometimes apparently sound callus will bend. This is particularly apt to occur in the leg if the bones are not in correct alignment. Failure of correct alignment means great deflection of the weight of the body. I have seen shortening of the femur increase during the third month after a fracture. Mr. Jones, of Liverpool (Ibid), points out that the surgeon can refracture bones by manipulation up to four months after the break. It is obvious that fractures are not soundly united as early as we used to believe, and that a patient must not be allowed to walk too early.

Vicious or **faulty union** is union with great deformity (Fig. 272). This occurs when no treatment has been employed, or when immobilization has been imperfect, or when deformity has not been reduced. It may arise because retentive dressings have been removed by the patient at too early a period, the

callus yielding. In many cases it is slight and produces little or no pain or impairment of usfulness. In other cases it is pronounced and produces functional impairment or disastrous pressure on nerves or vessels. Vicious union near a joint always impairs function. If there is pronounced vicious union the bone should be rebroken and set as a fresh fracture. In some recent cases the bone is broken by manual force, and for a number of weeks after a fracture this can be easily accomplished. In older cases osteotomy should be performed.

Non-union of Fractures.—An ununited fracture is a fracture in which union is not effected at all or in which it is not brought about by bone (Figs. 271 and 273). Non-union is especially common in fractures of the upper third of the femur and of the middle third of the humerus. The causes are local and constitutional. The *local causes* are: (1) Want of approximation of fragments; a frequent cause of want of approximation is interposition of soft tissues—viz., muscle, fascia, or periosteum; this is a common cause of non-union, a cause responsible for a decided majority of the cases; if soft tissues are interposed between bone-fragments non-union is almost inevitable; (2) want of rest. As pointed out above, delayed union may result in non-union because of frequent meddlesome examinations. As Jones says, if there is no union at the end of the fifth week do not examine daily, but leave the parts alone for a fortnight at least; (3) want of blood-supply (as seen in the heads of the humerus and femur, or when a nutrient artery is torn, or when a thrombus forms in a vein near the fracture); (4) defective innervation; (5) bone disease; (6) the use of unsuitable splints; (7) tight bandaging. The *constitutional causes* are debility, scurvy, Bright's disease, syphilis, etc. Sometimes union fails without appreciable reason. In an ununited fracture the broken ends of the bone round off and the medullary canal of each fragment becomes closed by bone. The fragments may not be held together by any material, or they may be held by very thin and much-stretched fibrous tissue (*membranous* union), or by strong, thick, fibrous tissue (*ligamentous* or *fibrous* union). When the ends of the bones come together, are held by a fibrous capsule, and move on each other, there exists a *false joint* or *pseudo-arthrosis*. Such a joint may after a time secrete serous fluid for lubrication. In very rare cases a fracture once apparently soundly united may at a later period be obviously ununited, callus having been absorbed or broken. Pain on active motion in the region of a fracture a number of weeks old suggests non-union. If there is also tenderness non-union is highly probable. If, with pain and tenderness, there is marked thickening from callus, non-union is certain ("Brit. Med. Jour.," Dec. 7, 1912).

Treatment of Fractures.—If a man is found in the street with a fracture, further injury must be prevented by applying, after cutting off the clothing over the fracture, some temporary support. If an ambulance or patrol-wagon cannot be obtained, move the patient by hand. If the lower extremity be involved, an improvised stretcher (a board or a shutter) is placed on the ground beside the patient, who is laid on the stretcher, the surgeon lifting the injured limb, and the patient is then carried to the hospital and carefully transferred to a fracture-bed, or, if taken home, to a small ordinary bed, several boards being placed transversely beneath a rather hard but even mattress. The temporary appliances are now removed and a diagnosis is made by the methods before given. Whenever possible have x-ray pictures taken (see page 523). After determining the nature of the injury the fragments must be adjusted. This should, if possible, be done at once, because a fracture remaining unreduced may become compound, the fragments may injure important structures, and they are apt to cause intense pain. Reduction is easily effected during shock, as the muscles are in a state of relaxation. Early reduction and fixation largely prevent swelling. If there is very great swelling, reduction may be impossible, and the part must then be supported, moderate

cold, sorbefacients, and gentle pressure being used, ice and tight bandaging, which predispose to gangrene, not being employed. In most cases we can reduce displacement in spite of swelling and cure swelling by the reduction. Set the fracture at the first possible moment. Velpeau's axiom was to reduce fractures at once, regardless of pain, spasm, or inflammation, as reduction is their cure. The longer we wait to reduce a fracture, the greater the amount of force necessary to accomplish it because of progressive infiltration of the soft parts with inflammatory exudate and blood, a process which lessens and finally destroys tissue elasticity. In reduction try to get broken ends in even apposition. In this we may fail, but we must at least strive to obtain a correct alignment. In order to obtain apposition or alignment it may be necessary to make traction by pulleys, and if this is done the patient must be anesthetized (Jones, "Brit. Med. Jour.," Dec. 7, 1912). He says that "end-to-end apposition with an angle of deflection is less satisfactory than slight overlapping in the presence of correct alignment" (Ibid.).

If the patient is very nervous, if the pain is severe, or if rigid muscles antagonize the efforts of the surgeon, reduce the fracture under anesthesia. In some fractures (as those of the clavicle) adjustment is effected by altering the position, and in others (as those of the femur) by extension and counterextension, aided perhaps by pulleys; in some by tenotomy, and in some by kneading, bending, and coaptation. When extension is employed, always endeavor to get a point of counterextension. The extension is to be made on the broken bone (if possible, in the axis of the bone), is to be steady, and neither jerky nor violent. In some cases complete reduction is impossible. This may be due to spasm, to swelling, to the catching of soft parts between the fragments, to the existence of a loose fragment, to locking, or to impaction. An impaction by rotation can generally be released, but it is sometimes undesirable to unlock it. If the fragments cannot be adjusted without violence, retain them in the best attainable position, combat the antagonistic cause, and set them properly as soon as possible or else operate.

After adjusting the fragments maintain them in position by some apparatus. Do not use set splints for each variety of injury. The splints we describe as commonly used are suited to many cases, but in each case a surgeon uses the plan of treatment which in his opinion is suitable to that case. In a given case the routine plan may prove unsuitable. The treatment is to be adjusted to the individual case. The case is never to be forced to an unsuitable routine treatment. All sorts of materials are used for splints, among them may be mentioned wood, felt, pasteboard, plaster of Paris, silicate of sodium, tin (Levis), and aluminum (Elsberg). Avoid pressure over joints or bony prominences and particularly guard against tight or improper bandaging. In fracture of a bone of a limb the circulation in the fingers or toes must be observed as an index of circulation in the limb; hence leave those digits exposed. A retentive apparatus should prevent the redevelopment of deformity, and not be itself productive of pain or harm. For the first few days of treatment of a simple fracture the dressing is removed every day, to make sure that deformity has not recurred, and if it does recur the fragments must at once be reset. The splints should be padded thoroughly, especially when over joints or bony prominences, and they should, if possible, fix the joints immediately above and below the break. A primary roller should not be used unless plaster is to be employed. By a primary roller is meant a bandage applied to the extremity before splints are placed upon it.

Some surgeons at once apply an immovable dressing. This proceeding is safe in simple fractures without much displacement or soft-part injury. This dressing is valuable in military practice, for the old and feeble whom we fear to put to bed, for the young who are very restless, and for the insane or the

delirious. If, however, there is great deformity, much soft-part injury, or marked swelling, immovable dressings may induce sloughing, edema, gangrene, or faulty union. In the above-named cases use ordinary splints for the first few days; then, if it is desirable, the immovable dressing can be applied. Plaster-of-Paris bandages are used with great care in very young children, as gangrene might result from careless application. It is dangerous to keep old or feeble persons long in bed, as they are prone to develop bed-sores and hypostatic pulmonary congestion. The period for the artificial retention of the fracture varies with the seat of the fracture and the age and condition of the patient. Passive motion is to be made in most fractures in from two to three weeks, though it is sometimes made earlier to prevent ankylosis, and sometimes later because of risk of non-union. Landerer strongly advocates massage, believing that it hastens union and prevents wasting. He applies it as soon as there is no danger of the callus bending (in from eight to fourteen days). Massage should not be used when great edema points to the possibility of venous thrombosis. The movements might break up a clot and cause fatal embolism.[1] Very early massage may cause fat-embolism. In fracture of the patella wiring is frequently performed, and wiring or plating is frequently practised in fracture of the clavicle, fracture of the tibia, fracture of the upper third of the femur, and other regions. If fragments cannot be approximated or retained by ordinary methods, an incision should be made, approximation effected, and the fragments retained by wire, a clamp, a plate, or a bone ferrule.

The plan known as the **ambulatory treatment** of fractures of the lower extremities has had warm advocates. The ambulatory splint is an apparatus which enables a man to walk about a few days after receiving a fracture of the leg or thigh. It was devised by Hessing, a carpenter dwelling in a village near Augsburg. Its aim is not only to get the patient about on crutches, but also to cause him to use the limb. It is held that this plan of treatment greatly lessens the patient's sufferings and actually favors union by the stimulation of walking. Bardeleben, in his report to the German Surgical Congress, gave the records of 111 fractures of the lower extremity thus treated (77 simple and 12 compound fractures of the leg, 17 simple and 5 compound fractures of the thigh). The patients were gotten about a few days after the accident, were able to attend to business, had excellent appetites, digested their food perfectly, slept well, and were saved from muscular atrophy. Pilcher has warmly advocated the method. It can be used in fractures as high up as the middle of the femur. The apparatus which we should employ in the ambulatory treatment reaches below the sole of the foot, and is supported firmly above the seat of fracture, the weight of the body being transferred from above the fracture to the firm pad below the sole of the foot on which the patient walks (Figs. 274 and 275). This appliance in a fractured thigh is put on about one week after the infliction of the injury. While the patient sits on the ischial tuberosities extension is made upon the leg. The seat of fracture is encircled by a thin plaster cast. The sole of the other foot is raised by a cork sole. Albers, when treating a fractured thigh, uses plaster of Paris strengthened by bits of wood, running from *below* the sole of the foot to the iliac crest. Krause says in fracture of the ankle carry the dressing to the head of the tibia; in fracture of the leg carry it to the middle of the thigh; in fracture of the lower end of the femur carry it to the pelvis.[2] Bradford warmly advocates the use of Thomas's splint often combined with plaster of Paris. During the last few years surgeons have come to recognize that ambulatory treatment must not be used for all fractures of the lower extremity and is only suited to selected cases.

[1] Cerne's case, in "Normandie méd."; "Bull. med.," 1895, No. 44.
[2] "Centralbl. f. Chir.," vol. xxii, 1895.

Prevention and Treatment of Complications.—In every case of fracture of an extremity feel for the pulse between the periphery and the seat of injury in order to be sure the artery is not ruptured. If the soft parts are badly contused, try to prevent sloughing by employing rest and relaxation and by applying heat. If superficial sloughing occurs, treat antiseptically, remembering that even a superficial excoriation can admit bacteria which, carried by the blood or lymph, may infect the bones. If a slough leads down to the fracture, treat the case as a compound fracture. If there be great blood extravasation the danger is gangrene, and after fracture of the lower extremity the foot of the bed may be elevated, or, better, after fracture of the upper or lower limb the extremity, to which splints and bandages are to be loosely applied, is to be raised and surrounded with hot bottles. If a bleb forms, it is to be opened

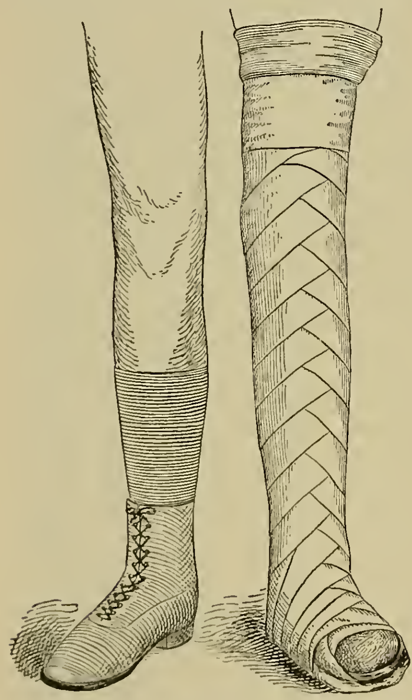

Fig. 274.—Ambulatory dressing of plaster of Paris for fracture of the bones of the leg (Pilcher).

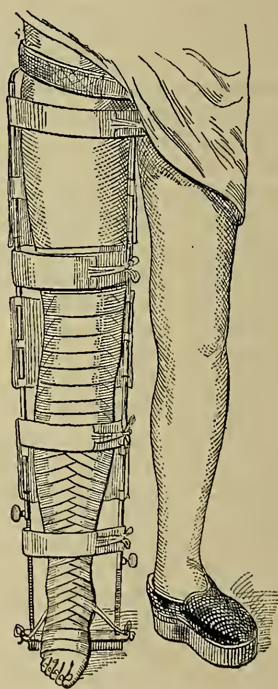

Fig. 275.—Ambulatory dressing apparatus for fracture of thigh (Harting).

with a clean needle and dressed antiseptically. If gangrene occurs, treat by the usual rules. Frequently after fracture of a bone blebs containing reddish serum form on the skin. The appearance of *blebs* when the circulation is good does not mean gangrene, and is not of any particular consequence. If blebs are distinct symptoms of circulatory impairment, gangrene impends or already exists.

Edema may be due to tight bandaging. If it is due to phlebitis, there is danger of pulmonary or cerebral embolism. In phlebitis elevate the limb, remove all constriction, and employ locally ichthyol ointment; do not use massage, and give stimulants by the mouth. In edema due to weak circulation or venous relaxation use daily frictions and firm bandaging. If the fracture involves a joint, carefully adjust the fragments, make passive motion early, and inform the patient that he is in danger of a permanently stiff joint.

A *dislocation occurring with a fracture* is reduced at once if possible. To do this, splint the limb and give ether, and try to reduce while the limb is massaged, using the splint as a handle. Allis is often able to reduce a dislocation accompanied by a fracture. He uses the untorn portion of periosteum as a hinge, pulls upon the lower fragment, and thus draws down the upper fragment and pushes it in place by manipulation. If this fails, it is best to incise and pull the separated end in place by the hook of McBurney and Dowd (Figs. 276–278); but some surgeons say, get the bones in the best possible position, set them, await union, and then treat the unreduced dislocation. A *rupture of the main artery* of the limb presents the symptoms of absent pulse below the rupture, a tumor which may pulsate, and possibly a whirring sound or an aneurysmal thrill and bruit. This condition demands that the surgeon should apply an Esmarch bandage, cut down upon the tumor, turn out the clot, and ligate each end of the vessel. *Rupture of the main vein* of a limb causes intense edema and calls for sutures, lateral ligature, or complete ligation. If these measures fail after injury of vein or artery it is seldom successful to ligate higher up. Such a course might succeed in the upper extremity. It would almost certainly fail in the lower. Amputation will probably be necessary. If gangrene appears, amputate at once above the seat of the fracture.

Fig. 276.—Fracture-hook (McBurney and Dowd).

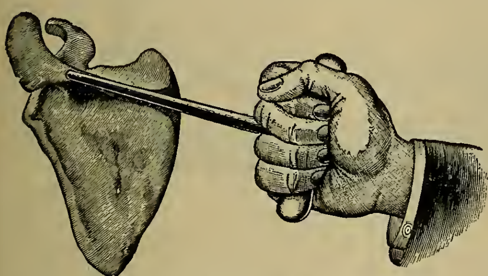

Fig. 277.—Fracture-hook applied at base of acromion process (McBurney and Dowd).

Inflammation is to be treated by compression, rest, moderate cold, and later by 50 per cent. ichthyol ointment. *Muscular spasm* requires morphin internally, firm bandaging, or even tenotomy. Fat-embolism is treated by stimulants and inhalation of oxygen, and possibly artificial respiration. Shock, delirium tremens, urinary retention, etc., are treated according to the ordinary rules of surgery.

Functional Result of Non-operative Treatment.—Union with a good anatomical result means a good functional result in over 90 per cent. of the cases. We used to suppose that a good functional result is usual even with a poor anatomical result, but Jones ("Brit. Med. Jour.," Dec. 7, 1912) shows that we get it in less than 30 per cent. of cases in which the anatomical result is bad.

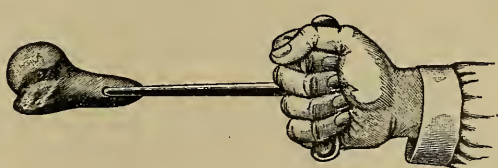

Fig. 278.—Fracture-hook inserted in displaced fragment (McBurney and Dowd).

Treatment of Compound Fractures.—It must first be decided, in a case of compound fracture of a limb, if amputation is necessary, and the x-rays are of great value in determining the condition of the bones in a crushed part.

Amputation is demanded when the limb is completely crushed or pulpified through its entire thickness; when extensive pieces of skin are torn off; when the main artery, vein, and nerve are torn through; and sometimes when there is violent hemorrhage from a deep-seated vessel or when an important joint is splintered. What is to be done is to some extent determined by the patient's age and general health. In a healthy young person, if in doubt, give the limb the benefit of the doubt and try to save it; if the artery alone is ruptured, cut down upon it and tie both ends; if the vein alone is torn, suture it, apply a lateral ligature, or tie both ends; if the nerve is severed, suture it; if a joint is opened, drain and asepticize. If an attempt is made to save the limb, be ready at any time to amputate for gangrene, secondary hemorrhage (if religation at original point and compression high up fail), extensive cellulitis, and profuse and prolonged suppuration.[1] When it is determined to try to save the limb, the part must be cleansed thoroughly by the antiseptic method (in no injuries is this more important). If a small portion of bone protrudes, cleanse the skin of the extremity and the protruding bone, push the spicule out a little more, and cut it off. If a large piece of bone is protruded it must not be cut

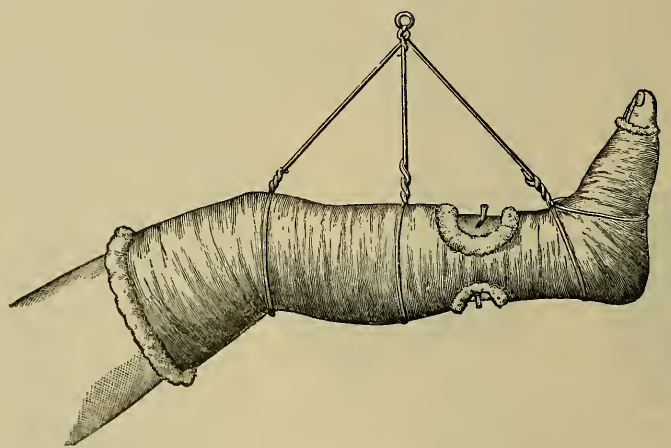

Fig. 279.—Fenestrated plaster-of-Paris dressing. Drainage-tube pulled through limb.

away, but should be thoroughly disinfected, and after the skin wound has been enlarged should be returned into place. Hemorrhage requires a free incision to permit of ligation of bleeding points. In most comminuted fractures splinters should not be removed. To remove them favors non-union. In all cases a drainage-tube must be carried down to the seat of fracture, and in some cases a counteropening must be made and the tube be pulled through the limb (Fig. 279).

After inserting the tube the wound is sutured, a plentiful antiseptic dressing is applied, and the extremity is dressed with plaster. The plaster can be applied over a narrow strip of wood, trap-doors or fenestra being cut in the plaster before it sets (the *fenestrated splint*) (Fig. 279). The wound is then covered with gauze and a bandage.

The bracketed splint is a better dressing than the one just described. After the wound has been dressed with gauze, plaster is at once applied over the ends of brackets (Fig. 280). The above methods not only immobilize the fractured bones, but keep the parts aseptic and afford easy access to the wound. The drainage-tubes are usually removed, if suppuration does not occur, in from

[1] See Howard Marsh, on "Fractures," in Heath's "Dictionary of Practical Surgery."

forty-eight to seventy-two hours. The wound is treated as any other wound. In some compound fractures there is difficulty in retaining the fragments in apposition (lower end of femur, upper third of femur). In such cases the ends of the bone should be resected and the bones should be fastened together as in a case of ununited fracture, with silver wire, aluminum wire, chromicized catgut, kangaroo-tendon, or the bones should be plated. In a *compound fracture of the patella,* after free incision and disinfection, investigate to determine the gravity of the injury. In an ordinary case in which there are two or three fragments, open the joint, irrigate with saline fluid, drill the fragments, and fasten them with silver wire. Very small fragments should be removed. A tube is carried into the joint, the wound is sutured and dressed, and the limb is immobilized in extension. In a case of severe compound comminuted fracture of the patella, after disinfection, any completely loose piece should be removed and "the remaining portions made smooth with bone forceps and the sharp spoon."[1] The wound is only partially sutured, is drained and dressed, and the limb is placed on a straight posterior splint. If a fracture of a rib is compound internally, resect the rib; if it is compound externally, dress antiseptically.

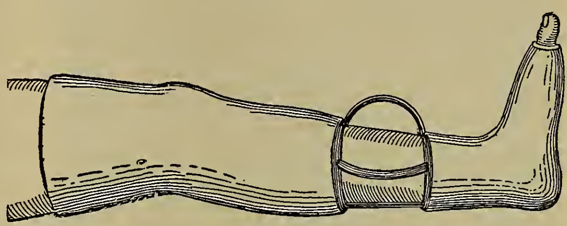

Fig. 280.—Bracketed plaster-of-Paris dressing.

Compound fractures may be followed by gangrene, sloughing, periostitis, septicemia, pyemia, osteomyelitis, necrosis, etc.

Operative Treatment of Recent Fractures.—Many cases are now operated upon primarily. Others are operated upon because non-operative methods fail to obtain or to maintain good position. In some fractures reduction and fixation are only possible by operation.

Skiagraphs have demonstrated that the ordinary non-operative treatment is often followed by permanent displacement. In many cases this does not seriously impair function, in not a few it does. There is much impairment of function after fracture of the patella with wide gaping of the fragments, and after fracture of the femur with repair in a position of marked angulation or decided overlapping.

The most perfect results are obtained by operation, which exposes the fracture and enables the surgeon to correct the deformity and solidly fix the fragments. Practically all surgeons agree that for fracture of the patella, fracture of the olecranon, and fracture of a long bone with incomplete reduction, or in which deformity recurs in spite of splintering, operation gives the best chance for a good functional result. In most fractures of long bones treated conservatively perfect apposition of the fragments is not obtained, although we may think it has been. Bloodgood points out that in fractures near joints there is great difficulty in reduction and little evidence of deformity.

The Special Committee of Inquiry of the British Medical Association in a recent report warmly advocates operation in many cases. Jones, of Liverpool, although believing as a general rule in non-operative treatment, says that if in any case there is sound reason to doubt the successful outcome of non-operative treatment, operation should be performed. He opposes waiting to see what happens because the delay may lose the chance of obtaining a good functional result ("Brit. Med. Jour.," Dec. 7, 1912).

[1] Lilienthal's "Imperative Surgery."

Personally, I follow Mr. Jones's rule and operate when I fear that conservative treatment may fail. I operate primarily for:

Fracture of the patella.

Fracture of both bones of the leg in the lower third.

Most fractures of the os calcis.

Some cases of Pott's fracture.

Most cases of fracture of the upper third of the femur.

Some fractures of the neck of the femur in the young and middle aged.

Some fractures of the surgical neck of the humerus.

Fractures of the olecranon, especially those in which the upper fragment has rotated.

Some fractures of the elbow-joint.

Some fractures of both bones of the forearm (in order to preserve pronation and supination).

Some fractures of the metacarpus.

Fractures of the zygoma.

Some fractures of the mandible.

Fractures of the clavicle when complete reduction is impossible or when sharp-pointed fragments threaten to pierce the skin or damage important structures.

In compound fractures, in many comminuted fractures, if an important nerve or blood-vessel has been divided.

Most children are managable by conservative methods and do not do as well as adults after operation. Hence in children I am more conservative than in adults.

Again, do not forget that operation may not give a good functional result. It often fails to do so. If this is not well understood both the surgeon and patient may be disappointed after operation. There is, of course, some risk in the treatment by incision, and it is only justifiable in competent hands and amid proper surroundings. The occasional operator should look to it with less confidence than the daily operator. If infection occurs it will be a catastrophe, and may cause death, hence perfect asepsis is imperatively required. It can never be routine treatment and will never be extensively employed outside of a hospital.

If operation is determined upon, an incision is made, the bone is inspected, tissue intervening between the fragments is removed, and the fragments are coaptated and fixed by screws and a perforated plate, by silver wire sutures, bone-ferrules, chromic catgut, nails, or some form of clamp.

Plates and screws give the best results. Wire used for fracture of a long bone acts as a hinge, and in a wired fracture the alignment is apt to be disturbed. Wire was first used for this purpose in 1775 by Lapeyode and Sicre, of Toulouse (Geo. W. Guthrie, "Amer. Med.," March 7, 1903). It is now seldom used except for the patella, the olecranon, the clavicle, the zygoma, and the anatomical neck of the humerus. I prefer the steel plates of Arbuthnot Lane (Fig. 281) or the silver plates of Halsted. These plates are perforated for screws. The plate is not removed unless it loosens or gives trouble. After operation the extremity must be carefully fixed by splints or plaster of Paris; the circulation must be watched, guarded, and maintained; massage should be used and passive motion be employed as in a case treated by the non-operative method. If rigid fixation of the fragments is obtained and maintained repair will usually occur with very little callous formation.

Treatment of Delayed Union and Ununited Fracture (see page 692).—When delayed union exists, seek for a cause and remove it, treating constitutionally if required, and thoroughly immobilizing the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussion over the fracture,

and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodin or firing it has been employed. If the union be very long delayed, forcibly separate the fragments and put up the limb in plaster as we would a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places. Buechner advocates the induction of hyperemia by a constricting band, just as Bier induces congestive hyperemia in treating tuberculous areas. At first the constriction is permitted to remain but a short time, but the period is lengthened every day, until in a few days it remains almost continuously day and night. It is to cause a pinkish-blue flush of skin, but not pain. The limb must be warm to the touch. During the two or three hours daily that the band is off raise the limb to relieve edema. Ten days of this treatment will inaugurate union in many cases. Helferich devised this method in 1887. In several cases I have thought that it did good. I also administered thyroid extract to these patients. Lannelongue and Menard inject a 1:10 solution of zinc chlorid between the fragments. I have had several successes with this plan. Leaving acupuncture

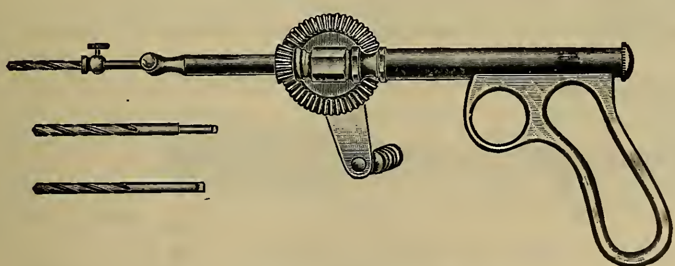

Fig. 282.—Richter's bone-drill (pistol grip).

needles in for days is approved by some, and electropuncture is advocated by others. Cases of ununited fracture must be treated by excision of the bony ends and fibrous tissue, securing the fragments together by periosteal sutures, by pins, by screws and plates, by ivory pegs, by screws, by silver or aluminum

bronze wire, by kangaroo-tendon, by Senn's bone-rings or bone-ferrules, or by chromicized catgut. Personally, I use Lane's plates, made of vanadium steel. Delorme makes an incision, removes bone-splinters and fibrous tissue, smooths

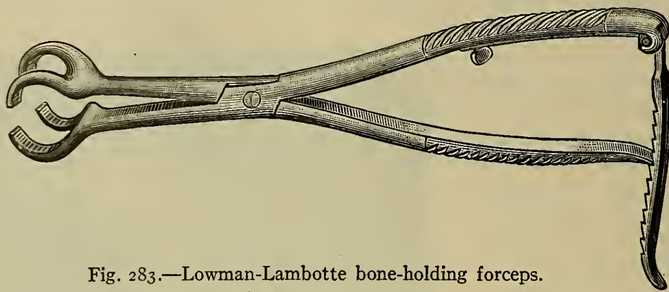

Fig. 283.—Lowman-Lambotte bone-holding forceps.

off one end, forces this into the bored-out medullary canal of the other fragment, and sutures the periosteum. Gussenbauer's clamp will often give a good result, and was used for years by Billroth. This is a metal bar with two nails set at right angles to the bar. One nail is driven into each fragment. Langenbeck fixed a screw into each fragment and connected the screws by a piece of iron. Parkhill's clamp, which is an improvement on Langenbeck's instrument, secures absolute immobility and is a very useful instrument.

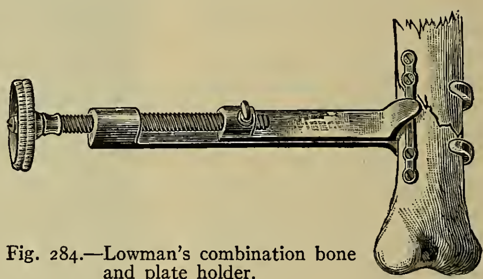

Fig. 284.—Lowman's combination bone and plate holder.

Sometimes union fails in spite of a formidable operation. In such cases there is no tendency to bone production. A bone-graft may be partially separated from one of the fragments and interposed between the freshened ends, a bone-graft may be taken from the sound tibia and be interposed, fresh bone-splinters may be interposed, or a portion of a rib may be used with screws or nails as a clamp. It is always desirable to take the bone-graft from the individual. Such a graft is more powerfully stimulating to bone growth than a graft from another individual or from one of the lower animals. Transplantation from the lower animals has, however, been successfully practised (see page 503).

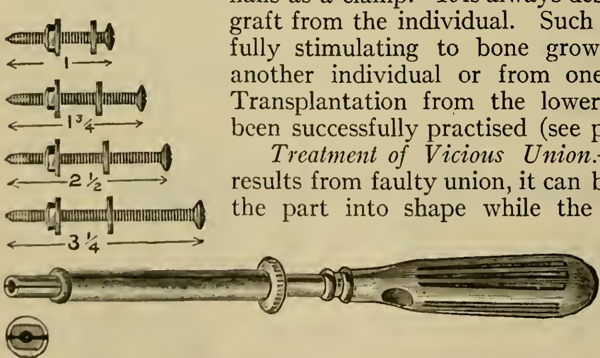

Fig. 285.—Sherman's bone bolts and nut-driver.

Treatment of Vicious Union.—If angular deformity results from faulty union, it can be corrected by molding the part into shape while the callus is soft. If the callus has become hard, the bone can be refractured. If faulty union occurs with overriding, an osteotomy can be performed.

Special Fractures.—Nasal bones, because of their situation, are often broken. The commonest seat of fracture is through the lower third, where the bones are thin and lack support. The fracture is usually compound externally or through the mucous membrane internally. The *cause* is direct violence. Displacement may not occur at all, but when present it arises purely from

force, and never from muscular action, no muscle being attached to these bones. If the force is from the front, the nose is flattened; if from the side, it is deflected. Displacement is soon masked by swelling. Crepitus can sometimes be elicited by lightly grasping the upper part of the nose with the fingers of one hand and moving it gently below from side to side with the fingers of the other hand. Preternatural mobility is valueless as a sign, because of the natural mobility of the cartilages. Nose-breathing is difficult because of blocking of the nostrils by blood-clot. Diagnosis may be almost impossible when deformity is absent.

The complications that may be noted are cerebral concussion, brain symptoms from implication of the frontal bone or cribriform plate of the ethmoid bone, and extension of the fracture to the superior maxillary or lachrymal bones. Emphysema of the root of the nose, the eyelids, and the cheeks is common, and means either a rent in the mucous membrane of Schneider or a crack in the frontal sinus. There may be much discoloration because of subcutaneous hemorrhage. Epistaxis is usual, and is recognized from the epistaxis produced by fracture of the base of the skull by the facts that the bleeding in the first condition, although profuse, is, as a rule, soon checked, and is not followed by oozing of cerebrospinal fluid, whereas in the second condition it is profuse, continued, and is perhaps followed by a flow of cerebrospinal fluid. Fracture of the bony septum occasionally complicates nasal fractures, and deviation of the cartilaginous septum often takes place. Suppuration may occur and necrosis of bone or cartilage may follow. The prognosis is usually good.

Treatment.—Whenever possible nasal fractures should be treated by a rhinologist. After cocainizing the nares a careful inspection should be made by means of a mirror and a light to determine if there is any injury of the septum. This point must be determined in order that the deformity of the septum may be corrected at the same time as the deformity of the nasal bones. When there is no displacement, or when a displacement does not tend to be reproduced after reduction, employ no retentive apparatus of any kind. Order the patient not to blow his nose for ten days and syringe it daily with a solution of bicarbonate of sodium. If deformity be noted, correct it at once, as the bones soon unite in deformity. If the attempts at reduction are very painful, or if the subject be a child, a woman, or a nervous man, give ether to obtain primary anesthesia. Reduction is effected by a grooved director or steel knitting-needle wrapped in iodoform gauze and passed into the nostril; the fragments are lifted with this instrument, and the fingers externally mold them into place. A rubber dilator can be used in reduction. This is pushed into the nose and inflated by air or water. If the septum is deviated and cannot be pushed in place by a metal sound, it must be twisted into place by means of septum forceps. If bleeding is moderate, check it with cold; if severe, by plugging. "For fractures high up with displacement, gauze packing carried well up will be required to retain the elevated bones. For lower deviations the Asch tube will be needed" (Scudder, on "The Treatment of Fractures"). A hollow vulcanite plug is inserted in each nostril and the nose is molded into correct shape over the plug. The patient breathes through the hollow plug. A thread runs from each plug and is fastened to the cheek by adhesive plaster. Once or twice a day the plugs are removed, cleaned, and greased with iodoform ointment. The nose is cleared and the plugs are reinserted. If flattening tends to recur, pass a Mason pin (Fig. 286) just

Fig. 286.—Mason's pin.

beneath the fragments, through the line of fracture and out the opposite side. Steady the fragments by a piece of rubber externally caught on each end of the pin, or with figure-of-8 turns around the ends with silk. Leave the pin in place for five days. The instrument of Mason is a sharp, strong, nickel-plated pin, with a triangular point.

If lateral deformity tends to recur, hold a compress over the fracture or fix a molded-rubber splint over the nose by a piece of rubber plaster $1\frac{1}{2}$ inches broad and long enough to reach well across the face, and use compression for ten days. In neither of the above cases is the nose to be blown, and in both cases it is to be syringed once or twice a day. In fractures rendered compound by tears in the mucous membrane, irrigate with normal salt solution or boric acid solution, holding the head so that the solution will not run into the mouth; plug with iodoform gauze around a small rubber catheter, which instrument permits nose-breathing; carefully remove the gauze daily and syringe. In fractures compound externally cleanse antiseptically externally, and dress with a film of cotton soaked in iodoform collodion or compound tincture of benzoin, or apply sterile gauze. Fractures of the bony septum, if showing a tendency to reproduction of deformity, require packing as above explained, or the use of a special splint within the nostrils (Fig. 287), or the application of vulcanite plugs, so made that the patient can breathe through them and threads can be attached to them. Fractures of the nasal cartilages are to be pinned in place. Fractures of the nose are entirely united in from ten to twelve days.

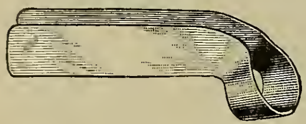

Fig. 287.—Jones's nasal splint.

Fractures of the Lachrymal Bone.—The lachrymal bone may be broken when the nasal bones, a superior maxillary bone, or the lateral plate of the ethmoid are fractured, and union is solid in from three to four weeks. The question of how much deformity is to be expected is always uncertain, and in not a few cases obstruction of the nose follows fracture because of damage to the septum.

Treatment.—Treat the chief injury, which is the fracture of the other bone or bones. Maintain the patency of the lachrymal duct by frequently passing a clean probe.

Fractures of the Superior Maxillary Bone.—Although a fragile bone, the superior maxillary is rarely broken except through the alveolar border. It may be broken by transmitted force from blows on the chin, or on the head when the chin is fixed; but direct violence is the usual cause. The walls of the antrum may be crushed in. Comminution is the rule, and the injury is often compound. These fractures induce great swelling, pain, and inability to chew. Mobility and crepitus may be detected. Deformity is due to the breaking force, and not to the action of any muscle. When a portion of the alveolar arch is fractured, as may occur in pulling teeth, the small fragment is depressed backward, and there exist irregularity of the teeth (some of which may be loosened) and inability to chew food. Fracture of the nasal process is apt to injure the lachrymal duct. When the antrum is broken in there are great sinking over the fracture, depression of the malar bone, and emphysema. Transverse fracture of the upper part of the body of the bone may cause no deformity. The force required to break the superior maxillary bone is so great that fractures of other bones almost certainly occur, and concussion of the brain not infrequently exists. Injury of the infra-orbital nerve is not unusual, causing pain, numbness, or an area of anesthesia involving one-half of the upper lip, the ala of the nose, and a triangle whose base is one-half the upper lip and whose apex is the infra-orbital foramen. There is

also loss of sensation in the gums and upper teeth of the injured side. Fractures of the superior maxillary bone occasionally induce fierce hemorrhage from branches of the internal maxillary artery; and if this has happened, be on the watch for secondary hemorrhage (these vessels being in firm canals).

Fig. 288.—Hard-rubber splint; wire arms and chin-piece held together by metal rods and nuts.

Treatment.—If the fracture does not implicate the alveolus, or if no deformity exists, apply no apparatus, but feed the patient on liquid food for four weeks. Reduce deformity, if it exists, by inserting a finger in the mouth. If the antrum is broken in, put the thumb in the mouth and push the malar bone up and back. In certain cases of deformity make an incision at the anterior border of the masseter muscle, insert a tenaculum or aneurysm needle, and pull the bone into place (Hamilton). If the malar bone or malar process is driven into the antrum, Weir tells us to incise the mucous membrane above and external to the canine tooth of the upper jaw, break into the antrum with a bone-gouge, insert a steel sound, lift out the malar bone, and pack the antrum with gauze. Loose teeth are not to be removed; they are pushed back into place and held by wiring them to their firmer neighbors. Hemorrhage is arrested by cold and pressure. If hemorrhage is dangerously profuse or prolonged, tie the external carotid artery.

Fig. 289.—Front view of splint (Fig. 288), with mouth closed (Moriarty).

If the line of the teeth, notwithstanding the wiring, is not regular, mold on an interdental splint. The usual splint for the upper jaw is the lower jaw held firmly against it by the Gibson, the Barton, or the four-tailed bandage. There is a great amount of dribbling of saliva during the treatment, and a dressing must be used to catch this fluid. Every day remove the bandage and dressing,

and wash the face with ethereal soap. The patient, who is ordered not to talk, is to live on liquid food administered by a nasal tube or by pouring it into the mouth back of the last molar tooth by means of a tube or a feeding-cup. Never pull a tooth to obtain a space; but if a tooth is lost, utilize the vacant space for this purpose. After every meal wash out the mouth with peroxid of hydrogen, followed by chlorate of potassium, boric acid, or normal salt solution, and thus prevent foulness and the digestive disorders it may induce. Dispense with the dressings in six weeks, and let the patient gradually return to ordinary diet.

In fractures compound externally do not remove fragments, antisepticize, arrest bleeding as far as possible by ligature, by pressure, or by plugging, wire the fragments if feasible, dress with gauze, and wash the mouth with great frequency. Fractures compound internally are treated as simple fractures, except that the mouth is washed more frequently.

The **malar bone** is rarely broken alone. Hamilton says no uncomplicated case is on record. The malar is a strong bone resting on a fragile support, and hence it may become a wedge to break other bones and yet itself be unfractured. The *cause* of fracture is violent direct force. A fracture of the orbital surface of this bone causes subconjunctival hemorrhage like that encountered in fracture at the base of the skull, and may produce irritation of the infra-orbital nerve. Protrusion of the eye may result either from hemorrhage or from crushing in of the malar bone. There is a hollow below and to the outer side of the orbit. Occasionally the line of fracture is detectable, but mobility and crepitus are very rarely discoverable. Chewing is apt to cause pain, and often the motions of the lower jaw are limited, the coronoid process being pressed upon by a depressed malar bone, an associated fracture of the zygoma, a blood-clot, or swollen tissue (see Scudder, on "The Treatment of Fractures").

Fig. 290.—Hard-rubber splint in position, upper teeth resting upon it (Moriarty).

Treatment.—If no deformity exists, there is practically nothing to be done. If deformity exists, try to correct it as in fractures of the superior maxillary bone. If correction is impossible by ordinary methods and the movements of the lower jaw are impeded by the displaced bone, make a small incision and through this insert an instrument and endeavor to lift the bone into place. As these cases are almost invariably complicated by fracture of the upper jaw, they are treated in the same manner as the latter injury. The union is complete in three weeks.

Fractures of the zygomatic arch are very rare. The *causes* are: (1) direct violence; (2) indirect force (from depression of the malar), and (3) forcing foreign bodies through the mouth. Direct violence is the usual cause. Direct violence causes inward displacement, and indirect force may cause outward displacement. The usual seat of fracture is at the smallest portion of the

process—that is, on the temporal side of the temporomalar suture (Matas). The symptoms are pain, ecchymosis, swelling, displacement, and difficulty in moving the jaw (because of injury to the masseter muscle).

Treatment.—In simple fracture give ether and try to push the arch in place. Many surgeons do not make an incision, as depression will do no harm and the functions of the jaw will be restored. Simply dress with a compress, adhesive strips, and the crossed bandage of the angle of the jaw. Union will take place in three weeks. Matas[1] advises operation. An anesthetic is administered and the parts are antisepticized. A long semicircular Hagedorn needle is threaded with silk, is entered 1 inch above the middle of the displaced fragment, is passed well into the temporal fossa, and is made to emerge ½ inch below the arch. The silk is used to pull a silver wire around the fracture, and this wire is employed to pull the bone into position. A firm pad is applied externally and the wire is twisted over the pad. Antiseptic dressings are applied, and on the ninth or tenth day the wire, splint, and dressings are removed permanently. I have employed this plan in 2 cases with perfect satisfaction.

Fractures of the inferior maxillary bone may, and usually do, involve the body, although they occasionally occur in the rami. Any part of the body may be fractured, the most usual seat being near the canine tooth or a little external to the symphysis (Pick). A portion of alveolus may be broken off. In fractures of the ramus either the angle, the condyloid neck, or the coronoid process may be broken. In fractures of the body the posterior fragment generally overrides the anterior. Fractures of the lower jaw are often multiple and are almost always compound, because the oral mucous membrane and alveolar periosteum are torn. The *cause* is usually direct violence. Indirect violence (lateral pressure) may fracture the body anteriorly. Fractures near the angle are always due to direct violence. Indirect violence may fracture the condyle (falls on the chin), and so may direct violence. Fractures of the coronoid process are very rare, and they arise from great direct violence (usually a gunshot-wound or some other penetrating force).

Fig. 291.—Hamilton's bandage.

Symptoms.—In fracture of the body preternatural mobility and crepitus generally exist. The gum over the fracture swells rapidly and decidedly. There is bleeding because of laceration of the gum; saliva dribbles constantly; the patient supports the jaw with the hand; great pain exists (possibly from injury of the nerve), and deformity is present, shown by inequality of the teeth if the fracture is anterior to the masseter, the anterior fragment going downward and backward and the posterior fragment going upward and forward. The downward displacement is due to muscular action (action of the digastric, geniohyoid, and geniohyoglossus). The backward displacement is due to the violence. The temporal, internal pterygoid, and masseter muscles draw the posterior fragment upward and to the front. Two or three days after fracturing the jaw some of the cervical lymph-glands enlarge. When a fracture of the lower jaw is compound internally, suppuration usually takes place and the odor of decomposition becomes marked. In fracture of the neck of the condyle the jaw

[1] "New Orleans Med. and Surg. Jour.," Sept., 1896.

is drawn toward the injured side, and the condyle is pulled inward and forward by the action of the external pterygoid muscle. In fracture of the coronoid process the temporal muscle pulls the small fragment upward.

The *complications* are: digestive disorders and dirrahea from swallowing foul discharges; loosening of the teeth; lodgment of loosened teeth between the fragments; bleeding (usually only oozing from the gum, but there may be hemorrhage from the inferior dental artery), and suppuration. Necrosis may follow these fractures, an abscess of the neck may develop, or a sinus may form.

Treatment.—Correct deformity with great care and be sure to bring the teeth into normal alignment. As a rule, push loose teeth into place and put back detached ones; but occasionally a tooth obstinately prevents perfect approximation, and if it does it must be removed. Remove a tooth if it lies between the fragments, but replace it in its socket after reducing the fracture. Wash the mouth with hot water to clean it and to check bleeding. If bleeding is very severe, compress the carotid artery for a time. The fracture can be dressed with a pad of lint over the chin and Hamilton's four-tailed bandage (Fig. 291). A common plan is to take a splint of pasteboard, felt, or gutta-percha; pad it lightly with cotton, mold it to the part, and hold it in place with a Barton or a Gibson bandage. If apposition of the fragments cannot be maintained by the above methods, fasten the teeth together with wire, wire the fragments together, or have a dentist apply an interdental splint (Figs. 292, 293). Fracture of the lower jaw can often be satisfactorily treated by Angle's bands. These bands are of great value in complicated cases, in which two or more fractures exist. Each band consists of thin metal and a screw and a nut to fit the screw. The band is adjusted around a firm tooth and a nut is applied so as to hold the band tightly. Several bands are placed upon teeth in both jaws. Silver wire or silk is thrown around the pins of the bands so as to catch, and the jaws are thus held firmly together. The patient is to be fed on liquid food (see Fracture of the Upper Jaw), the mouth is to be washed frequently with peroxid of hydrogen, followed by boric acid solution or normal salt solution, and if bandages are used they should be changed every second day. The union should be complete in five weeks. The best plan of treatment in all cases not operated upon is to send the patient to a skilful dentist and have him apply an interdental splint and direct the treatment. Though these fractures are usually compound, they do not endanger life.

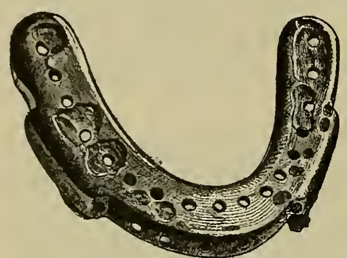

Fig. 292.—Vulcanite splint with boxes vulcanized on each side. If the jaw is fractured in the region of the molars, considerable pressure is required to get the parts in position; therefore it is best to vulcanize on to the sides of the vulcanite splint boxes into which wire arms can be inserted (Pilcher).

Fig. 293.—Interdental splint.

Fractures of the Hyoid Bone.—These fractures are uncommon injuries, and are caused by hanging, by throttling, and by falls in which the neck strikes some obstacle. If the bone breaks by throttling, it is its body which fractures (indirect force). Fractures by muscular action are most unusual.

Symptoms.—The symptoms are: A sensation of something breaking;

bleeding from the mouth if the mucous membrane be lacerated; pain, which is worse on opening the jaws or on moving the head or tongue; difficulty in swallowing; muffled, hoarse voice or aphonia; swelling, and frequently ecchymosis, of the neck. There are observed occasionally, though rarely, harsh cough and dyspnea, irregularity of bony contour, and crepitus. Always look into the mouth and see if there can be detected ecchymosis or laceration of the mucous membrane or projection of a bony fragment. The displacement is produced by contraction of the middle constrictor of the pharynx. A fracture of the hyoid bone may destroy life.

Treatment.—For dyspnea, be ready to perform intubation or tracheotomy at a moment's notice. Edema of the glottis is a great danger. Try to restore the fragments with one hand externally and with a finger in the mouth. Put the patient to bed and have him lie back upon a firm rest so that his shoulders are elevated. His head is to be placed between extension and flexion, a pasteboard splint or collar is molded on the neck, and a bandage is applied around the forehead, neck, and shoulders to keep the head immobile. The patient must not utter a word for a week; he must at first be fed by enemata, and then for some time on liquid diet, which is given through a tube early in the case. Endeavor to control the cough by opiates. A fractured hyoid bone requires about four weeks to unite.

Fractures of laryngeal cartilages are caused by direct violence, as throttling, blows, or kicks. They are rare in young persons, and are commonest when the cartilages have begun to ossify. They are very grave injuries, death tending to occur from obstruction to the entrance of air.

The *symptoms*, which are severe, are pain, aggravated by attempts at swallowing or speaking; swelling, ecchymosis it may be, and emphysema of the neck; cough; aphonia; intense dyspnea; and bloody expectoration if the mucous membrane is ruptured. There can be detected inequality of outline (flattening or projection) and perhaps moist crepitus. The usual seat of the injury is the thyroid cartilage.

Treatment.—Cases without dyspnea require quiet, avoidance of all talking, feeding with a stomach-tube, the application of compresses and adhesive strips over the fracture, and the use of remedies to quiet cough. The surgeon must be ready to operate at any moment. In most cases dyspnea exists, due to projection of the fragments or submucous extravasation. When there is dyspnea, emphysema, or spitting of blood, at once practise intubation, or, if unable to do this, open the larynx or trachea below the seat of fracture. If laryngotomy or tracheotomy is performed, try to restore displaced fragments to proper position. If the fragments will not remain reduceD, introduce a Trendelenburg cannula or a tracheotomy tube, and pack gauze around it. Take out the packing in four days, and remove the tube as soon as the patient breathes well, when the opening may be allowed to close. In these cases feed with a stomach-tube and keep the patient absolutely quiet. Union takes place in four weeks.

Fractures of the Ribs.—The ribs, owing to their shape, elasticity, and mode of attachment, readily bend and as readily recover shape, and thus withstand considerable force without breaking. Notwithstanding these facts, the situation of the ribs so exposes them that in 16 per cent. of all cases of fractures noted by Gurlt these bones were involved. In children fracture of a rib seldom occurs and is usually incomplete; it is common in adults and the aged, and in them is generally complete. It is more frequent among men than among women. The ribs commonly broken are from the fifth to the ninth, the seventh being the one that most frequently suffers. Fracture of the first rib alone is an excessively rare accident. The eleventh and twelfth ribs are seldom broken. A rib may be broken in several places, and several

ribs are often broken at the same time. Fracture of a single rib is not nearly so common as fracture of several ribs. These fractures may be compound, either through the skin or through the pleura, a damaged lung permitting pneumothorax. Fractures compounded by a wound of the skin surface are very rare, except from bullet-wounds.

Causes.—Direct force, as buffer accidents, kicks, blows with heavy instruments, or being jumped on while recumbent, may produce these injuries. A fracture from direct violence occurs at the point struck, and the ends, projecting inward, may damage a viscus. *Indirect* force, as great pressure or blows which exaggerate the natural bony curves, tends to produce fractures near the middle of the ribs or in front of their angles and to force the ends outward. A number of ribs are apt to be broken. Muscular action, as in coughing, sneezing, lifting, or parturition, occasionally, but very rarely, is a cause.

Symptoms.—In connection with the history of the accident the symptoms are: acute localized pain (a stitch) on breathing, increased by pressure over the seat of pain, pressure backward over the sternum, cough, and forcible inspiration or expiration; respiration is largely diaphragmatic, the patient endeavoring to immobilize the injured side; cough is frequent and is suppressed because of pain. Crepitus is often, but not invariably, found. The surgeon seeks for it, first, by resting the palm of his hand over the seat of pain while the patient takes long breaths; second, by placing a thumb before and one behind the seat of pain and making alternate pressure; third, by auscultation. It should be remembered that incomplete fractures are the rule in children; hence in them do not expect crepitus. Deformity is usually trivial unless several ribs are broken, because shortening cannot occur and the intercostal attachments prevent vertical displacement. Preternatural mobility may occasionally be elicited, when the region is not deeply covered with muscles, by pressing on one side of the supposed break and observing that a part of, and not the entire, rib moves. If air gathers in the subcutaneous tissue and there is no wound of the surface, it is proof of rib fracture with lung damage. In such a case the lung has been penetrated by a fragment, and air has been forced out into the tissues. This condition is recognized by great and growing swelling, which crackles when touched. Such a collection of air is known as *cellular emphysema.* Bloody expectoration suggests lung injury; bloody expectoration and cellular emphysema, without an external wound, prove injury of the lung. A simple, uncomplicated case of fracture of a rib or ribs in a young person gives a good prognosis.

The *complications* are: additional injury, making the fracture externally or internally compound; laceration of the pleura, pericardium, heart, lung, diaphragm, liver, spleen, or colon; rupture of an intercostal artery; hemothorax; cellular emphysema; pulmonary emphysema; pneumothorax; pyothorax; traumatic pleurisy; pneumonia; bronchitis; congestion or edema of the lungs.

Treatment.—In an uncomplicated case the patient is not kept in bed, as breathing is easier when erect than when recumbent. Angular displacement outward is corrected by direct pressure. Displacement inward is soon corrected, as a rule, by the expansion of ordinary respiratory action; but if it is not thus corrected, etherize, the deep breathing of the anesthetic state almost always succeeding. If ether fails, and dangerous symptoms ensue, incise under strict antiseptic precautions, elevate, or sometimes resect a portion of the rib.

After correcting any existing deformity immobilize the injured side. If a man, shave the chest. Direct the patient to raise his arms above his head, to empty his chest of air by a forced expiration, and to keep it empty until a piece of rubber plaster (2 inches wide) is forcibly applied a number of inches below the fracture and from the spine to the sternum. The patient is now

allowed to take a breath and is directed to empty the chest again, another piece of plaster being applied, covering the upper two-thirds of the width of the first strip. This process is continued until the side is strapped well above and well below the fracture (Pl. 7, Fig. 13). Over the plaster light turns of a spiral bandage of muslin are carried, or a figure-of-8 bandage of the chest is applied, the turns crossing over the seat of injury. About once a week the plaster is removed and fresh pieces applied after rubbing the chest with soap liniment, drying, and anointing excoriations with an ointment of oxid of zinc. The dressing is worn for three or four weeks. The patient avoids cold, damp, and drafts. The diet must be nutritious but non-stimulating, and any cough should be treated by opiates and expectorants. A person with this injury who has reached the age of sixty must take stimulant expectorants (ammonii carb., 10 gr., in infus. senegæ, ½ oz., *t. i. d.*) or employ a steam-tent several times a day. The old method of treatment, in which the chest was included in a forcibly applied broad rib-roller, is not to be used except as a temporary expedient; it compresses the entire chest, causes pain and dyspnea, and tends to loosen and slip.

Fracture of the ribs complicated by visceral injury is highly dangerous, and requires confinement to bed. The treatment is that of the visceral injury. If there be bloody expectoration, apply adhesive strips as above indicated, put the patient to bed reclining on a bed-rest, keep him quiet, subdue the circulation, and employ opium, diaphoretics, and expectorants (a good mixture consists of squill, ipecac, ammonium acetate, and chloroform; opium is given separately). Inflammations of the lung or the pleura, fortunately, are apt to be localized, and are treated as ordinary inflammations of these parts. If signs of pulmonary injury are severe from the start or become worse under medical treatment, incise, resect a rib, arrest hemorrhage, and drain the pleura. In laceration of an intercostal artery incise and try to ligate; if unable to ligate, resect a rib and apply a ligature. If the signs point to internal bleeding, resect a rib, search for the bleeding point, and ligate. Emphysema usually soon disappears; but if it does not, make many small incisions in the cellular tissue, dress antiseptically, and employ pressure. When there arises a sudden attack of dyspnea, which is prone to happen in these cases, and in which the face becomes blue, the heart labors, and suffocation seems imminent, bleed the patient almost to syncope.

Fractures of the costal cartilages are not common, even in the aged. Such fractures occur either through the cartilages or through their points of junction with the ribs. These injuries generally arise from direct violence, the cartilage of the eighth rib being most prone to suffer. Bennett, of Dublin, has seen over 25 specimens of fracture of the first costal cartilage. Indirect force (such as a blow upon the shoulder) is occasionally the cause, but when it is the cause some other injury besides the fracture of the cartilages is apt to be noticed. Muscular action is a possible cause.

Symptoms.—Displacement is often absent; but if present, it is forward or backward of either fragment, and is due chiefly to the force of the injury, but partly, it may be, to muscular action. When displacement is absent, crepitus will not often be found; in fact, crepitus is usually absent in these injuries. Localized pain, swelling, and ecchymosis are noted. Preternatural mobility may or may not be detected. Union by bone is to be expected.

Treatment.—If displacement exists, try to reduce it. If the fragment is displaced backward, reduce by deep inspirations; if the fragment is displaced forward, reduce by pulling back the shoulders. In this attempt failure is the rule, and the surgeon may then adopt Malgaigne's expedient of applying a truss over the projection for a day or two. Dress and treat the case as if a rib were broken, dispensing with dressings in four weeks.

Fractures of the Sternum.—The sternum may be broken, along with the ribs and spine, from great violence. Fractures of the sternum alone are infrequent, because the bone rests on a spring-bed of ribs. Fractures of the sternum may be simple or compound, complete or incomplete, single or multiple. The most usual injury is a simple transverse fracture at or near the gladiomanubrial junction, at which point dislocation may also occur. Both fracture and separation of the ensiform cartilage are very rare. The sternum may be broken along with the ribs or clavicle.

Causes.—These are: *direct* force, as by a fall of an embankment or of a wall, by a car-crush, or by the passing of a cart-wheel over the body; *indirect* force, as by a fall upon the head, thus driving the chin against the chest; by a fall upon the feet, the buttocks, or the shoulder; by forced flexion or extension of the body over an edge or angle (as may occur during labor-pains).

Symptoms.—In fracture of the sternum displacement is not always present, but when it does occur the lower fragment is apt to pass forward; displacement may, however, be transverse or angular, or there may be overriding. The posterior periosteum, which rarely tears, limits displacement, but some deformity can, as a rule, be detected. The history of the nature of the accident has a valuable bearing upon the question of diagnosis. The position assumed by the patient is with the head and body bent forward, as attempts to straighten up cause much suffering. There is fixed and localized pain, increased by deep respiratory action, by body movements, or by cough. Crepitus is sought for by auscultation and by placing the hand over the injury and directing the patient to make quick respirations. Mobility may become manifest on external pressure, during respiration, or while attempts are being made to bring the body erect. Respiration in these cases is usually much interfered with. It is not important to separate diagnostically diastasis from fracture.

Complications.—Other fractures generally complicate fracture of the sternum, and laceration of the pleura or pericardium and hemorrhage into the anterior mediastinum may exist. Abscess of the mediastinum and necrosis of the sternum may appear as late consequences. The *prognosis* is good in uncomplicated cases.

Treatment.—The deformity attending fracture of the sternum is to be corrected, if possible, by external pressure. If overriding is found, effect reduction by bending the body back over a firm pillow and ordering the patient to respire deeply; if this method fails, give ether and then bend the body backward. The deformity, after reduction, tends to recur, but the bones unite well even in deformity, and no great harm results. The fragments need not be cut down on or be hooked up unless there be internal injury. After reducing the deformity, cover the front of the chest with adhesive strips extending laterally from one axillary line to the other, and covering a region from above the fracture down to the ensiform cartilage. Place over this covering an anterior figure-of-8 bandage of the chest. In some cases, where deformity recurs after reduction, a circular bandage of the chest is applied and the shoulders are pulled strongly back with a posterior figure-of-8 bandage. The plaster is to be reapplied once a week. Some surgeons treat these cases by means of a large compress held by adhesive plaster and a broad tight roller.

The patient goes promptly to bed, and reposes, erect or semi-erect, on a bed-rest. This position favors easy respiration and antagonizes the tendency to displacement. The diet should be light, nutritious, and non-stimulating. Convalescence is established in four weeks, and the plaster should be permanently removed in five weeks. When the ensiform cartilage is so bent in as to cause intense pain or to injure the stomach, it should be exposed

by incision and resected. Edema of the skin and fever, if they appear, indicate pus, in which case an incision should be made at the edge of the sternum and the pus-cavity should be irrigated and drained.

Fractures of the Pelvis.—In some of the indicated fractures serious injury of the pelvic contents is apt to be found.

Fractures of the False Pelvis.—Fractures of this region are seldom dangerous unless comminuted. There may be fracture of the iliac crest or of the anterior superior spine, or the line of fracture may traverse the entire length of the flanged-out ilium, or the bone may be comminuted with the association of grave visceral damage. The anterior superior and posterior superior spines may be broken off.

Causes.—The cause of fracture of the false pelvis is generally violent *direct* force, as the passage of a wagon-wheel, the fall of a wall, the kick of a horse or mule, or the force of car-crushes. Violent contraction of the rectus femoris muscle may tear off the anterior inferior spine of the ilium.

Symptoms.—In fracture of the false pelvis the history of violent force is noted. The patient leans toward the injured side. Pain exists, which is aggravated by movements (particularly by bending forward), by coughing, or by straining to empty the bowels or the bladder. Ecchymosis and swelling are manifest. Crepitus and preternatural mobility are detected by moving the iliac crest. Deformity is very rarely present. Cases uncomplicated by visceral injury make good recoveries.

Complications.—The fracture may be, but rarely is, compound, as the parts are well protected by muscles. The colon may be injured when comminution has taken place.

Treatment.—If there are symptoms of injury of the colon, perform laparotomy, search for the injured region, and suture it. In treating an ordinary fracture of the false pelvis put the patient on a fracture-bed, raise the shoulders, and apply a canvas binder about the pelvis, or encase the pelvis in broad pieces of rubber plaster, or employ the belt or girdle. The pressure of the binder, girdle, or plaster must not be so great as to force the fragment of ilium inward. Place the knees over two pillows so as to semiflex the legs and thighs, and tie the knees together. To restrain thigh movements it may be necessary to encase a restless patient in splints or bind him to sandbags. If the pelvic binder displaces the fragments or causes pain, abandon it and trust to position. If the fragment cannot be retained in place, wire it. The dressings can be removed in six weeks, and the patient is allowed to get up in eight weeks. In simple, uncomplicated fracture of the false pelvis the prognosis is good. In compound fractures of the false pelvis asepticize, drain and dress, put on a binder, and direct the same position to be maintained as for simple fractures.

Fractures of the True Pelvis.—The most usual seat of these fractures is through the obturator foramen, the ascending ischial and horizontal pubic rami being broken. A fracture may occur near the symphysis pubis, the symphysis may be separated, a line of fracture may run near to or into the sacro-iliac joint; the same may involve each side of the body of the pubis, and there may be multiple fractures. Fractures of the acetabulum and of the tuberosity of the ischium may occur. Before the seventeenth year the innominate bone may be broken into its three anatomical segments. Fractures of the true pelvis are highly dangerous because of the damage which is apt to be inflicted on the pelvic contents. There may be laceration of the bladder or membranous urethra, injury of the vagina, the rectum, the uterus, or the small gut. The *cause* of pelvic fracture is violent force, direct or indirect. Front force tends to produce direct, and side force indirect, fracture. The acetabulum may be broken by falls upon the feet.

Symptoms.—In pelvic fracture there is a history of violent force. There are great shock, ecchymosis which is possibly linear, swelling, and intense pain increased by attempts at motion, coughing, and straining. There is also inability to sit or to stand. Mobility becomes obvious on grasping an ilium in each hand and moving the hands. Crepitus may be noticed by this maneuver or by moving an ilium with one hand, a finger of the other hand being inserted in the rectum or vagina. In making movements for diagnostic purposes be very gentle, as rough manipulation may cause injury by sharp fragments. There may be doubt as to whether crepitus is to be referred to pelvic fracture or to fracture of the neck of the femur; in this case follow the rule of John Wood: "The surgeon grasps the femur with one hand and places the other firmly upon the anterior superior iliac spine or crest or upon the pubes; then, on moving the femur and abducting it freely, if a crepitus be detected, it will be felt the more distinctly by that hand which rests on or grasps the fractured bone."

Fig. 294.—Rugh's case of fracture of the acetabulum with internal dislocation of femur.

Rupture of the bladder is made manifest by pain in the hypogastric region, intense desire to micturate, inability to pass urine in quantity, although a few drops of bloody urine may be voided, great shock, sometimes dulness on percussion in the loins, and evidences of extravasation in the prevesical space. The condition is proved to exist by practising the maneuvers suggested under Rupture of Bladder. The symptoms of ruptured urethra are set forth later. Bleeding from vagina or rectum points to laceration of the part by a fragment. The vagina may be badly lacerated and the bowels may emerge from the laceration (Maurice H. Richardson's case). Intestinal injury is apt to induce septic peritonitis. Fractures of the acetabulum occur. Fracture of the brim of the acetabulum permits dorsal dislocation of the femur to occur, which dislocation will not remain reduced, and causes shortening, which at once recurs when extension is abandoned; also inversion and adduction, although the power of eversion and abduction is preserved (Stokes). There is crepitus, and the

head of the bone goes with the fragment upward and backward (Stokes). If the head of the femur be driven through the acetabulum into the pelvis, the injury is very grave; there are then found shortening, adduction, and semi-flexion of the thigh, absence of the prominence of the great trochanter, and more capacity for movement than is noted in dislocation. This injury is called *internal dislocation* of the femur (Fig. 294). Fracture of the ischium rarely occurs alone.

Treatment.—Examine carefully to determine if the bowel, the bladder, the urethra, or the vagina is injured. If such an injury exists, radical operation is, of course, demanded. Always use a catheter to see if the urine is bloody. Bloody urine suggests, but does not prove, the existence of a torn bladder. It may be due to simple contusion of the bladder or to contusion of the kidney. In treating a pelvic fracture endeavor to restore the parts to a normal position, employing external manipulation and inserting a finger in the rectum or in the vagina. If reduction is difficult, administer ether. The pelvis should be encircled by a canvas binder and the patient should be placed upon a Bradford frame. If this is done he can be cleaned readily and the bed-pan can be easily used. If movements of the thighs distort the pelvic bones, each thigh should be bound to the frame. In fracture with separation of the pubic bones the bones should be wired together. If urinary extravasation from urethral rupture occurs, perform perineal section. If there are signs of bowel injury or intraperitoneal rupture of the bladder, perform laparotomy; and if the bladder is found to be torn, apply sutures. All visceral injuries are treated by general rules. Remove the dressings in six weeks and allow the patient to get about in twelve weeks. In fracture of the acetabulum, if the limb is shortened, give ether and reduce by extension and counterextension. Treat these fractures in the same way as intracapsular fractures of the femur. Fractures of the ischium are best treated by the application of a pad and adhesive plaster, and rest in bed.

Fractures of the Sacrum.—This bone may be broken by direct force, such as a kick, but the injury is rare. The sacral plexus is usually injured, and if it is, paralysis is observed in the territory of its branches.

The *symptoms* of fracture of the sacrum are pain, frequently incontinence of feces and retention of urine, irregularity of the sacral spines, ecchymosis, and crepitus. Crepitus may be sought for with one hand externally and a finger of the other hand in the rectum. The lower fragment passes forward and may obstruct or may tear the rectum. Paralysis may be found in the area of distribution of the sacral plexus.

Treatment.—In any case of fracture of the sacrum, if there are evidences of pressure upon nerves by displaced bone, expose and elevate the depressed bone. If the rectum is lacerated, sutures must be inserted. In many cases of fracture of the sacrum the older conservative treatment is sufficient. The conservative treatment is as follows: Press the fragments into place with a hand externally and a finger in the rectum. Do not plug the rectum. Put a pad over the upper fragment, hold it by a plaster or a binder, place the patient recumbent on a fracture-bed, and insert a large cushion underneath the pad. Some surgeons give opium to induce constipation, and allow a fecal support to accumulate in the rectum. Use a clean catheter regularly, and guard against bed-sores. Union occurs in about four weeks, when the dressing can be removed. The patient can get about again in six weeks. If urinary retention persists, or if intractable bed-sores form after eight or ten weeks, cut down on the seat of injury and elevate or remove the portion of bone causing pressure.

Fractures of the Coccyx.—The coccyx may be broken or be separated from the sacrum by a fall, a blow, a kick, or the straining of parturition. Its mobility is so great, however, that it does not often break.

Symptoms.—The chief symptom of fracture of the coccyx is pain, which is much aggravated by sitting, walking, or straining at stool. If the index-finger is inserted into the rectum, the displaced bone is felt; if the thumb of the same hand is also placed externally, a rocking motion will develop crepitus and preternatural mobility.

Treatment.—In treating fracture of the coccyx reduce by external pressure and by the manipulations of a finger in the rectum and put the patient to bed. In four weeks the fracture should be united. If union does not take place, defecation and all movements of the coccyx will cause excruciating pain by pressure on the last sacral nerve. This condition is known as *coccygodynia.*

It must not be understood that coccygodynia always results from fracture of the coccyx, or that fracture of the coccyx is the only cause. As a matter of fact, coccygodynia is a rare condition and is seldom a result of fracture of the coccyx. It may arise after confinement, or a fall or blow upon the region of the coccyx, or may be due to caries.

In most cases it is a referred pain due to some central trouble, and is common in various functional disorders of the nervous system. It is especially common in hysterical, neurasthenic, or anemic women. In the traumatic neuroses it is commonly complained of and it is frequently associated with irritable spine. In very rare cases it is a neuralgia. The treatment is aimed at the causative condition. In very obstinate cases it demands a subcutaneous division of the nerve or of the muscles which move the coccyx, or a resection of the bone.

Fractures of the Vertebræ.—(See page 852.)

Fractures of the Skull.—(See page 789.)

Fractures of the Clavicle.—The clavicle is more often fractured than any other bone. The fracture may occur at any age, but is commonest before the sixth year (Hulke says one-half of the recorded cases). It may be simple, multiple, comminuted, oblique, transverse, complete, incomplete, or, very rarely, compound. Both clavicles may be broken. Fractures are most apt to occur just external to the middle, at the point where the inner or large curve meets the outer or small curve, at which junction the bone is at its smallest diameter. Fractures of the acromial end are more frequent than fractures of the sternal end, and less frequent than fractures of the shaft. The *causes* of fracture of the clavicle are direct violence, indirect violence, and, very rarely, the contractions of "the deltoid and clavicular fibers of the great pectoral" (Treves, in "Applied Anatomy," from Polaillon).

Fractures of the shaft are usually due to indirect violence, as falls upon the shoulder or upon the outstretched hand. In the latter accident, which is the usual mode of origin, the concusssion of the fall travels up and the body weight travels down, and these two forces compress the bone, which snaps at its weakest point. Fractures from indirect force are oblique, and in children are of the green-stick form. Fractures from direct force are usually transverse, and are occasionally comminuted. Fractures from muscular action have been recorded (Rubini, the tenor, recorded by Melay).

Symptoms.—In fracture of the shaft of the clavicle the attitude of the patient is peculiar. He supports the elbow or wrist of the injured side with the hand of the sound side, and also pulls the extremity against the chest; the head is turned down toward the shoulder of the damaged side, as if trying to listen to something in the joint, thus relaxing the pull of the sterno-cleidomastoid muscle upon the inner fragment. The shoulder is nearer the sternum, on a lower level, and farther front than that of the sound side. Loss of function is shown by inability to abduct the arm, and in many cases by inability to place the hand on the top of the erect head. Considerable pain exists, which is increased by motion, by pressure, and by the extremity hanging down without support.

The deformity above noted is described by stating that the shoulder goes downward, inward, and forward (D. I. F.). The *downward* deformity is chiefly due to the weight of the extremity, which pulls down the unsupported outer fragment, and is contributed to by the action of the pectoralis minor muscle. The *inward* deformity is chiefly due to the contraction of the pectoralis minor and subclavius muscles assisted by the action of the pectoralis major. The *forward* deformity is due to rotation of the outer fragment, which is brought about by the serratus magnus muscle carrying the scapula forward. In this deformity the inner end of the outer fragment is below and behind the outer end of the inner fragment, which overrides it. The inner fragment, though pulled on by the sternocleidomastoid muscle and relatively higher than the outer fragment, is really but little, if at all, elevated, marked elevation being prevented by the attachment of the rhomboid ligament. After noting the deformity, detect with the finger the irregularity of bony contour. Examine for preternatural mobility and crepitus by raising and throwing back the shoulder. In looking for these signs in children it is to be remembered that the fracture is probably incomplete. The prognosis is good, the bone uniting, but, if unoperated upon, with some shortening or inequality.

Complications.—Fractures of the shaft are rarely compound, because the sharp end of the outer fragment passes backward and because of the free play the skin makes over the bone (Pickering Pick). Both clavicles may be broken. One or more ribs may be fractured at the same time. In fractures from direct force deeper structures may be injured by fragments. Thus, injury of the brachial plexus will induce paralysis. There are 11 recorded cases of simple fracture of the clavicle complicated by laceration of a large vessel. Eight of these cases died. The vessel ruptured may be the subclavian vein, the subclavian artery, or the jugular vein. After a rupture a huge blood-clot forms (Gallois and Poillet, in "Rev. de Chir.," July and Aug., 1901).

Fig. 295.—Fox's apparatus for fractured clavicle.

Treatment.—In treating a fracture of the shaft of the clavicle correct the deformity as soon as possible by throwing the shoulder upward, outward, and backward. If the patient is a girl, it is desirable to minimize the deformity. Place her upon her back upon a hard bed, with a small pillow under her head, a firm and narrow cushion between the shoulders, a bag of shot resting over the seat of fracture, and the forearm lying on the front of the chest, the arm being held to the side by a sand-bag. In three weeks there will be union, practically without deformity. In a child with an incomplete fracture a handkerchief sling for the forearm, worn three weeks, is all that is needed. In a fracture of the collar-bone of an adult the Velpeau bandage is usually efficient. Before applying it, place lint around the chest and cotton over the elbow. Change the bandage every day for the first week, and after that period every third day. Each time it is changed rub the skin with alcohol, ethereal soap, or soap liniment, dry carefully, and examine for excoriations; if any are found, they are anointed with zinc ointment before the dressing is reapplied. The dressing is permanently removed at the end of four weeks, the arm being carried in a sling for

another week. The classical apparatus of Desault is now rarely used. The posterior figure-of-8 bandage associated with the second roller of Desault, some turns being made from the elbow of the injured side to the shoulder of the sound side, can be used in cases in which the forward deformity is apt to return. The apparatus of Fox, which is very comfortable and useful, consists of a pad for the axilla, a sling for the forearm, and a ring for the opposite shoulder, to which ring are tied the tapes from both the pad and the sling (Fig. 295).

The dressing of Moore, of Rochester, is valuable in an emergency. It consists of a piece of cotton cloth, 2 yards long, and folded like a cravat until it is 8 inches in width at the middle. The center of the bandage rests upon the elbow, the posterior tail is carried across the front of the shoulder of the injured side. The forearm is at an acute angle with the arm, and the other end of the bandage is carried across the forearm, across the back over the opposite shoulder, and around the axilla, where the extremities are stitched together. The forearm is suspended in a bandage sling (S. D. Gross, in "A System of Surgery"). The four-tailed bandage is preferred by Pick. Sayre's dressing has many advocates (Fig. 296). For this there are required two pieces of rubber plaster, each piece being 3 inches wide and sufficiently long to go around the chest one and a half times. The end of one piece encircles the arm of the injured side just below the arm-pit; the plaster strip is pulled across the back to the other side, to the front of the chest, and returns again to the middle of the back. This procedure pulls the elbow back and throws the shoulder out. The hand of the injured side is placed on the breast of the opposite side, cotton being interposed, and the second strip of plaster runs from the elbow of the injured side to the front of the opposite shoulder, around, and back, pressing the elbow forward, upward, and inward. In children, if it is found difficult to immobilize the parts, the most satisfactory result is obtained by the application of the Velpeau bandage, which is overlaid by a thin plaster-of-Paris bandage. If the fragments cannot be coaptated, sterilize the parts, administer ether, incise, clear away the muscle from between the fragments, saw the ends, bore each end and hold them in contact by means of kangaroo-tendon or silver wire. The same procedure should be pursued when a fracture is compound or threatens to become so, or if signs indicate pressure upon vessels or nerves. If a large vessel has been injured, the operation is imperatively necessary. If a patient suffering under a fracture which threatens to become compound refuses the aid of operation, keep him in bed and hold the arm in abduction. In a number of cases I have wired the fragments with excellent results. Year by year I become more inclined to recommend wiring in cases of fractured collar-bone. It secures union without deformity, saves the vessels and nerves, and obviates the necessity of prolonged and very uncomfortable fixation of the arm and forearm.

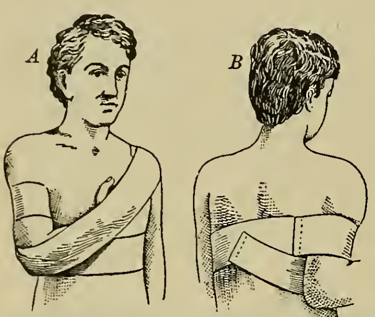

Fig. 296.—Sayre's adhesive-plaster dressing for fracture of the clavicle (Stimson): *A*, First piece; *B*, second piece.

After a broken collar-bone has united, if the shoulder is found to be stiff, make passive movements daily; if these fail, move the joint forcibly, first giving ether or nitrous oxid.

Fractures of the acromial end of the clavicle are due to direct force. If the fracture is between the two coracoclavicular ligaments, deformity is very slight, crepitus is elicited by manipulating with the fingers, and pain exists, but

loss of function is not markedly manifest unless it is due to pain. These fractures are treated by interposing cotton between the arm and the side, binding the arm to the side with the second roller of Desault, and hanging the hand in a sling. In fractures external to the ligaments crepitus is manifest on moving the shoulder, the outline of the bone is irregular, severe pain is developed by movement, and deformity is pronounced. The deformity is due to the serratus magnus muscle rotating the scapula forward, the inner end of the outer fragment of the clavicle often coming in contact with the anterior surface of the outer portion of the inner fragment. Fracture of the acromial end of the clavicle is reduced by pulling both of the shoulders strongly backward, and it is kept reduced by the use of a posterior figure-of-8 bandage. In fracture external to the ligaments the displacement frequently cannot be corrected by position and manipulation. Such cases demand incision and wiring. In either variety of fracture the dressings are worn for four weeks.

Fractures of the sternal end of the clavicle are very rare. They are caused by either direct or indirect force. In such a fracture there are found crepitus, projection at the seat of fracture, rigidity of the sternocleidomastoid muscle, and shortening of the clavicle. The inner end of the outer fragment always passes forward, and often also downward and inward. Reduce these fractures by pulling the shoulders back, and treat them by means of the posterior figure-of-8 bandage worn for four weeks. Wiring may be necessary.

Fractures of the Scapula.—This bone is not often broken, as it rests upon thick muscles and elastic ribs; it is freely movable, and it has attached to it a bone which easily breaks.

Fractures of the Body of the Scapula.—These are due to direct violence. The *symptoms* are pain (which becomes agonizing on attempting to rotate the shoulder-blade), ecchymosis, and swelling. Crepitus is sought for by placing the hand over the bone and making movements of the arm; also by holding the point of the shoulder and lifting up the lower angle of the bone. The latter plan may develop mobility. The spine of the scapula is uneven only when it is itself fractured. Examine for unevenness of the vertebral border of the shoulder-blade. In fractures of the body of the scapula a shoulder-cap is applied, a gutta-percha splint is molded over the scapula, the arm is bound to the side, and the hand is carried in a sling. The apparatus is worn for four weeks.

Fractures of the spine of the scapula are treated as fractures of the body of the bone, and for the same time.

Fractures of the Neck of the Scapula.—Fracture of the *anatomical neck* has not been proved to exist. Fracture of the *surgical neck* is evinced by flattening of the shoulder, prominence of the acromion, and the presence of a lump in the axilla, crepitus being developed by pressing the axillary prominence upward and backward. The coracoid process descends with the humerus. The deformity is reduced with ease, but it at once recurs. The condition is treated by placing a pad in the axilla, a shoulder-cap on the shoulder, applying the second roller of Desault, and supporting the forearm and elbow in a sling. A Velpeau dressing can be used, associated with the application of a folded towel in the axilla. The dressing is to be worn for five weeks.

Fractures of the glenoid cavity are not very unusual, and may occur with or without dislocation. Fracture of this region arises from direct force applied to the shoulder. The existence of this fracture is determined by excluding fractures of other bones and by detecting crepitus when the arm is at a right angle to the body and the humerus is pushed against the glenoid cavity, the crepitus not being found when the arm hangs by the side.

Treatment is by the second roller of Desault and a forearm sling worn

for four weeks; careful passive movements limit ankylosis. If ankylosis occurs, adhesions must be broken up while the patient is under ether or nitrous oxid.

Fractures of the acromion process are often met with as the result of direct violence. The existence of fracture of the acromion is indicated by pain, by inability to abduct the arm, by flattening of the shoulder, by sudden lowering of the point of the shoulder, by mobility, and by crepitus. To treat a case of this kind, put a large pad with the base down in the axilla, bind the arm over the pad with the second roller of Desault, lifting the elbow with turns of the roller carried over it and the opposite shoulder, thus splinting the bone in place by the head of the humerus pushing against the coraco-acromial ligaments. The dressing is to be worn for four weeks.

Fractures of the coracoid process rarely happen alone, and may arise from direct force or from muscular action. But little displacement is found. Crepitus and mobility are usually detected. Inability to shrug the shoulder inward was pointed out as a symptom by Byers. Such a case is well treated by a Velpeau bandage, which is to be worn for four weeks.

Fractures of the humerus are divided into: (1) fractures of the upper extremity; (2) fractures of the shaft, and (3) fractures of the lower extremity. In examining any fracture of the humerus, feel at once for the pulse, so as to ascertain if the artery has been torn; in any fracture near the head of the humerus be certain that dislocation does not exist.

Examination of the Shoulder.—In some cases ether must be administered. Compare the injured shoulder with the sound shoulder, the patient, if not anesthetized, being seated on a chair or stool. The direction of the axis of the arm is noted. The surgeon grasps the flexed elbow with one hand and the shoulder with the other; he thus can move the extremity and palpate the joint and adjacent points. The shoulder is moved gently in every direction, and the surgeon notes if the head of the bone moves with the shaft. Examination shows if the head of the bone is in place or if the glenoid cavity is vacant—if the head of the bone is in an abnormal situation, if it is altered in contour, if there is crepitus or preternatural mobility, and if any movement is impaired. The acromion process, outer end of the clavicle, coracoid process of the scapula, and neck of the scapula are also investigated. The length of the arm is obtained by measuring from the apex of the acromion process of the scapula to the apex of the external condyle of the humerus, and it is compared with the length of the sound extremity.

Fractures of the upper extremity of the humerus include: (*a*) fractures of the anatomical neck; (*b*) fractures of the surgical neck; (*c*) fractures of the head, oblique and longitudinal, and (*d*) separation of the upper epiphysis.

Fractures of the Anatomical Neck of the Humerus.—The anatomical neck is the constricted circumference of the articular surface, and fractures of it, though rare, do occur, especially in the aged. The line of fracture in some cases follows the insertion of the capsule, in others it is entirely within the capsule, but in most it is without the capsule above and within the capsule below; hence the term "intracapsular" is rarely correct as a designation. Such a fracture may be impacted. The *cause* is direct violence or a fall or a blow upon the elbow when the arm is abducted. Polloson, of Lyons,[1] has reported a case due to muscular action. The patient died in eclampsia, and at the necropsy it was found that both humeral heads were fractured and impacted. The fractures must have been produced by the muscles throwing the heads of the bones violently against the glenoid cavities, probably by adduction.

The *symptoms* of fracture of the anatomical neck are pain, tendinous swelling, ecchymosis, slight irregularity of the shoulder (which irregularity is soon hidden by tumefaction), and inability to actively abduct the arm. Deformity, as a rule, is slight or is absent, because the capsule is rarely entirely torn from the lower fragment. If deformity exists, it is due to the muscles inserted on the bicipital groove and to the coracobrachialis, which pull the lower fragment inward and forward. Treves says that a tear of the reflected fibers of the capsule leads to subsequent necrosis of bone because this joint has no ligamentum teres. In unimpacted cases there is crepitus, and mobility of the shaft can be detected near the head of the bone. In some cases impaction occurs, the upper fragment impacting into the lower. In this condition there are very slight shortening and trivial shoulder-flattening, no crepitus unless the tuberosity is broken off, no mobility, and, as Erichsen says, the head of the bone, while it can be felt through the axilla, is not in the axis of the limb.

Fig. 297.—Fracture at upper end of the humerus. Note hand, forearm, and elbow bandaged; axillary pad and strap, plaster-of-Paris shoulder-cap, sling (Scudder).

Fig. 298.—Fracture at upper end of the humerus. Arm and elbow bandaged. Axillary pad and shoulder-cap in position. Application of circular bandage to trunk and shoulder. Sling not shown (Scudder).

The *prognosis* of fracture of the anatomical neck is usually good for bony union (Hamilton, Pick, and R. W. Smith), but a stiff joint is apt to result.

Treatment.—Feel the pulse to be sure the artery is untorn. In most cases an anesthetic should be given in order to examine with ease and dress with satisfaction. Sometimes the fragments are readily coaptated; occasionally they are not. In a case reported by Carl Beck the axes of the fragments were at right angles and they could only be kept in contact by holding the arm at a right angle to the body ("New York Med. Jour.," April 5, 1902). Albee, of New York, reported a series of these fractures treated by wiring and maintaining the arm at a right angle with the body. The result was complete preservation of function. Some surgeons treat this fracture by simply hanging the wrist in a sling and suspending a bag of shot from the elbow to make extension. The usual plan of treatment is as follows: abduct the arm to a right angle with the body, and carry up from the base of the fingers to above

the elbow the turns of a spiral reversed bandage made of flannel. Interpose lint between the arm and the side, and place a V-shaped pad with the apex upward in the axilla, tying the tapes over the opposite shoulder. A shoulder-cap made of pasteboard (Pl. 7, Fig. 8) or plaster of Paris (Fig. 297), molded to fit and well lined with cotton, is applied. The plaster-of-Paris cap is the most satisfactory. It is applied "so as to cover the whole shoulder, the anterior and posterior aspects of the chest, and the outer side of the upper arm down to the external condyle of the humerus" (Scudder, on "The Treatment of Fractures") (Fig. 297). The arm with the shoulder-cap is fixed to the side by the second roller of Desault, and the wrist is hung in a sling (Fig. 298). The edges of the bandage should be stitched together. This apparatus is changed daily for the first few days, the body and arm being rubbed at each change with alcohol, soap liniment, or ethereal soap. After this period a change every third or fourth day is often enough. Massage is begun at the end of one week, but rotation and motion of the joint are not employed until after three weeks. The dressings are removed at the end of four weeks, the forearm being carried in a sling for two weeks more. In impacted fracture do not pull apart the impaction, do not use a pad, but apply a cap to the shoulder and fix the arm to the side for five weeks. The fracture unites with deformity.

Fractures of the Surgical Neck of the Humerus.—The surgical neck is the constricted portion of bone between the tuberosities and the upper line of the insertion of the muscles on the bicipital groove. Fractures in this region are usually transverse, but they may be oblique. The *causes* are: direct force almost always; indirect force occasionally; and muscular action in rare instances.

Fig. 299.—Internal angular splint and shoulder-cap in fracture of the surgical neck of the humerus.

The *symptoms* in fracture of the surgical neck are: pain running into the fingers from pressure upon the brachial plexus; crepitus; mobility on extension; and flattening, which differs from the flattening of dislocation in that it occurs farther below the acromion and that this process is not so prominent. Shortening to the extent of an inch is noted. The head of the bone can be felt in the glenoid cavity, but it does not move on rotating the arm. The upper end of the lower fragment is felt and moves on rotating the arm. The displacement is pronounced. The lower fragment is pulled upward by the deltoid, biceps, coracobrachialis, and triceps; inward by the muscles of the bicipital groove, and forward by the great pectoral; thus, the upper end of the lower fragment projects into the axilla, and the elbow lies from the side and backward. Péan holds that the violence drives the lower fragment forward. The upper fragment is abducted and rotated outward, which position is due, it is generally taught, to the action of the supraspinatus, infraspinatus, and teres minor muscles. In some cases displacement is forward, and in other cases it is not obvious. The lower fragment may impact into the upper, in which case the symptoms are obscure and the diagnosis is made by exclusion. If the impaction is solid and complete, there are the history of direct force, the impaired movements, the slight deformity, and the absence of crepitus. In all fractures of the upper end of the humerus the distinction can be made from dislocation by feeling the head of the bone under the acromion and by noting that it does not move on rotating the arm.

The *prognosis* of fracture of the surgical neck of the bone is good.

Treatment.—Some surgeons treat a fracture of the surgical neck in exactly the same manner as a fracture of the anatomical neck. I prefer the following plan: In many cases give ether in order to examine and dress. Feel the pulse to see that the artery has not been damaged. Reduce by traction and manipulation; if there is an impaction, pull it apart. Take an internal angular splint (Pl. 7, Fig. 6) and pad it well, putting on extra padding at the points that are to rest against the palm, the inner condyle, and the axillary folds. Lay the arm and pronated forearm upon the splint. Apply a padded shoulder-cap. Fix the splint and cap in place with a spiral reversed bandage terminating as a spica of the shoulder, and hang the hand or forearm in a sling (Fig. 299). The dressing is to be worn for four weeks, and the rules to be followed in changing it are the same as in fracture of the anatomical neck. Massage is used after one week, and passive motion to amend stiffness after four weeks. In rare cases—those with strong anterior projection of the lower end of the upper fragment—apply an anterior angular splint. In some cases when the deformity strongly tends to recur support by a plaster-of-Paris trough on the back and sides of the arm and shoulder, or maintain extension by weights and pulleys, the patient being kept in bed (Stimson). In a case with great deformity abduction with extension is a very useful method. I have reached the conclusion that many cases of fracture of the surgical neck are best treated by incision and fixation.

Fig. 300.—Fracture of humerus below surgical neck.

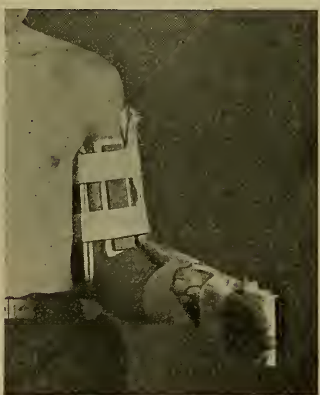

Fig. 301.—Preliminary splinting for complete dressing as shown in Fig. 304.

Longitudinal and Oblique Fractures of the Head of the Humerus.—By this term may be designated separation of the great tuberosity or separation of a portion of the articular surface, together with the great tuberosity, from the shaft and lesser tuberosity (Pickering Pick, Guthrie, and Ogston). The *cause* is usually direct violence to the front of the shoulder, but the greater tuberosity may be torn off by muscular action.

The *symptoms* in longitudinal and oblique fracture of the head are broadening and flattening of the shoulder with projection of the acromion. The upper fragment passes upward and outward, and the lower fragment passes

upward and inward to rest on the margin of the glenoid cavity below the coracoid process. The elbow is drawn from the side, there is some shortening, and the patient cannot abduct his arm. If the surgeon grasps the patient's elbow and holds it to the side and rotates the arm while with his other hand he grasps the upper fragment, crepitus is very positive. Examination develops wide separation of the fragments. The deformity cannot be entirely corrected, because the biceps tendon is apt to get between the fragments (Ogston), but a useful limb can usually be obtained.

Fig. 302.—Linear fracture of humerus.

Treatment.—The plan which gives the best result in treating longitudinal and oblique fracture of the head of the bone is to place the patient on his back upon a hard bed with a small, firm pillow under his head, abduct the arm above the head, rotate it outward so that the back of the hand rests on the bed, and hold it in place by sand-bags. This position should be maintained for three weeks, at the end of which period the fracture can be treated for three weeks more as a fracture of the anatomical neck. If the patient refuses to go to bed, treat the injury as a fracture of the anatomical neck, padding well over the tuberosities. The dressings should be worn for five weeks, passive motion being made after four weeks. In the above injury feel at once for the pulse, to see if the artery has been torn.

Separation of the Upper Epiphysis of the Humerus.—The epiphysis is united during the twentieth year. Separation is a rare accident and is produced by direct force.

Symptoms.—The chief symptom in separation of the upper epiphysis is projection of the upper end of the lower fragment inward, forward, and upward beneath the coracoid, and consequently a projection of the elbow backward and from the side. If the lower fragment passes forward and not inward, the elbow simply passes back. The upper end of the lower fragment is smooth and convex. Rotation of the shaft develops soft crepitus when the fragments are in contact.

The *prognosis* is good for bony union, though the future growth of the limb may be impaired.

The *treatment* for separation of the upper epiphysis is a pad in the axilla, a shoulder-cap, binding the arm to the side, and hanging the hand in a sling. Wear the dressing for four weeks, and begin passive motion as directed when dealing with fracture of the upper end of the humerus.

Fracture of the shaft of the humerus is a very common accident. The *cause* is usually direct violence, such as a blow. The fracture may arise from indirect violence, such as a fall upon the elbow. Muscular action is not rarely also a cause, as in throwing a ball, in catching a tree-limb while falling, or in turning another's wrist outward as a test of strength (Treves). This test of strength is known by the French as "le tour de poignet."

The opponents sit opposite to each other and each rests his elbow on a table. They clasp hands and each one strives to rotate the other's hand outward. Ashhurst collected 57 cases due to throwing a ball and 23 cases due to "le tour de poignet." He believes that in some cases the humerus is broken as a stick may be broken by holding one end and swinging the other through the air and that in other cases fracture results from twisting (Astley P. C. Ashhurst, in "University of Pennsylvania Med. Bulletin," Feb., 1906). In fracture due to muscular action the break is nearly always below the deltoid insertion and the line of fracture approaches the transverse.

The *symptoms* of fracture of the shaft of the humerus are pain, tendinous swelling, ecchymosis, inability to move the arm, mobility, and distinct crepitus. Shortening to the extent of $\frac{3}{4}$ inch occurs. The displacement varies with the situation of the fracture and the direction of the force. If the fracture is above the insertion of the deltoid, the lower fragment is pulled up by the triceps, biceps, and deltoid, and pulled out by the deltoid, and the upper fragment is pulled inward by the arm-pit muscles. In fracture below the deltoid this muscle is apt to pull the lower end of the upper fragment outward, while the lower fragment passes inward and upward because of the action of the biceps and triceps. Injury of the *musculospiral nerve* sometimes occurs. The nerve may be contused, producing pain at the seat of bruising, and tingling and numbness in the region supplied by the nerve. In most cases the symptoms soon pass away, but sometimes neuritis ensues. A severe contusion produces not only pain, but paralysis of the muscles supplied by the nerve, and surface anesthesia. In most cases this condition is recovered from in a few weeks, but sometimes it lasts a long while or even permanently. In musculospiral

Fig. 303.—Fracture of middle of humerus.

Fig. 304.—Apparatus for fracture of the humerus at any point above the condyles.

paralysis the patient is unable to extend the wrist and fingers or to supinate the forearm. There is "complete loss or impaired sensation in the lower half of the outer and anterior aspect of the arm and in the middle of the back of the forearm as far as the wrist" (Scudder, in "The Treatment of Fractures"). The nerve may be divided by a sharp fragment, paralysis of motion and anesthesia resulting at once. In some cases the nerve is caught in and compressed by callus, scar-tissue, or fragments, motor and sensory disturbances resulting.

The *prognosis* is good, but the fact should always be remembered that ununited fractures are commoner in the humerus than in any other bone. Treves believes this to be due to entanglement of muscle between the fragments, lack of fixation of the shoulder-joint, and imperfect elbow support. Hamilton believes that it is due to the facts that the elbow soon becomes fixed at a right angle, and that any movement of the forearm moves the seat of fracture and not the elbow.

Treatment.—It is rarely necessary to anesthetize unless the patient be a nervous woman or an excitable child. Feel the pulse, to be certain the artery has not been lacerated. Reduce the fracture by extension, counterextension, and manipulation. Apply four humeral splints (Fig. 301). The internal splint

reaches from the axilla to just above the internal condyle of the humerus. A short straight splint is applied front and another back, each being the length of the arm. A shoulder-cap is applied, which cap "is prolonged below into an external angular splint reaching as far down as the lower third of the forearm" (Fig. 304) ("Manual of Surgical Treatment," by Cheyne and Burghard). The elbow is brought to a right angle with the arm and the forearm is placed midway between pronation and supination. As Cheyne and Burghard say: "It is necessary that the arm should hang vertically at the side with the long axis of the forearm parallel with the anteroposterior diameter of the trunk; if the forearm be brought at all forward across the chest, rotation of the lower fragment upon its vertical axis is apt to take place." Splints are to be worn for five or six weeks, and after the removal of the splints the wrist is hung in a sling. The sling is dispensed with eight weeks after the infliction of the injury. Passive movements are not to be made until the

Fig. 305.—Fracture of the shaft of the humerus. Note bandage to hand, forearm, and elbow; axillary pad and strap; coaptation splints and sling. Bandage does not cover fracture (Scudder).

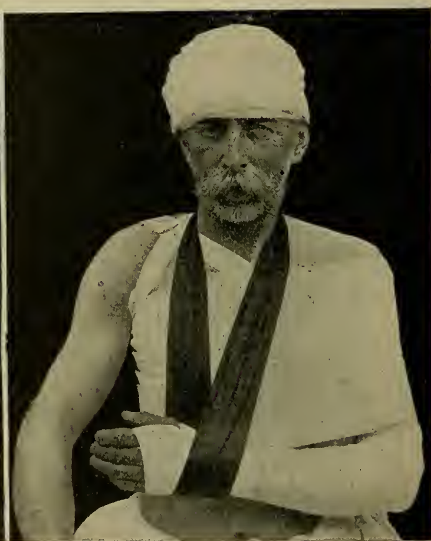

Fig. 306.—Fracture of the shaft of the humerus. Note bandage to hand, forearm, and elbow; adhesive-plaster swathe holding arm upon axillary pad and covering coaptation splints. Sling (Scudder).

fracture is well united (after five or six weeks), for, if made too soon, they predispose to non-union, and, as no joint is involved, genuine ankylosis will not occur. Many surgeons treat these fractures by applying plaster of Paris to the forearm and the arm (the elbow being flexed to a right angle), binding the arm to the side, and hanging the wrist in a sling. Others apply a trough to the arm and forearm. Scudder prefers to bandage the hand, forearm, and elbow, and apply an axillary pad, coaptation splints, a swathe of adhesive plaster holding arm to the side, and a sling (Figs. 305, 306). In any case in which it is impossible to obtain and maintain correct apposition of the fragments, cut down upon them, and apply a plate. If the nerve is divided, an incision must be made at once, the nerve sutured, and the bone plated. If the nerve is caught in the callus, after repair has taken place it must be liberated by chiseling the callus away. Neuritis is treated by blisters over the nerve, the use of the descending galvanic current, and the administration of salicylate of ammonium and the bromids.
